Extra-hepatic portal venous obstruction (EHPVO) is blockage of the portal vein either in the lumen, in the wall or extrinsic compression from outside the portal vein. EHPVO is a form of non-cirrhotic portal hypertension (NCPH) characterised by obstruction (acute, chronic or insidious) of the extra-hepatic portal vein, with or without the involvement of intra-hepatic portal veins or splenic or superior mesenteric veins. Most commonly, the blockage occurs at the site of portal vein formation (90%). Isolated occlusion of the splenic vein or superior mesenteric vein does not constitute EHPVO. Portal hypertension in EHPVO is pre-sinusoidal and the hepatic blood flow is normal or decreased.

EHPVO is common in India and is responsible for 6% to 40% of all patients with portal hypertension in various series; this proportion is <10% in the West. Males are predominantly affected. In children, EHPVO accounts for up to 70% of cases of portal hypertension.

AETIOPATHOGENESIS

The aetiology of EHPVO differs in different age groups. Thrombosis of the portal vein is the most important mechanism causing EHPVO. However, it is debatable whether phlebosclerosis is the primary pathology with thrombosis supervening later on. The major cause of EHPVO in adults and children are shown in **Table 1**.

Table 1: Causes of Extra-Hepatic Portal Venous Obstruction (EHPVO)

Children	Adults
Idiopathic Approximately 50% of children with EHPVO	**Hypercoagulable state** Prothrombotic disorders, more often occult than overt, are more frequently detected in adult patients with EHPVO. Myeloproliferative disorders, typifid as JAK_2 mutation, deficiencies of antithrombin III, protein C and protein S, prothrombin gene mutation, factor V Leiden mutation and methylene tetrahydrofolate reductase gene mutation are examples of such disorders
Infection Neonatal umbilical sepsis and umbilical vein cannulation. Intra-abdominal sepsis, severe dehydration due to a diarrhoeal illness, abdominal surgery, Others Trauma Multiple exchange transfusions	**Intra-Abdominal Infection** Portal pyaemia, biliary infection, post-surgical sepsis, etc. (These play a role in a small proportion of adult-onset EHPVO)
Developmental anomaly Portal vein stenosis or atresia are rare causes of EHPVO. These children usually have other associated congenital anomalies	**Others** Oral contraceptives, pregnancy and abdominal surgery may also incite development of portal vein thrombosis
Hypercoagulable states It may contribute to the development of EHPVO in a few children. However, factor V Leiden and prothrombin gene G20210A mutations are uncommon in EHPVO	**Secondary involvement of portal vein** Liver diseases (cirrhosis, hepato-cellular carcinoma) and pancreatic diseases (chronic pancreatitis, trauma, tumours) are also known causes of EHPVO

CLINICAL FEATURES

EHPVO has a bimodal distribution of age of presentation, with one peak in childhood and the other in adult age group. In children, EHPVO is mostly chronic and presents with variceal bleeding. In adults, EHPVO may present either as an acute or as a chronic condition.

Children

Recurrent upper gastrointestinal (GI) bleeding from oesophageal varices presenting as haematemesis and melaena, is the most common presentation. The bleeding episodes are usually tolerated well. Some patients develop transient ascites following episodes of upper GI bleeding.

Splenomegaly is nearly universal in patients with EHPVO. A few children with EHPVO may present with a left upper abdominal lump/discomfort (due to massive splenomegaly), as the only complaint. It may be associated with a dragging feeling or mild pain in the splenic area or pain due to splenic infarcts.

Although hypersplenism is common, it is usually asymptomatic. Though, some patients may present with symptomatic anaemia or thrombocytopaenia.

About 50% of children with EHPVO show evidence of growth retardation. Reduction in portal blood flow to the liver affects growth hormone and reduced levels of insulin-like growth factor are believed to be the likely factors.

Adults

Acute portal vein thrombosis (PVT) in adults most frequently presents as acute abdominal pain. Other features in these patients include fever, ascites and intestinal ischaemia. Collaterals are not found in these patients.

In patients with chronic portal vein obstruction, recurrent upper GI bleeding from oesophageal or gastric varices is the main presenting feature. These patients can also bleed from ectopic varices located in the duodenum (presenting as melaena) or anorectal region.

Some patients develop transient transudative ascites following upper GI bleeding. Uncommon presentations of EHPVO include symptomatic hypersplenism and portal biliopathy. The latter is characterised by abnormalities of biliary ductal system due to paracholedochal collaterals compressing the bile duct from outside. The pathogenesis is not well known. It is postulated that external pressure and/or ischaemia may play a role. Though portal biliopathy is demonstrable by cholangiography in about 80% patients of EHPVO, it is rarely symptomatic in the form of biliary colic, obstructive jaundice or cholangitis.

Some patients develop liver dysfunction during long-term follow-up. Moreover, these patients are at-risk of acquiring

hepatitis B and hepatitis C virus infections through blood transfusions administered for recurrent GI bleeding.

DIAGNOSIS

The diagnosis of EHPVO is based on the presence of a typical clinical presentation (a child or young adult presenting with well-tolerated episodes of haematemesis and moderate to massive splenomegaly), normal liver function tests (LFT), demonstration of PVT and portal cavernoma on Doppler studies, and preserved liver architecture on liver biopsy to rule out compensated cirrhosis of liver.

In EHPVO, liver function tests are generally normal. However, in some patients with long-standing EHPVO, prolonged prothrombin time and reduced serum albumin levels may occur. Hypersplenism may lead to reduction in one or more blood cell lines.

Investigations for prothrombotic states, such as estimation of serum anti-thrombin III, protein C, protein S levels and the presence of factor V Leiden mutation may be useful. Overt myeloproliferative disorders can be diagnosed by bone marrow biopsy. Occult myeloproliferative disorders require more complex tests. Prothrombin gene mutation has been reported in Western populations, but not in India.

Upper GI endoscopy is used to diagnose the presence of oesophageal varices. Nearly 40% of patients also have gastric varices. Ectopic varices in the duodenum may be detected in some patients.

Most common differential diagnoses of EHPVO include other causes of portal hypertension, such as non-cirrhotic portal hypertension and liver cirrhosis. Patients with EHPVO do not have dilated venous collaterals over the anterior abdominal wall, whereas such veins can occur in intra-hepatic causes of portal hypertension. Presence of abdominal wall collaterals reliably excludes EHPVO, as does the presence of a normal portal vein at ultrasonography and Doppler studies.

It is sometimes difficult to differentiate EHPVO from well-compensated cirrhosis. The situation becomes more complex when cirrhosis is associated with PVT. The presence of dilated collaterals on anterior abdominal wall (if present) and nodularity of liver on ultrasound suggest a diagnosis of cirrhosis. Liver biopsy is often required to exclude cirrhosis. Other causes of non-cirrhotic portal hypertension like congenital hepatic fibrosis in children, veno-occlusive disease, nodular regenerative hyperplasia and partial nodular transformation of liver should be excluded.

TREATMENT

The management of EHPVO depends on the patient's age, the site of venous obstruction and clinical presentation. Acute variceal bleeding can be often easily and effectively controlled using endoscopic variceal ligation. Endoscopic variceal ligation followed by endoscopic sclerotherapy (EST) is better than EST alone in Children with EHPVO. They require fewer sessions and have fewer complications. However, evolution of gastric varices and portal hypertensive gastropathy is similar in both children and adults. Overall prognosis of patients with EHPVO is excellent, especially after variceal obliteration. Gastric varices are usually dealt with using injection of cyanoacrylate glue. In a follow-up of nearly 20 years after variceal eradication by EST only one-sixth had reccurrence of bleeding. Bleeding is unusual after 10 years have passed since initial variceal eradication. Recurrent bleeding can be prevented by producing variceal obliteration by repeated use of the above endoscopic means. Beta blockers (propranolol) have also been found to be effective in prevention of variceal rebleeding.

Shunt surgery or devascularisation surgery is indicated for patients in whom endoscopic therapy has failed. Shunt surgery is also required for patients with symptomatic portal biliopathy, symptomatic hypersplenism and in children with growth retardation. Mesenteric-left portal vein bypass may prevent growth retardation.

In elective situation, even transabdominal gastroesophageal devascularisation without transection effectively controls bleeding. Growth impairment and neurocognitive ability is of prime importance in children. For this a bypass surgery like mesenteric-left portal vein bypass (Rex shunt) gives near cure. The role of prophylactic porto-systemic shunt surgery in EHPVO is not yet conclusively studied.

The underlying prothrombotic state may need treatment in its own right. Anticoagulants are indicated in patients with acute PVT. The role of life-long anticoagulation in patients with chronic EHPVO and a demonstrable prothrombotic state is still debatable. Anticoagulation is needed in the post-operative phase after shunt surgery.

Symptomatic portal biliopathy can be managed with endoscopic biliary stenting and stone extraction. If surgical biliary-enteric anastomosis is planned for persistent symptomatic biliopathy, usually shunt surgery is also necessary to reduce portal pressure to decompress the pericholedochal venous collaterals and biliary bypass later on or at the same sitting.

Symptomatic hypersplenism should be treated using shunt surgery with or without splenectomy.

COMPLICATIONS

Presentation of EHPVO is usually by its own complications in the form of haematamesis, splenomegaly or biliopathy.

PROGNOSIS AND PREVENTION

Prevention of perinatal infection and proper care of hyper-coaguable states may prevent EHPVO.

14.11 Non-Alcoholic Fatty Liver Disease

Yogesh K Chawla, Sunil Taneja

INTRODUCTION

The term non-alcoholic steatohepatitis (NASH) was first introduced in 1980 to describe liver histology changes resembling alcoholic hepatitis in patients with no or insignificant alcohol intake. This condition was described as more common among women and persons with morbid obesity, diabetes mellitus or metabolic syndrome. Since then, it has been realised that NASH is a part of a wider group of conditions, now called as non-alcoholic fatty liver disease (NAFLD). NAFLD encompasses a spectrum of liver disorders characterised by macrovesicular hepatic fat accumulation alone (steatosis), or accompanied by signs of hepatocyte injury, mixed inflammatory cell infiltrate, and variable hepatic fibrosis (non-alcoholic steatohepatitis, NASH), leading to cirrhosis. Approximately 20% to 30% of adults in the general population in Western countries have non-alcoholic fatty liver disease and its prevalence increases to 70% to 90% among persons who are obese or have diabetes. It is an increasingly recognised cause of liver-related morbidity and mortality. NASH can progress to cirrhosis and end-stage liver disease and is projected to be the leading cause of liver transplantation by 2020; furthermore, emerging evidence suggests that NAFLD overall is associated with an increased cardiometabolic risk.

EPIDEMIOLOGY

The true incidence and prevalence of NAFLD are unknown. The prevalence of NAFLD has increased over the last few years. Based on imaging studies, the prevalence of NAFLD in the adult population ranges from 14% to 31%. The global epidemic of obesity and diabetes in all age groups may be partly responsible for the increase. Incidence of steatosis clearly increases with obesity. A large population-based study found that 91% of obese individuals [Body mass index (BMI) >30 kg/m^2] had evidence of steatosis on ultrasound. The prevalence of NASH is even more difficult to determine as large population-based studies are not possible, as liver biopsy is required for diagnosis of NASH.

Urbanisation and associated changes, such as sedentary life style and fat rich diet, and a higher inherited tendency for diabetes mellitus makes Indians more prone to metabolic syndrome or insulin resistance and its manifestations, such as NAFLD and NASH. In a more recent, community-based epidemiological study, 1911 inhabitants of a rural area in West Bengal were studied. The prevalence rates of NAFLD, NAFLD with elevated alanine aminotransferase, and cryptogenic cirrhosis were 8.7%, 2.3%, and 0.2%, respectively. The risk of NAFLD was the highest in those with BMI >25 kg/m^2.

Both fatty liver and NASH have been reported in all age groups, including children, with highest prevalence in those between 40 and 49 years of age. Recent studies have shown that NASH occurs with equal frequency in males and females.

AETIOPATHOGENESIS

Several mechanisms have been postulated to explain the pathogenesis of NASH. The 'multiple hit' hypotheses is currently favoured. The first 'hit' is development of hepatic macro-steatosis as a result of increased lipolysis and free fatty acids. Postulated mechanisms leading to hepatic steatosis include increased lipogenesis, decreased lipid export, and a reduction of free fatty acid oxidation with insulin resistance leading to fatty acid dysregulation. Several potential 'second hits' include oxidative stress from reactive oxygen species in the mitochondria and cytochrome P450 enzymes. Other second hits include the presence of endotoxins, cytokines, adipokines, and environmental factors. These complex interactions of the various factors lead to insulin resistance, and serum and liver iron overload and oxidative stress that lead to necroinflammation and fibrosis. NAFLD is associated with metabolic syndrome which leads to insulin resistance resulting in fat deposition in hepatocytes by inducing increased lipolysis, increased uptake of fatty acids and reduced export of very low-density lipoprotein (VLDL). Truncal or central obesity is more strongly associated with NAFLD. In severely obese people, the risk of liver disease increases progressively with the number of features of metabolic syndrome present. Family studies suggest that genetic factors may also play a role in the progression of NAFLD.

CLINICAL PRESENTATION

Most patients with NAFLD are asymptomatic. Diagnosis most often follows incidental detection of raised liver enzymes or of fatty liver on ultrasound. These abnormalities are usually picked up during evaluation for dyspepsia, malaise or fatigability, prior to medical procedures like organ donation, or routine health examination. A smaller fraction of patients experience symptoms indicative of more serious liver disease and may develop pruritus, anorexia, and nausea. The development of ascites, anasarca, variceal hemorrhage, or symptoms of hepatic encephalopathy indicates decompensated cirrhosis. Similarly, jaundice occurs late in the course of NASH and indicates advanced liver disease. No specific symptoms can distinguish NAFLD or NASH from other type of liver diseases. The diagnosis of NAFLD requires the exclusion of other specific etiologies of liver disease and excessive alcohol consumption. The majority of patients have one or more risk factors for metabolic syndrome, such as type 2 diabetes, obesity, hypertension, or hyperlipidaemia. Clinical examination is often unremarkable though nearly half the patients have mild hepatomegaly. Jaundice or signs of liver failure are absent.

DIAGNOSIS

NAFLD should be suspected as a cause of asymptomatic elevation of aminotransferases. However, it is important to remember that NAFLD can be present with normal or fluctuating aspartate aminotransferases (AST) and alanine aminotransferases (ALT). In general, ALT is higher than AST. The diagnosis of NAFLD is

strongly suggested when metabolic syndrome is present and other specific aetiologies for hepatic dysfunction have been excluded. About 30% to 50% of patients with NASH have either diabetes or glucose intolerance. A fasting lipid profile shows hypertriglyceridaemia in 20% to 80% of patients.

Ultrasound may show liver steatosis as a hyperechogenic image, that is, 'bright liver'. Radiologic techniques used to evaluate NAFLD include ultrasound, computed tomography (CT), magnetic resonance imaging, and magnetic resonance spectroscopy (MRS). However, these radiologic modalities are accurate in detecting hepatic steatosis only when there is moderate to severe steatosis. Although these modalities can detect hepatic steatosis, none is able to distinguish simple steatosis from NASH or determine the stage of hepatic fibrosis. Fibroscan (tissue elastography) is a new non-invasive modality in detecting liver fibrosis and its role in various liver diseases, including NAFLD, is still evolving.

Liver biopsy is diagnostic, but may not be routinely required. It allows semi-quantitative assessment of amount of fat deposition and of associated necro-inflammation and fibrosis. Typical histological features of NAFLD predominate in perivenular regions, i.e. zone 3 of hepatic acinus and include the presence of macrovesicular steatosis, lobular neutrophilic inflammation, presence of Mallory bodies, ballooning degeneration, lipogranuloma and pericellular fibrosis.

Non-Alcoholic Fatty Liver Disease (NAFLD) in India

NAFLD is an important cause of liver disease in India. Epidemiological studies suggest prevalence of NAFLD in around 9% to 32% of general population in India with higher prevalence in those with overweight/obesity and those with diabetes/prediabetes. Indian population has a higher body fat content and abdominal adiposity; the latter is particularly associated with insulin resistance and thus NAFLD, even if the BMI is normal. Indians also more often have atherogenic dyslipidaemia (combination of hyper-triglyceridaemia, low high-density lipoproatein (HDL)-cholesterol and high low-density lipoprotein (LDL)-cholesterol), and diabetes. These factors, along with urbanisation and associated sedentary life-style and fat-rich diet may make Indians particularly prone to metabolic syndrome, insulin resistance, and NAFLD/NASH.

In Indian patients with NAFLD, the disease is usually milder, often with either no or mild inflammation and fibrosis on liver biopsy even in those with elevated liver enzymes.

Role of NAFLD in Cryptogenic Cirrhosis and Hepato cellular Carcinoma (HCC)

NASH is associated with cryptogenic cirrhosis. Patients with NASH and fibrosis can progress to cirrhosis with the risk varying from 0% at 5 years to 12% over 8 years. It has been observed that when patients progressed to cirrhosis, inflammation and fat disappeared from their liver biopsy. A number of epidemiologic studies of cryptogenic cirrhosis have estimated that antecedent NASH constitutes a large proportion of cryptogenic cirrhosis cases. An early asymptomatic phase followed by appearance of decompensated cirrhosis is now a recognised complication of NASH. Once cirrhosis develops, patients are at high-risk of developing HCC.

TREATMENT

Currently, there are no approved therapies for NAFLD. There are many proposed agents being evaluated currently, each targeting a different step in the pathogenesis of development of hepatic steatosis or progression to steatohepatitis. The proper dosing, duration of treatment, safety, and tolerability of these treatments is still evolving (**Table 1**).

At the present time, the initial approach involves dietary modification based on the metabolic profile (obesity, diabetes, hyperlipidaemia, hypertension) and getting patients to increase

Table 1: Therapy for Non-Alcoholic Fatty Liver Disease

Treatment	Effects	Mechanism of Action	Side Effects
Insulin sensitisers			
Metformin	Enhance weight loss Improve insulin sensitivity and plasma glucose levels Reduce metabolic syndrome	Decrease production of hepatic glucose and increasing the uptake of peripheral glucose by skeletal muscle and fatty acid oxidation	Gastrointestinal (GI) intolerance
Thiazolidinediones			
Pioglitazone and Rosiglitazone (Not in use)	Improve ALT, histological steatosis and inflammation	Stimulate free fatty acid (FFA) oxidation, increase adiponectin expression	Weight gain and lower extremity oedema
Antioxidants			
Vitamin C and E	Improve ALT and steatosis	Decrease oxidative stress	No significant adverse effects
Hepatoprotective Agents			
Betaine	Improves ALT, steatosis and inflammation	Increases S-adenosylmethionine levels	
Ursodeoxycholic acid	Marginally significant benefit on various liver enzymes	Bile acid, which has various cytoprotective, anti-apoptotic and immunomodulatory properties	GI side effects: diarrhoea, motility disorders
Pentoxifylline	Improves ALT and histology	It functions by inhibiting TNF-α	Minor GI side effects
Lipid lowering Drugs			
Statins, poly unsaturated fatty acid (PUFA) and Probucol	Improves aminotransferases, steatosis and slows progression of fibrosis	Lowers elevated triglycerides and improves low HDL	Risk of hepatotoxicity reduced HDL with probocul, safety concern in patients at high cardiovascular risk
L-Carnitine	Improve steatosis, and amino-transferases	A modulator of mitochondrial FFA transport and oxidation	Well tolerated

levels of physical activity. Even small changes in body weight (0.5 to 3 kg) can achieve improvement in hepatic necro-inflammatory activity and/or radiologic resolution of hepatic steatosis and/or reversal of insulin resistance. The role of weight-reducing pharmacologic regimens, such as phentermine, sibutramine, and orlistat in NAFLD is not established. The most consistent and spectacular evidence for treatment efficacy against NASH comes from literature on obesity surgery in which highly reproducible benefits against steatosis, steatohepatitis, and hepatic fibrosis have been reported. In patients with morbid obesity, bariatric surgery may be considered.

Various other treatment modalities used for NAFLD have included treatment of risk factors like diabetes mellitus and hyperlipidaemia, and use of insulin sensitizing agents such as biguanides (metformin), thiazolidinediones (rosiglitazone, pioglitazone) and antioxidants and various hepatoprotective agents. Weight loss, thiazolidinediones (especially pioglitazone), and antioxidants have been extensively evaluated. Weight loss is safe and improves histological disease activity in NASH, but more than 50% of patients fail to achieve target weight loss. Thiazolidinediones improve steatosis and inflammation, but cause significant weight gain. Studies show conflicting results with antioxidants. Antioxidants are heterogeneous in relation to type and dose of drugs, their duration of action and implementation of life-style intervention. Other agents like pentoxifylline, telmisartan, L-carnitine and vitamin E are being evaluated.

CONCLUSION

NAFLD is a major cause of liver-related morbidity in both developed and developing countries. It is frequently associated with the presence of insulin resistance. There is increasing evidence that NAFLD can progress to cirrhosis and liver failure. Physicians should actively check for the presence of NAFLD in those who are overweight and/or diabetic. There is no established treatment for NAFLD. Treatment usually is directed toward optimising body weight and role of pharmacological therapy is under evaluation.

14.12 Acute Liver Failure

SK Acharya , Shalimar

INTRODUCTION

The term liver failure is used when the survival of an individual is endangered as a consequence of multiple metabolic and haemodynamic disturbances resulting from severe acute or chronic liver injury. In a clinical setting, hepatic injury is usually recognised by appearance of jaundice and liver failure is recognised by occurrence of encephalopathy, ascites or coagulopathy.

Authors prefer to categorise liver failure into three distinct groups: acute liver failure (ALF), subacute hepatic failure (SHF) and chronic liver failure (CLF). ALF is defined as occurrence of hepatic encephalopathy with or without coagulopathy within 4 weeks of the onset of acute hepatitis. Occurrence of progressive ascites with or without encephalopathy after 4 weeks, but before 6 months of the onset of acute hepatic illness is termed as SHF. Occurrence of progressive ascites or encephalopathy after 6 months of recognisable or unrecognised hepatic illness is considered as CLF.

DEFINITION AND NOMENCLATURE

Trey and Davidson define ALF as occurrence of encephalopathy with or without coagulopathy within 8 weeks of onset of symptoms of acute hepatitis in an individual without any history of pre-existing liver disease. Patients who develop ALF within 7 to 10 days of the onset of icterus have significantly higher survival rates than those who develop encephalopathy later. Therefore, in Western countries, ALF is classified into hyperacute if encephalopathy develops within 10 days of onset of icterus and acute if it occurs between 10 days and 4 weeks of onset of jaundice.

Liver failure occurring more than 4 weeks after the onset of acute hepatic illness manifests with progressive ascites. In these patients, encephalopathy as a presenting feature is extremely rare. This condition, named as (SHF), behaves differently than ALF and majority do not survive beyond 6 months. The overall mortality rate is 70%; in addition, 60% of the survivors develop chronic sequelae.

AETIOLOGY OF ACUTE LIVER FAILURE

The causes of ALF are listed in **Table 1**. Geographical variations in the occurrence of common causes of ALF are well recognised and probably influence the clinical behaviour of such patients. ALF in the Eastern World, particularly in the developing world, is predominantly caused by various hepatotropic viruses (**Table 2**). Conditions like paracetamol overdose, metabolic liver diseases like Wilson's disease, acute fatty liver of pregnancy, *amanita* poisoning and drug-induced liver injury are important causes of ALF in the West, whereas these are extremely infrequent in the Eastern World (**Table 3**).

Table 1: Various Causes of Acute Liver Failure

Broad Category	Individual Aetiological Agents
Infections	Hepatotropic viruses (A-E) Cytomegalovirus Herpes simplex virus
Metabolic diseases	Wilson's disease Acute fatty liver of pregnancy Galactosaemia
Drugs	Paracetamol Rifampicin and isoniazid Sodium valproate Halothane Zidovudine Didanosine
Toxins	*Amanita phalloides* *Bacillus cereus* Akee fruit (hypoglycin)

Table 2: Causes of Acute Liver Failure in India

Author	Year	No. of Patients	Causes							
			HAV	HBV	HCV	HDV	HEV	Mixed	Non-A, Non-E	Drugs
Acharya *et al*	1999	458	4%	11%	4%	0%	23%	6%	47%	5%
Khuroo *et al*	1997	119	3%	15%	2.5%	2.5%	38%	NR	38.6%	0.8%
Jaiswal *et al*	1996	95	4%	27%	2%	5.2%	41%	4%	15%	0%

HAV = Hepatitis A virus; HBV = Hepatitis B virus; HCV = Hepatitis C virus; HDV = Hepatitis D virus; HEV = Hepatitis E virus; NR = Not reported.

Table 3: Differences in Aetiology of Acute Liver Failure (ALF) in Various Geographical Areas

	India	USA	UK	France
Viral	95%	60%	30%	50% to 60%
Drugs	4.5%	30% to 35%	60%	15% to 20%
Other	0.5%	5%	10%	10% to 15%
Viruses	HEV, HBV, Mixed viral infection	Cryptogenic HBV: 15% HAV: 8% to 10%	NANB HBV HAV	HBV HAV
Drugs	Anti-tuberculars	Acetaminophen	Acetaminophen	Other drugs

NANB = Non-A, non-B viral hepatitis.

CLINICAL PRESENTATION AND NATURAL COURSE

Demographic and clinical profile of 423 consecutive patients with ALF admitted to AIIMS, New Delhi, during 1987 to 1993 is summarised as follows. Most of the patients (n = 334) were below 40 years of age. Females outnumbered males. Twenty-five-per cent of females were pregnant in contrast to a 3% pregnancy rate in the general population, indicating that pregnant women who develop acute viral hepatitis are more likely to develop ALF

than non-pregnant women. Most patients (88%) had a prodrome preceding the icteric illness; mean duration of the prodrome was 4.7 days. The interval between prodrome and onset of encephalopathy was similar in survivors and non-survivors indicating that rapidity of onset of encephalopathy did not influence the outcome. The survival rate using conservative and aggressive supportive therapy was 34%.

ALF and Pregnancy

Mortality is similar in pregnant and non-pregnant women, and is independent of the cause or trimester

Pregnancy *per se* should not be regarded as a poor prognostic factor

COMPLICATIONS

Complications encountered in patients with ALF may involve several organ systems, either in isolation or in combination.

Neurologic Manifestations

Neurologic complications include rather distinct, but overlapping syndrome of cerebral oedema manifesting as increased intracranial pressure (ICP) and encephalopathy. The grading of encephalopathy is depicted in **Table 4**.

Table 4: Grading of Encephalopathy in Acute Liver Failure (ALF)

I	Loss of sleep rhythm, drowsiness, confusion, hepatic flap
II	Features of grade I encephalopathy with loss of sphincter control
III	Unconsciousness, no response to oral commands, but responds to painful stimuli
IV	No response to pain, deep unconscious state

In addition to changes in mental status, signs of raised ICP include myoclonus, focal seizures, decerebrate postures, absent pupillary reflexes and hyperventilation. Papilloedema is usually absent. Lowering the ICP in patients with ALF is important because raised ICP decreases cerebral perfusion pressure and oxygenation of the brain tissue. Unlike porto-systemic shunting, which is the major cause of encephalopathy in patients with cirrhosis, encephalopathy in ALF is usually multifactorial. Ammonia, mercaptans, biological amines, short chain fatty acids, pseudo-neurotransmitters from aromatic aminoacids, gamma amino butyric acid (GABA) have been implicated in the causation of encephalopathy.

Identification of elevated ICP is important because cerebral oedema resulting in brainstem herniation is the commonest cause of death among patients with ALF.

Renal

Renal failure occurs in 30% to 70% of patients with ALF in western countries where drugs and toxins are the usual causes of ALF. In contrast, renal failure occurs in only 3% to 5% of Indian patients where hepatotropic viruses are the predominant cause of ALF. Presence of renal failure is considered to be a bad prognostic indicator. Decreased water clearance, electrolyte imbalance, increased ammonia production due to raised blood urea are sequelae of renal failure which aggravate encephalopathy and cerebral oedema in patients with ALF.

Pulmonary

Pulmonary infection is the commonest form of respiratory problem encountered in ALF. In addition, acute respiratory distress syndrome, atelectasis, aspiration and pulmonary oedema may occur.

Cardiovascular

Cardiac arrhythmias may occur due to electrolyte imbalance, hypoxaemia, acidaemia, or during placement of pulmonary artery catheter. Usually patients with ALF have a hyperdynamic circulatory state similar to septic shock. This may be caused by decreased systemic vascular resistance subsequent to a vasodilator substance which under normal conditions is cleared by liver. Candidate vasodilator substances implicated in ALF include endotoxins, nitric oxide, glucagon, substance P, vasoactive intestinal polypeptide, GABA, atrial natriuretic factor and bradykinin.

Coagulopathy

Most proteins that promote or inhibit coagulation are synthesised in the liver. Further, Kupffer's cells in the liver act as scavengers for the activated coagulation factors in the circulation. With the exception of factor VIII, the levels of all coagulation factors are reduced in patients with ALF.

The coagulation test that can be easily performed in most laboratories is prothrombin time. Almost all patients with ALF show a variable degree of prolonged prothrombin time. Prothrombin time is a good indicator for prognosis.

Other coagulation problems that may be encountered in patients with ALF are thrombocytopaenia (which may be due either to marrow suppression or hypersplenism), disseminated intravascular coagulation and fibrinolysis. Each of these conditions may cause life-threatening bleeding, such as intracranial haemorrhage and gastrointestinal (GI) bleeding.

Sepsis

Sepsis occurs in 55% to 80% of patients with ALF. Bacterial infections are the commonest cause (70% to 80%) of sepsis and fungal infection occur in 10% to 20% of these patients. The reasons for this propensity to develop sepsis include abnormal opsonisation due to reduced hepatic synthesis of proteins like fibronectin, impaired Kupffer cell function, decrease in complement synthesis and neutrophil dysfunction.

Metabolic

Three distinct metabolic complications have been documented in patients with ALF. Hypoglycaemia occurs due to decreased insulin clearance, impaired gluconeogenesis, and loss of glycogen store due to liver damage. Both acidosis and alkalosis can occur in ALF. Respiratory alkalosis can occur due to central neurogenic hyperventilation, whereas depression of respiratory centre due to raised ICP may cause respiratory acidosis. Acidosis can also result from hypoxaemia or hypotension leading to accumulation of lactate, pyruvate, citrate, acetoacetate, and free fatty acids (FFAs). Electrolyte imbalance is common in patients with ALF secondary to renal failure, dehydration, drugs, tissue damage, and acid-base imbalance.

PROGNOSIS

The assessment of prognosis soon after initial presentation is crucial in order to allow most efficient use of available therapeutic options, particularly orthotopic liver transplant (OLT) which is increasingly becoming available in the developing countries like India. Arterial ammonia concentration higher than 124 μmol/L, associated with severe hepatic encephalopathy, cerebral oedema

and high mortality. Prognostic markers in Indian patients with ALF are: age ≥40 years, clinical evidence of cerebral oedema at admission, serum bilirubin ≥15 mg/dL and prothrombin time ≥25 seconds more than the normal. More than 90% of the patients with ALF having three or more of these factors die (**Tables 5 and 6**). Anti-tuberculosis therapy (ATT) induced ALF has a poor prognosis as compared with viral hepatitis.

Table 5: King's College Prognostic Criteria in Acute Liver Failure (ALF), Predicting High Mortality

Non-Paracetamol-Induced ALF	Paracetamol-Induced ALF
Prothrombin time >100 seconds or Any three of the following Age <10 or >40 years Aetiology: non-A, non-B hepatitis Drug-induced hepatitis Icterus-encephalopathyinterval >7 days Prothrombin time >50 seconds (INR >3.5) Serum bilirubin >17.5 mg/dL	Plasma pH <7.30 or Prothrombin time >100 seconds (INR >6.5) and serum creatinine >3.4 mg/dL in patients with grade 3 to 4 encephalopathy

Table 6: Clichy Criteria (France) for Poor Prognosis in Patients with Acute Liver Failure

Factor V levels < 20% of normal in patients < 30 years of age
Factor V levels < 30% of normal in patients > 30 years of age

Causes of Death

Survival rate of patients with ALF is approximately 34%. Two-thirds of deaths occur within the first 72 hours of hospitalisation, indicating that any therapeutic intervention for such patients must be instituted soon after hospitalisation, and that early referral of such patients to advanced centres should be encouraged. The median survival time is 4 days. Cerebral oedema, sepsis, renal failure, and GI bleeding are the most important causes of death.

TREATMENT

All the patients diagnosed to have ALF should ideally be admitted to an intensive care unit. The use of aggressive monitoring, and of respiratory and cardiovascular support particularly in the presence of cerebral oedema is probably responsible for modest improvements in the survival. However, if OLT is available, early referral of such patients may reduce greater post-transplant mortality and morbidity. The essential supportive measures are listed in **Table 7**.

MANAGEMENT OF COMPLICATIONS

Cerebral Oedema

Patients with advanced grades of encephalopathy and/or with overt cerebral oedema need measures to prevent further rise in ICP and specific therapeutic intervention to decrease ICP.

Measures to prevent rise of ICP include positioning of head and trunk at 35° to 40° angle above horizontal, avoiding unnecessary motions of the head, and avoiding hypoxaemia, hypercapnoea, fluid overload and acid-base imbalance. For treating raised ICP, rapid infusion of mannitol (20%) at a dose of 100 mL is the first step; it can be repeated hourly as long as patient maintains adequate renal function. Usual recommendation is to keep the ICP below 25 mm Hg; however, it is probably more important to maintain the cerebral perfusion pressure (mean arterial pressure minus intracranial pressure) above 50 mm Hg. The placement of intra cranial transducers in patients with ALF may be associated with life-threatening bleeding and sepsis. In patients with advanced encephalopathy without overt features of cerebral oedema and intact renal function, authors use 20% mannitol at a dose of 1 g/kg body weight every 8 hourly. Hyperventilation using a ventilator and administration of corticosteroids has not been found to be useful in the treatment of cerebral oedema. Induction of barbiturate coma may be used as a rescue therapy if mannitol fails. Phenobarbital is used at an initial intravenous dose of 5 mg/kg followed by an infusion rate of 1 to 3 mg/kg per hour. However, hypotension is a major problem during such therapy and intra-arterial pressure monitoring is necessary during such therapy. Seizures might complicate advanced hepatic encephalopathy and worsen prognosis, phenytoin prophylaxis neither improves cerebral oedema nor survival.

Table 7: Supportive Therapy in Acute Liver Failure

- Hospitalisation in intensive care unit
- Detailed clinical evaluation and assessment of grade of encephalopathy, cerebral oedema and prognostic indicators
- Laboratory investigations
  - Complete blood counts, platelet count, smear for malarial parasite
  - Blood grouping
  - Electrolytes, blood urea nitrogen, creatinine
  - Serum bilirubin, transaminases, albumin, alkaline phosphatase, amylase
  - Prothrombin time, fibrin degradation products
  - Arterial blood gases, arterial ammonia
  - Urine analysis, urine output
  - Bacteriologic evaluation: blood, endotracheal aspirate in intubated patients and urine culture for bacteria and fungi
  - Serology including HBsAg, IgM anti-HBc, IgM anti-HEV, IgM anti-HAV, anti- HCV, anti-HDV
- 24-hour urine copper, serum copper, serum caeruloplasmin, anti-nuclear antibody, anti-smooth muscle antibody, anti-liver kidney microsomal antibody
- Bedside ultrasonography to rule out liver abscess, acute hepatic venous out flow tract obstruction
- Other measures
  - Central venous line insertion
  - Chest X-ray
  - Assisted ventilation in patients with cerebral oedema and grade IV encephalopathy
  - Intravenous H2 blockers, nasogastric tube placement, blood glucose, monitoring for gastrointestinal bleed, oliguria, sepsis
  - Nutritional supplement through nasogastric tube
- Optional measures
  - Placement of extradural or subdural transducers to measure ICP
  - Prophylactic broad-spectrum intravenous antibiotic and antifungal therapy
  - Dialysis, if acute renal failure supervenes

Sepsis

Sepsis, as described above, is the second major cause of death among Indian patients with ALF. Gram-negative bacteria are the major cause of sepsis in these patients. Prophylactic parenteral antibiotics using third-generation cephalosporins may reduce the incidence of sepsis.

Renal Failure

In patients with ALF developing oliguria despite maintenance of adequate central venous pressure, low dose dopamine (2 to 2.5 µg/kg/hr) may be beneficial. However, mainstay of management of renal failure in patients with ALF is haemodialysis or continuous arterio-venous haemofiltration or continuous veno-venous haemofiltration. However, these procedures are associated with problems, such as, hypotension, aggravation of cerebral oedema due to fluid overload and increased risk of bleeding. The only satisfactory treatment in patients with ALF associated with renal failure seems to be liver transplant.

Coagulopathy

Coagulopathy associated with ALF is currently not preventable. Prophylaxis use of fresh frozen plasma (FFP) and vitamin K has not been shown to prevent bleeding. However, once bleeding occurs, FFP and platelet transfusion may help.

Other Complications

Hypoglycaemia, hypokalaemia and metabolic acidosis should be looked for and treated promptly.

SPECIFIC THERAPIES

Many therapeutic measures have been tried in an attempt to improve liver function, to reduce hepatocyte necrosis, or to improve encephalopathy.

Acetylcysteine

N-acetylcysteine (NAC) is useful in patients with paracetamol overdose, probably through an increase in the concentration of hepatic glutathione which converts paracetamol to its non-toxic metabolite. However, it is most effective if given within 8 hours of the drug overdose. Even in non-paracetamol ALF patients, this drug may produce improvement in haemodynamic parameters like cardiac index and mean arterial pressure, leading to improved tissue oxygen delivery. Recent data suggests NAC is well tolerated in this group and is associated with improved non-transplanted survival, but only in those treated early in the course and with Grade I-II encephalopathy.

Antivirals

Lamivudine for hepatitis B or acyclovir for HSV related ALF, might improve outcomes, but data is scarce.

L-Ornithine L-Aspartate (LOLA)

LOLA does not improve ammonia concentration, hepatic encephalopathy or survival in ALF. Novel agents like L-ornithine phenylacetate are being investigated.

Prostaglandins

Intravenous prostaglandin E1 has been used in patients with ALF with conflicting results.

Other Forms of Therapy

For *Amanita phalloides* poisoning, infusions of penicillin and silymarin appear to be effective. Penicillin antagonises the effect of mushroom toxin, amatoxin, and silymarin blocks its hepatocellular uptake.

Liver Transplantation (LT)

Urgent LT is now the standard therapy for ALF in individuals who, on clinical and laboratory criteria, have a less than 20% chance of survival. Contraindications to LT include irreversible brain damage, uncontrolled bacteraemia, human immuno-deficiency virus infection, concurrent malignant disease and the presence of failure of any organ which would preclude a satisfactory outcome.

Auxiliary liver transplantation is another treatment option for ALF. The native liver is left *in situ*. The procedure aims to provide temporary liver support until the native liver recovers. In one such study, native liver regenerated in 68% of those surviving more than 3 months. At this stage, immunosuppression can be withdrawn in the majority of patients and the donor liver can either be removed surgically or left in place to atrophy.

In India, cadaveric LT has not been able to take off due to lack of organisational priority, severe donor shortage and lack of awareness. Living-donor liver transplant (LDLT) programme is being offered in some institutions in India.

Other Methods of Liver Support

The frequent lack of donor livers for urgent transplantation has necessitated the use of liver support or replacement therapies until a liver becomes available. Several different approaches have been tried. All of these methods involve the use of very expensive and complicated equipment and their role awaits clarification by randomised clinical trials. These include extracorporeal liver assist devices, bioartificial liver, and extracorporeal wholeorgan perfusion.

Hepatocyte Transplantation

Uncontrolled trials using infusion of human hepatocytes into the splenic artery or portal vein have shown encouraging preliminary results. The mass of hepatocytes required to provide adequate support remains unknown.

Therapies Not Useful in Acute Liver Failure

1. Lactulose
2. L-ornithine L-aspartate
3. Branched-chain amino-acids
4. FFP transfusion in absence of bleeding
5. Enteral decontamination
6. Prophylactic phenytoin
7. Prophylactic hyperventilation for raised intracranial hypertension

PREVENTION

Public health measures like availability of safe drinking water; screening of blood in blood banks; vaccination for hepatitis B and use of disposable syringes will reduce the incidence of hepatitis A, B and E viral infections, which are the major causes of ALF in our country. Empirical use of ATT should be avoided, whenever possible.

14.13 Inherited Metabolic Disorders of the Liver

P Advaitham

INTRODUCTION

Inborn errors of metabolism include a variety of disorders with varied presentations and pathophysiology. These may present as an acute life-threatening illness in the neonatal period or may manifest as chronic liver disease during adolescence and progress to liver failure, cirrhosis or hepato-cellular carcinoma. In the United States of America, 5% of liver transplants are performed for metabolic liver diseases. Although liver transplantation is life-saving for these patients, new non-transplant treatment options have become available for some of these conditions.

The presenting features of metabolic liver diseases are diverse and can range from hypoglycaemia, hyperammonaemia, psychomotor retardation, elevation of aminotransferase levels, hepatosplenomegaly, acidosis, ascites, jaundice, bleeding diathesis, coma, short stature or failure to thrive. An infant presenting with cholestasis should undergo evaluation for metabolic liver disease; as should an infant with progressive neuromuscular disease; developmental delays or regression of developmental milestones.

A history of consanguinity in parents, multiple miscarriages or early infant death may suggest metabolic derangement. History of undiagnosed liver disease, progressive neurological or muscular disease or undiagnosed developmental delay in family members should raise suspicion. Introduction of certain foods may correlate with the onset of symptoms, as in urea cycle defects, galactosaemia or fructosaemia. Since patients with metabolic liver disease often present with recurrent symptoms, it is important to investigate the patient early. Apart from screening tests (**Table 1**), liver biopsy can be a useful diagnostic tool. Serum and urine samples should always be saved and frozen for definitive studies.

Table 1: Screening Laboratory Tests for Metabolic Liver Disease

WILSON'S DISEASE AND HAEMOCHROMATOSIS

Refer to chapter on Wilson's disease and Haemochromatosis in Metabolism Section.

ALPHA-1 ANTITRYPSIN DEFICIENCY

Alpha-1 antitrypsin deficiency is inherited as an autosomal-recessive disorder. The gene responsible is located on chromosome 14q31. Alpha-1 antitrypsin is synthesised and secreted predominantly by the liver. It is present in tears, duodenal fluid and saliva. Homozygous protease inhibitor phenotype ZZ (PiZZ) alpha-1 antitrypsin deficiency is the most common genetic cause of liver disease in children. In adults, it is associated with chronic liver disease and hepato-cellular carcinoma. Currently, there is no evidence that heterozygous forms, such as PiMZ, PiMS, PiSZ cause liver disease in children; their role in adults remains unclear. The hypothesis to explain liver damage include: proteolytic imbalance, abnormal immune response and inefficient over-accumulation of the mutant alpha-1 antitrypsin Z protein in liver cells.

Clinical Features

Neonatal jaundice occurs between 2 and 3 weeks of age but this may occur any time within the first 4 months of life. Jaundice usually lasts for 2 to 3 months, but may persist for up to one year. Hepatosplenomegaly is seen in 50% of symptomatic infants. Biochemical analysis shows both cholestasis and hepato-cellular damage. Liver disease may also occur in late childhood or adolescence. The affected children may present with signs of decompensated liver disease with portal hypertension. In adults, this disorder manifests clinically at some point during their lifetime in two-thirds of subjects with homozygous form of the deficiency and the rest are asymptomatic. This will present in about 40% of adult cases as cirrhosis of liver with portal hypertension including ascites and variceal bleeding. Hepato-cellular carcinoma occurs in up to 40% of cirrhotics due to this disorder.

Diagnosis

Liver biopsy shows characteristic periodic acid-Schiff (PAS) positive, diastase-resistant globules in the endoplasmic reticulum of hepatocytes. Alpha-1 antitrypsin phenotyping and serum alpha-1 antitrypsin levels are diagnostic.

Treatment

In the absence of cirrhosis of liver, alpha-1 antitrypsin deficiency is managed by supportive therapy. Avoidance of smoking and hepatotoxic agents (including alcohol) is recommended to prevent lung and liver disease, respectively.

In advanced liver disease, liver transplant is the treatment of choice. Other therapies that have been tried include synthetic androgens, such as danazol to raise the alpha-1 antitrypsin level, inhalational alpha-1 antitrypsin in cases with pulmonary disease and gene replacement therapy.

GLYCOGEN STORAGE DISEASES

In glycogen storage diseases (GSDs), enzyme deficiencies cause impaired glucose production and accumulation of abnormal

glycogen in the liver causing organ damage, leading to formation of hepatic adenomas and rarely progressing into hepato-cellular carcinoma. Clinically, three types of GSDs are common (type I, III and IV).

GSD type I (Von Gierke's) is due to deficiency of glucose-6-phosphatase which is the most common type of GSD seen clinically. It manifests as profound hypoglycaemia, hepatomegaly due to adenomas, retarded growth, hyperlipidaemia, lactic acidosis and hyperuricaemia. Liver biopsy and direct measurement of glucose-6-phosphatase activity in the liver tissue are confirmatory. Carbohydrate challenge will demonstrate the absence of any rise in blood sugar level.

Treatment is aimed at maintaining normal blood glucose, by high carbohydrate meals taken at frequent intervals. In children, frequent feeding during the day and nocturnal feedings through nasogastric tube may be required. In adults, daytime frequent feeding alone is advised. Corn starch undergoes slow degradation to glucose and steadily releases glucose into the system, hence should be the major ingredient in the diet.

GSD type III (debranching enzyme deficiency) is due to deficiency of amylo-1,6-glucosidase (debranching enzyme). The development of hepatic fibrosis and, rarely, progression into end-stage liver disease due to the direct toxic effects of abnormal form of glycogen in the liver are distinguishing features of this disorder; in addition, hypoglycaemia, growth failure, progressive muscle weakness and enlarged liver are seen. The diagnosis is made by liver histology and confirmed by direct measurement of debranching enzyme activity using ^{14}C-labelled glucose. The treatment of choice is liver transplant apart from nutritional support in the form of high-protein, low carbohydrate diet and corn starch therapy for refractory hypoglycaemia.

GSD type IV (amylopectinosis) is caused by the absence of branching enzyme β-1,4-glycosyl transferase, which results in the formation of amylopectin-like polysaccharides. Its deposition in the liver leads to hepatic fibrosis and early cirrhosis. This rare disorder presents clinically as hepato-splenomegaly, signs of liver dysfunction; failure to thrive and muscular hypotonia. The diagnosis is confirmed by demonstrating pale, basophilic deposits within the liver cells and micronodular cirrhosis with broad bands of fibrous tissue. Liver transplant is curative; however, providing nutritional support in the form of high-protein and low carbohydrate diet can control the disease.

TYROSINAEMIA

Tyrosinaemia is an autosomal recessive disorder that affects numerous organ systems, including liver, kidneys and peripheral nerves. The underlying defect is a deficiency of fumaryl-aceto-acetate hydrolase, leading to accumulation of toxic metabolites. The acute form of this disorder presents as hypoglycaemia, ascites, bleeding diathesis, anorexia, irritability and jaundice in the first 6 months of age. Serum tyrosine, methionine and alpha-foetoprotein levels are elevated. Chronic forms usually present after one year of age with hepatomegaly, enlargement of kidneys, rickets, growth retardation, cirrhosis and hepato-cellular carcinoma. Diagnosis can be confirmed by estimation of fumaryl-aceto-acetate hydrolase enzyme in the liver tissue. Dietary restriction of tyrosine and phenylalanine. NTBC [2-nitro-4-(trifluoromethyl benzoyl)-cyclohexane-1,3-dione], a potent inhibitor of hydroxyphenylpyruvate dehydrogenase, which reduces the production of toxic intermediates that damage the liver and the kidney has been shown to be useful. Liver transplantation normalises the enzyme activity and liver function.

CYSTIC FIBROSIS

Cystic fibrosis (CF) is an autosomal recessive, multiorgan disorder. The responsible gene is located on the long-arm of chromosome 7. Liver disease may manifest in the newborn period, and neonatal cholestasis has been identified in up to 30% of patients. Liver disease is becoming more common since the mean duration of survival of patients with CF has increased with improvements in treatment. Up to 30% of patients may have clinical or symptomatic liver disease after neonatal period. Focal biliary cirrhosis is the pathognomonic lesion; however, 5% of patients have multilobular biliary cirrhosis.

Ursodeoxycholic acid (20 to 30 mg/kg body weight) has shown improvement in cholestasis and nutritional status. Orthotopic liver transplantation (OLT) has been successfully performed for patients with portal hypertension and stable pulmonary function.

PORPHYRIA

This diverse group of metabolic derangements are due to errors in haeme synthesis. For some of these conditions, liver is the primary site of expression. Haeme synthesis occurs both in liver (15% to 20%) and bone marrow (70% to 85%). The term acute porphyria refers to the occurrence of acute neurological attacks, which are often recurrent and life-threatening. A majority of porphyrias manifest with neurological or cutaneous symptoms. Hepatic involvement is variable. In general, acute porphyrias may be associated with elevated serum levels of amino-transferases and bile acids; this abnormality worsens during acute attacks. Liver biopsy may show fatty change and iron deposition. Although the changes are minor, these patients are at an increased risk of developing hepato-cellular carcinoma.

Porphyria cutanea tarda and hepatoerythropoietic porphyria are most commonly associated with hepatic complications like enlarged liver due to fatty changes, inflammatory and granulomatous changes. Siderosis and fibrosis may lead to cirrhosis and liver failure. In porphyria cutanea tarda, the liver damage may be due to the metabolic abnormality or to additional factors, such as alcoholism and hepatitis C virus infection. In protoporphyria, protoporphyrin may have a direct toxic effect on the liver.

Increased urine porphobilinogen may suggest the diagnosis. To differentiate between different types of porphyria, urine and stool samples should be sent for porphyrin studies.

UREA CYCLE DEFECTS

Although these syndromes are not associated with liver disease, the basic genetic defect is located in the liver, and their manifestation may mimic other metabolic liver diseases. The most common defect identified is ornithine transcarbamylase deficiency.

These defects, with the exception of arginase deficiency, present as acute life-threatening events in the neonatal period. Infants are usually normal in the first 24 to 72 hours, since feeding during this period provides the initial protein load for ammonia production. Symptoms are irritability, seizures, coma, vomiting, hypertonia, lethargy and respiratory distress. Plasma ammonia reaches >3,400 µg/dL.

Blood urea nitrogen level is low. Allopurinol loading test (300 mg orally) leads to excretion of orotic acid 10 to 20 fold greater than normal. Serum ammonia level should be restored to normal. Haemodialysis is more effective than exchange transfusions. On stabilisation, introduction of low-level dietary protein (0.5 to 1g/kg) may be started. Arginase deficiency usually presents with spastic diplegia, quadriplegia or seizures.

HEREDITARY FRUCTOSAEMIA

This disorder, caused by fructose aldolase deficiency, presents clinically as chronic hepatitis or steatohepatitis. Diagnosis is made on enzyme analysis on liver biopsy. Treatment consists of removal of all fructose, sucrose, and maltose from the diet. Water-soluble vitamins should be given.

GALACTOSAEMIA

This disorder, caused by a defect of galactose-1-phosphate uridyl transferase synthesis, presents as vomiting, hepatitis, liver failure and disseminated intravascular coagulation, usually with sepsis, when the infant is first exposed to milk feeds. Diagnosis is made by measurement of enzyme levels in the infant's red blood cells. Early management consists of removal of galactose from the diet and standard treatment for liver failure and sepsis.

INHERITED DISORDERS OF BILIRUBIN METABOLISM

See chapter 2, section 14 on Clinical Approach to a Patient with Liver Disease.

NIEMANN-PICK A, B AND C DISEASES

These rare conditions are considered together because of their clinical similarities. Types A and B are associated with deficiency of sphingomyelinase in leukocytes or fibroblasts and type C with an enzymatic defect of cholesterol esterification. The genetic defect is linked to a locus on chromosome 18. All these diseases can present with neonatal hepatitis, portal hypertension and neurological disorders like ataxia. Liver disease with liver failure occurs in about 10% of cases. The overall mortality is about 67%. Demonstration of cells that stain with periodic acid-Schiff in the bone marrow aspirate helps confirm the diagnosis. The treatment is symptomatic; combined liver and bone marrow transplantation may be tried.

GAUCHER'S DISEASE

It is the common lysosomal storage disorder due to deficiency of acid β-glucosidase. The clinical presentation is massive hepatosplenomegaly but cirrhosis and portal hypertension is uncommon. Demonstration of Gaucher cells in the liver is difficult and bone marrow aspirate shows the characteristic diastase-resistant, periodic acid-Schiff positive histiocytes. The diagnosis is confirmed by estimation of enzyme levels in leukocytes. Regular infusions of the deficient enzymes have been tried with some benefit, but long-term results are not unknown. For patients with bone marrow infiltration with pancytopenia, combined liver and bone marrow transplantation has been tried.

MITOCHONDRIAL RESPIRATORY CHAIN DISORDERS

Mitochondrial respiratory chain disorders (MRCDs) as a cause of liver diseases are seen mostly in children. There is no 'gold standard' for the diagnosis of these conditions. Primary liver disease in MRCDs may present as acute liver failure, steatohepatitis, or cirrhosis of liver. Management is not specific but only supportive. Since other organ systems are also involved, the prognosis is poor.

INBORN ERRORS OF BILE ACID NUCLEUS SYNTHESIS

It may occur in conditions like 3β-hydroxy-C_{27}-steroid dehydrogenase/isomerase and δ-4-3-oxosteroid 5β deficiencies. Patients may present with neonatal liver failure, haemo-chromatosis or neonatal cholestasis. Diagnosis is made by analysis of plasma and urine bile acid profiles on fast atom bombardment mass spectroscopy. Ursodeoxycholic acid along with fat-soluble vitamins may be useful in treating these conditions.

PROPIONIC ACIDAEMIA

In this condition, there is a deficiency of mitochondrial propionyl coenzyme, a carboxylase enzyme, involving all the tissues. It presents soon after birth with episodic vomiting, coma, hypoglycaemia and acidosis, which are precipitated by protein intake or infection and can be corrected by liver transplantation.

PRIMARY OXALURIA TYPE I

This condition is due to the deficiency of alanine glyoxylate aminotransferase, which is found only in liver peroxisomes. This enzyme is used for the catabolism of oxalate, which has been either produced by the liver or consumed as food constituents (particularly leafy vegetables, rhubarb and strawberries). Oxalate can precipitate in the kidneys and is nephrotoxic.

The typical presentation of primary oxaluria is with nephrolithiasis in adults. Occasionally, it may be diagnosed in infants, based on elevated plasma oxalate level and measurement in liver biopsy material of the deficient enzyme. The ideal treatment is liver transplantation before the development of renal damage. If renal impairment has already set in, combined liver and kidney transplanstation from the same donor is useful.

14.14 Parasitic Diseases of the Liver

Samir R Shah

INTRODUCTION

Parasites are organisms, which live on or inside, and derive nourishment from another living organism. Several parasites are known to produce liver disease (**Table 1**).

Table 1: Parasitic Diseases of the Liver

Protozoal Infections	Helminthiasis
Amoebiasis	Ascariasis
Malaria	Echinococcosis
Visceral leishmaniasis	Blood and liver flukes
Cryptosporidiasis	Visceral larva migrans
	Strongyloidosis
	Capillariasis

AMOEBIC LIVER ABSCESS

Amoebic liver abscess (ALA) is an inflammatory space-occupying lesion of the liver caused by *Entamoeba histolytica*. This disease is endemic in India and is the most common form of extra-intestinal or invasive amoebiasis. The amoebiasis is extensively discussed in section 17 chapter 53.

LIVER INVOLVEMENT IN MALARIA

All the four *Plasmodium* species, viz. *P. falciparum*, *P. vivax*, *P. malariae*, and *P. ovale*, multiply in hepatocytes during their life-cycle. *P. vivax* and *P. ovale* can persist in a dormant phase in the liver for long periods extending up to years, capable of causing recrudescence of the disease.

Pathophysiology

In the exoerythrocytic phase, the malarial parasites are confined to the hepatocytes. In uncomplicated malaria, significant hepatocyte damage is conspicuous by its absence. A persistent exoerythrocytic cycle of *P. vivax* and *P. ovale* is also not thought to produce pathological changes in the hepatocyte, except for the presence of hypnozoites. In all forms of malaria, pathological findings are similar and include sinusoidal dilatation and congestion, Kupffer cell hyperplasia, parasitised red cells and fine pigment in red cells and Kupffer cells. In severe falciparum infection, cytoadherence and sequestration of the infected erythrocytes leads to microcirculatory disturbances, which in turn lead to end-organ damage in the kidney, brain, intestines, retina and bone marrow. The resultant tissue hypoxia, lactate production and release of cytokines, such as tumour necrosis factor (TNF) and interleukin-1 is responsible for the characteristic clinical picture of the multiorgan failure. Loss of microvilli of bile canaliculi has been observed on electron microscopy; this may explain the cholestasis and conjugated hyperbilirubinaemia noted in some patients with severe *falciparum malaria*.

Clinical Presentation

Fever is the presenting complaint. Similar clinical presentation may occur in other common causes of community-acquired infections like viral fever, enteric fever and viral hepatitis. Mild jaundice during uncomplicated malaria is usually due to haemolysis. Complicated falciparum malaria may present with rapidly progressive jaundice, fever, altered sensorium, oliguria and shock. Coma in these patients is believed to be due to the involvement of the brain and not due to liver cell failure.

Diagnosis

Detection of malarial parasites on peripheral blood smear is the mainstay of diagnosis. However, multiple smears may need to be examined. In uncomplicated malaria, hyperbilirubinaemia is predominantly unconjugated in nature. Elevation of liver enzymes (AST/ALT) is mild, and much lower than the range seen in acute viral hepatitis. Enteric fever may have a similar clinical presentation, with fever, normal leucocyte count and hepato-splenomegaly; however, jaundice is uncommon. In complicated falciparum malaria, hyperbilirubinaemia is especially marked and may be predominantly conjugated.

Treatment

No specific treatment related to the liver is required either in uncomplicated or in falciparum malaria. Unconjugated hyperbilirubinaemia improves with clearance of the malarial parasites and regression of hepatosplenomegaly. In complicated falciparum malaria, treatment is directed towards the multiorgan failure with haemodynamic and respiratory support, treatment of metabolic acidosis, renal failure and hypoglycaemia; specific hepatic support is not needed. Conjugated hyperbilirubinaemia rapidly declines on clearance of parasites and improvement in renal failure.

TROPICAL SPLENOMEGALY SYNDROME

Tropical splenomegaly syndrome, also known as hyper-reactive malarial splenomegaly, is a condition that occurs in residents of areas endemic for malaria. It is postulated to be caused by repeated immunologic stimulation, and is characterised by high titres of total IgM and specific anti-malarial antibodies, hepatic sinusoidal lymphocytosis and splenomegaly.

Clinical presentation is with dragging abdominal pain due to an enlarged spleen (which is often enormous in size) and symptoms related to anaemia. Due to a prominent immunological response, malarial parasites may not be detected in the peripheral blood smear. However, most patients respond well to anti-malarial treatment with a reduction in IgM levels and splenomegaly. If untreated, the condition has a high mortality, primarily due to overwhelming sepsis.

HYDATID DISEASE OF THE LIVER

Hydatid disease is a zoonotic infection caused by larval stage of tapeworms of genus *Echinococcus*. It is characterised by the presence of medium-to-large sized cysts in the liver and other body organs. It is a public health problem in areas in Europe, Asia,

South America, Kenya and the Mediterranean region, where sheep are raised (*See chapter 59 of section Infectious Diseases*).

Clinical Presentation

Although the infection is usually acquired during childhood, most cysts are detected in third to fifth decades of life. The cysts may be asymptomatic and detected incidentally at imaging done for another reason. Symptoms are usually related to the presence of an expanding mass, pressure on surrounding structures, infection in the cyst or rupture of the cyst. Examination reveals an enlarged liver with or without palpable soft to firm masses. A thrill may be elicited over the mass. A calcified cyst may feel hard, and thus, needs to be differentiated from a liver tumour. Compression of the hepatic veins and inferior vena cava by the cyst can cause Budd-Chiari syndrome. A large cyst in the hilar area may compress the common bile duct and lead to obstructive jaundice. The cysts can rupture into the biliary tree, leading to biliary colic and cholestasis, with cholangitis; blockade of the ampulla by cyst contents can lead to acute pancreatitis. Cyst rupture into the peritoneal cavity can lead to anaphylactic shock; should the patient survive this acute catastrophe, implant of scolices on the peritoneal surface can cause extensive peritoneal cyst formation.

Diagnosis

Diagnosis can be made by detection of specific antibodies or circulating antigen. Enzyme-linked immunosorbent assay (ELISA) for IgG anti-echinococcus antibodies has a specificity of 88% to 96% with a sensitivity of 80% to 100% in patients with hepatic cysts. False positive tests can occur in persons living in endemic areas and in those with other parasitic infections. Positive tests require confirmation by arc-5 immuno-electrophoretic test, which detects antibodies against an antigen specific to the cestodes. Cross-reactions with *Taenia solium* do occur and need to be considered in regions where both the infections are a problem. A plain radiograph of abdomen may show curvilinear calcification in the liver cyst. Endocyst calcification is spotty in nature and appears as speckled calcification. Liver cysts are well seen at ultra-sonography. Cysts may appear uni- or multi-vesicular with clear fluid. Some cysts may have a hyperechoic solid pattern or may have reflective wall suggestive of calcification. Rupture of liver cyst into bile duct can be suspected on ultrasonography. Chest radiography and computed tomography (CT) can be used to concomitant cysts in other parts of the body.

Treatment

Surgery with the potential to cure patient was the standard modality of treatment till recently. It is the treatment of choice for patients with a large liver cyst, subcapsular cyst, pedunculated cysts and infected cysts. Surgery may not be possible in patients with multiple cysts, cysts that are difficult to access and in patients at extremes of age, or those with co-morbid conditions. Mebendazole (40 to 50 mg/kg/day), albendazole (10 to 15 mg/kg/day) and praziquantel have well-documented scolicidal activity. Administration of drugs in three cyclic one-month courses interspersed with drug-free intervals of 14 days each have been widely used. Recent data favour the use of uninterrupted drug therapy for 3 to 6 months. Addition of praziquantel (40 mg/kg once a week) increases the efficacy of benzimidazoles. Drug therapy is effective in small cysts (<4 cm in diameter) and cysts with thin walls. It leads to cyst disappearance in 30%, partial improvement in 30% and no response in 40%. It is recommended as primary therapy in patients at high surgical risk and as a concomitant therapy with percutaneous drainage. Benzimidazoles are hepatotoxic, can cause neutropaenia and thrombocytopaenia, and are teratogenic.

In recent years, percutaneous drainage of hepatic hydatid cysts known as PAIR (Puncture, Aspiration, Installation of scolicidal agent and Reaspiration) has gained acceptance. It is a treatment of choice in patients with liver cysts and a co-morbid condition precluding surgery, or those who refuse surgery. It is an effective procedure in uni- or multi-vesicular cyst with a few large daughter cysts. Liver puncture carries a potential risk of anaphylaxis and biliary communication of the cyst. Long-term follow-up has shown that secondary echinococcosis does not occur following percutaneous drainage.

HEPATOBILIARY ASCARIASIS

The normal habitat of the adult roundworm is the jejunum. In Indian subcontinent Ascariasis is highly endemic in Kashmir, Central and South-west India.

Clinical Presentation

Ascaris infestation is usually asymptomatic. Adult worms can enter the duodenum due to excessive load or abnormal motility, and may enter and block the ampullary orifice. They can advance further into the bile duct, hepatic ducts or cystic duct, blocking any one of these. The entry of these worms into the gall bladder or pancreatic duct is less frequent but known. Usually, the worms move out of the biliary system within a week's time. If they persist in the duct system for more than 10 days, they often die, serving as a *nidus* for the formation of bile duct calculi.

The clinical manifestations vary according to the site of involvement and include biliary colic, cholangitis, acute pancreatitis, and hepatic abscess. Ascariasis was found to be responsible for 37% of pancreatobiliary diseases in Kashmir. Due to the smaller size of their bile ductal system, children do not usually suffer from hepatobiliary ascariasis.

Diagnosis

Ultrasonography is a highly sensitive and specific method for detection of worms in the biliary tree. Endoscopy permits direct visualisation of worms in the duodenum and across the papilla. At endoscopic retrograde cholangiopancreatography, worms are seen as linear filling defects or curves and loops criss-crossing the hepatic ducts.

Treatment

Treatment of biliary ascariasis includes treatment of cholangitis by conservative means and oral administration of anti-helminthic agents to treat adult worms in the intestine. Endoscopic removal of the retained worms is performed when a patient does not respond to conservative means or when worms have not moved out of the duodenum at 3 weeks. It is successful in 90% to 100% of patients and is followed by rapid relief of symptoms. See chapter 58, section 17.

BLOOD AND LIVER FLUKES

Involvement of liver occurs in infection with *Schistosoma mansoni*, *S. japonicum*, and *S. mekongi*. Portal venous tracts are replaced by fibrous tissue resulting in peri-portal fibrosis with portal hypertension. Hepatic function is well preserved and the usual stigmata of chronic parenchymal liver disease are absent.

Clonorchis sinensis infection involves the bile ducts and causes ascending cholangitis with a risk of cholangiocarcinoma. *Fasciola hepatica* invade the liver and reside in bile ducts; clinical presentation is similar to *C. sinensis* infection, there is no association with cholangiocarcinoma. Praziquantel is the treatment of choice for all flukes, except *F. hepatica* for which bithional is recommended.

VISCERAL LEISHMANIASIS

This disease is caused by a protozoal infection with *Leishmania donovani* or related parasites *L. infantum* or *L. chagasi*. Cutaneous leishmaniasis is caused by several other species of the genus. The disease is common in Ganges and Brahmputra valleys of India. Visceral leishmaniasis is transmitted by sand fly, *Phlebotomus argentipes*, which rests in cattle sheds and bites humans at night. In the inter-epidemic period, the parasite survives in the skin of patients with post kala azar dermal leishmaniasis. The leishmaniasis is discussed extensively in infectious disease section.

14.15 Toxic and Drug Induced Liver Injury

Abraham Koshy

INTRODUCTION

More than 1000 drugs may produce drug-induced liver injury. About half of them produce only biochemical changes but about one-third lead to clinical acute hepatitis. Antibiotics including anti-tuberculosis drugs are the commonest group of drugs that produce liver injury. In India, nearly 50% of cases of drug-induced liver injury may be due to anti-tuberculosis drugs.

To manage cases with drug-induced liver injury, one must understand mechanisms, spectrum and the approach to diagnosis, treatment and prevention of this condition.

MECHANISMS

The basic mechanism may be allergic or toxic. If less than 1% of those who consume a particular drug develop liver injury, the mechanism is likely to be allergic. If more than 10% of those who consume the drug develop liver injury, the mechanism is likely to be toxic. Examples of each are given in **Table 1**.

Table 1: Mechanisms of Drug-induced Liver Injury

Mechanism	Frequency	Example
Allergic	<1%	Rifampicin
Reactive metabolite	<1%	Indomethacin
Toxic metabolite	<1%	Halothane
Dose dependant	>10%	Methotrexate
Mitochondrial toxicity	>10%	Amiodarone
Overdose	>10%	Colchicine
Toxic	>10%	Griseofulvin

SPECTRUM

The spectrum of drug-induced liver injury can be quite varied. The liver injury may be biochemical in nature, i.e. asymptomatic elevation of alanine aminotransferase (ALT) or aspartate aminotransferase (AST) [AST; 1.1-6.0 times the upper limit of normal (x ULN)] or alkaline phosphatase [(ALP); (1.1-1.7 x ULN)]. Other patients may have acute hepatitis-like picture, which includes symptomatic acute hepatitis or marked elevation of transaminases (>6.0 x ULN) or alkaline phosphatase (>1.7 x ULN). Less frequent manifestations are listed in **Table 2**.

Table 2: Spectrum of Drug-Induced Liver Injury

Manifestation	Definition
Biochemical, ALT/AST	1.1-6.0 x upper limit of normal (ULN)
Acute	Symptoms like acute hepatitis and AST/ALT >6.0 x (ULN)
Acute cytolytic	
Acute cholestatic	Defined histologically or biochemically
Fulminant hepatitis	
Granulomatous hepatitis	Defined histologically
Chronic hepatitis	Elevation of transaminases for > 6 months
Steatosis	
Vascular	
Benign tumour	Defined histologically
Malignant tumour	

ALT = Alanine aminotransferase; AST = Aspartate aminotransferase.

DIAGNOSIS

There is no reliable test for the diagnosis of drug-induced liver injury. All drugs taken during the 2-week period preceding the onset of liver injury should be suspected as the cause of liver injury. Therefore, the diagnosis depends on following the temporal relation of suspected drug intake to both the onset (<90 days) and recovery (<180 days) of liver injury; exclusion of other causes of liver injury; reappearance of liver injury on re-challenge with the same agent; and known association (previous published reports) of the suspected drug to liver injury.

A scoring system has been developed to help reach a diagnosis of drug-induced liver injury. In this system, known as the 'clinical diagnostic scale', points are given for each factor included in the scale and an overall scale calculated; a score of >9 had sensitivity of 88% and specificity of 98% for diagnosing drug-induced liver injury.

TREATMENT

Treatment essentially consists of withdrawal of all suspected drugs. N-acetylcysteine must be given for paracetamol (acetaminophen) toxicity. Corticosteroids should be used only if skin rash or other extra-hepatic manifestations are present.

If a suspect drug is considered essential, the decision to continue or withdraw the drug is based on determination of answers to the following questions: Is the drug absolutely essential? How severe is the liver damage? Can the drug dose be reduced or the drug replaced by another drug? Which is likely to be more dangerous—the underlying disease or the drug?

The liver injury should be considered severe and even an 'essential' drug should be withdrawn if the patient has hepatic encephalopathy, abnormal prothrombin time, serum bilirubin exceeding 2 mg/dL or levels of ALT or AST exceeding 3 x ULN.

If more than one drug is implicated, all the non-essential drugs should be withdrawn. Thereafter, the least implicated drug should be re-introduced the first, beginning with a lower dose and then gradually increased to the full dose, while closely monitoring the liver function tests. Thereafter, the second drug can be added in a similar manner.

Re-challenge should be avoided, unless it is considered essential to reintroduce the same drug.

PREVENTION

There is no general guidelines to prevent drug-induced hepatitis. Rifampicin and pyrazinamide should not be used for latent tuberculosis infection but rather isoniazid.

In patients with liver cirrhosis, a combination of isoniazid and rifampicin should be avoided; ethambutol and streptomycin are safer, and may be used in combination with newer fluoroquinolone.

14.16 Liver Transplantation

Subash Gupta, Ajay Kumar

HISTORY AND TERMINOLOGY

Since the first experimental transplantation of liver in dogs in 1955 by Welch and first successful human liver transplant in 1967 by Dr Thomas Starzl in the United States of America, liver transplantation has made a considerable progress. Today, it is the sole definitive treatment for end-stage liver disease. Apart from progress in technology, improvements in critical care, anaesthesia, better understanding of liver anatomy, organ preservation and immunosuppressive therapy have improved the outcome of this surgery. From the early 1980s before the introduction of cyclosporine A (csA) to the addition of newer drugs like tacrolimus, mycophenolate, sirolimus, the 5-year survival has improved from 20% to 80%.

Liver transplantation can be from a cadaveric liver where the whole liver from a brain-dead donor is transplanted or can be from living donor where the right lobe in adults and the left lobe in children is transplanted. In 1994, India adopted the Human Transplant Act which legally accepted brain stem death facilitating cadaver organ donation. However, this has not picked up much. For this reason, living donor liver transplant is done more frequently than cadaver transplant in India.

INDICATIONS AND TIMING OF TRANSPLANT

Liver transplant is indicated in irreversible acute or chronic end-stage liver disease. Common indications for liver transplant being done in India are given in **Tables 1 and 2**.

Table 1: Indications of Liver Transplant being done in India

Indications for Adult (n = 247)	N	% of Total
Hepatitis C (HCC, 25)	95	38.5
Alcoholic liver disease	49	19.8
Hepatitis B (HCC, 8)	29	11.7
Cryptogenic cirrhosis	32	13.0
Hepato-cellular cancer	39	15.8
(non B non C)	7	
Primary sclerosing cholangitis	9	
Autoimmune/PBC	8	
Wilson's disease	4	
Miscellaneous	10	

NB: HCC figures alone as well as with Hepatitis B and Hepatitis C, and therefore, the total is more than 249.
PBC = Primary biliary cirrhosis.

Various sets of parameters have been studied in different liver diseases to decide the timing of transplant. All these criteria help in determining the timing at which patient's chances of survival are better after transplant than without transplant.

In chronic liver disease, the Child-Pugh score has been used to prognosticate in patients with liver cirrhosis. This score is based on serum bilirubin, prothrombin time, albumin and presence or absence of ascites and encephalopathy. Patients who are Child C or if they have recurrent encephalopathy, refractory ascites, spontaneous bacterial peritonitis, uncontrolled portal hypertensive bleeding are advised a liver transplant. Model for end-stage liver disease (MELD) score is used for prioritising organ allocation. This is based on bilirubin, creatinine and prothrombin time. At MELD score 15 or above transplant is indicated. In LDLT, the MELD score may be used for patient selection but will have no role in allocation as the organ is for a specific recipient.

MELD score = 0.957 log e (serum creatinine mg/dL)
+0.378 log e (serum bilirubin mg/dL)
+1.120 log e (INR)
+0.643

Table 2: Indications for Paediatric Liver Transplant

EHBA	10
PFIC	2
Wilson's disease	4
Neonatal hepatitis	3
Congenital hepatic fibrosis	2
Cryptogenic cirrhosis	2
HCC	1
CNS	1
Total	**(N) 25**

EHBA = Extra-hepatic biliary atresia; HCC = Hepato-cellular carcinoma; CNS = Crigler-Najjar syndrome; PFIC = Progressive familial intra-hepatic cholestasis.

An increasing number of patients are being transplanted for hepato-cellular cancer. MILAN criteria (single nodule of <5.0 cm or less than 3 nodules none greater than 3 cm) are widely used for selecting candidates for transplant. However of late, there has been a relaxation of the criteria as good recurrence free survival can be obtained even with a single nodule as large as 6.5 cm in diameter, the so called University of California, San Francisco (UCSF) criteria.

In acute liver failure (ALF), liver transplantation is often a treatment option. The challenge is to find the right patient where survival without transplant is unlikely.

King's college criteria are used for transplant listing in patients with ALF due to paracetamol overdose. There has been suggestion from western data that if the interval between onset of jaundice to encephalopathy is more than 1 week, then mortality is high. But there has been conflicting reports from India. As a single criterion, deterioration in prothrombin time remains the most important predictor.

CONTRAINDICATIONS

The contraindications are mainly from either decreased life expectancy from co-morbid illnesses, such as, poor cardiovascular and pulmonary reserve, renal dysfunction, extra-hepatic or hepatic malignancy with extra-hepatic spread and active sepsis. Human immuno-deficiency virus patients with

negative viral load are now considered for liver transplant. Complete portal vein thrombosis is a relative contraindication.

SURGICAL TECHNIQUE

Organ Preservation

Once a donor is identified the liver needs to be preserved so that it remains viable once arterial and portal blood flow is restored. In cadaver organs, this is achieved by perfusing cold preservation fluids such as tryptophan ketoglutarute or University of Wisconsin solution through the aorta and through the portal vein. The organ is quickly cooled to 4°C, retrieved, placed in the cold preservation fluid and then packed in ice. This can be preserved for 12 to 16 hours but is kept to minimum possible time to prevent complications like ischaemia reperfusion injury, late rejection and biliary strictures. In LDLT, the organ is retrieved and then perfused with cold fluid through the portal vein in the back table. Recipient hepatectomy is part of transplantation in the presence of coagulopathy and portal hypertension. Following this, the implantation is done by three vascular anastomosis, i.e. hepatic veins, portal vein and hepatic artery and bile duct anastomosis. The hepatic artery and bile duct anastomosis is done after reperfusing the liver. Apart from the complexity of the surgery, liver transplant operation demands management of major metabolic shifts and haemodynamic changes.

Once the operation is over, the patient is initially managed in the intensive care unit and when the patient is conscious, haemodynamically stable and is breathing properly, patient is extubated the next day. Patient is constantly monitored for sepsis, rejection, patency of various anastomoses by Doppler and renal function. Oral feeding is started by the third day and the dose of anti rejection medicines is adjusted daily according to the drug levels and the results of the blood tests.

IMMUNOSUPPRESSION

Immunosuppresive agents are required to avoid rejection. The first agent to be used were steroids. However, steroids alone are not sufficient and high doses may cause serious side-effects. Azathioprine was the next agent to be introduced but was not as effective. With the introduction of calcineurin inhibitors, such as cyclosporine, there was a marked improvement in graft survival and in many ways marked a watershed in the history of transplantation. Graft survival improved to over 70% at one year.

Concurrently, there was development of biological agents, such as OKT3 and ATG which were antibodies against T cells. Although very potent to reverse acute rejection, they were often associated with side-effects, such as fungal and viral infections and the development of lymphoproliferative disorders.

Similar to cyclosporine in many ways, tacrolimus was found to be more effective than cyclosporine in preventing acute graft rejection. Both these drugs work by inhibiting interleukin 2, and thereby, preventing proliferation of T-cells when exposed to graft. This was a major advance as they were more specific and directly inhibited graft related T-cell stimulation rather than suppression of B cell related humoral immunity.

With the introduction of mycophenolate mofetil, immuno-suppression in liver transplantation quickly changed to an initial triple combination of calcineurin inhibitors, mycophenolate mofetil/azathioprine and steroids. Most centres now use steroids for 3 to 6 months and then these are tapered off.

With the current immunosuppressive strategy, patients are living longer. However, there are side effects of long-term immunosuppression such as of diabetes, hyperlipidaemia and hypertension. Both the calcineurin inhibitors are nephrotoxic and also carry higher risk of developing malignancies.

RESULTS

Liver transplantation is a very successful operation. The results of cadaveric transplants conducted between 1968 and 1988 showed a 10-year graft and patient survival of 31% and 36% respectively. In contrast the survival of grafts and patients who were transplanted between 1988 and 2004 improved to 53% and 61%, respectively. The trend is towards better results and the projected 10-year survival now is 80%.

LIVER TRANSPLANTATION IN INDIA

It was first successfully conducted in New Delhi in 1997. Now liver transplantation is conducted routinely in India in over 14 centres. Over 90% of the transplants in the country have been conducted in two centres in Delhi. Annually about 300 transplants are now carried out in the various centres in India with a success rate of 91%.

DISEASE RECURRENCE

More than rejection or infection or the development of malignancy, the long-term results of liver transplantation is plagued by disease recurrence.

In hepatitis B, disease recurrence can be prevented by the combined use of antiviral agents and hepatitis B immunoglobulins.

The major problem is with transplants for hepatitis C with disease recurrence of over 25% at 5 years and many of these patients will need a re-transplant as therapy for hepatitis C is only partly successful.

In transplants for HCC, if the transplants are conducted within the MILAN criteria or the UCSF criteria the survival at 5 years is around 80%.

In patients who are transplanted for alcoholic liver disease, recidivism may account for late graft loss. Most centres now insist on a period of abstinence of 6 months prior to transplantation.

CONCLUSIONS

Liver transplantation is a suitable treatment for end-stage liver disease, acute liver failure and HCC. Post-transplant care is complicated by monitoring of immunosuppressive medications and their side effects. Disease recurrence, such as hepatitis C affects the long-term results.

ALCOHOLIC LIVER DISEASE

Alcoholic liver disease is discussed in chapter 8 of section 14.

14.17 Pregnancy and Liver Disease

Ramesh Roop Rai

INTRODUCTION

Pregnant women may develop liver diseases that are aetiologically related to gestation or one of its complications. Invariably, these disorders become clinically evident during the second and third trimester or just after delivery. These diseases may be mild in presentation or may be severe, even life-threatening.

HYPEREMESIS GRAVIDARUM

Hyperemesis gravidarum occurs in 1 to 20 patients per 1,000 pregnancies; in the first trimester, usually between 4 and 10 weeks of gestation, but may occur as late as 20 weeks gestation.

The exact cause remains unknown. Multiple theories exist from psychologic predisposition, including conversion disorders to evolutionary adaptation to protect a mother and her foetus from certain potentially harmful foods. Hormone levels seem to play a role, as nausea and vomiting peak when human chorionic gonadotrophin and oestradiol levels are high. Risk factors include history of the disease, hyperthyroidism, psychiatric illness, molar pregnancy, pre-existing diabetes, multiple gestations, multiparity and high daily intake of saturated fat before pregnancy.

Symptoms include severe nausea and vomiting, at times requiring hospitalisation. Patients often present with dehydration and may show evidence of malnutrition with poor weight gain.

Although no standard diagnostic criteria exist, some commonly used include persistent vomiting with no other cause, evidence of acute starvation (usually with ketonuria), and evidence of acute weight loss. Up to half of hospitalised patients have abnormal liver enzymes. Aminotransferase levels may rise up to 200 IU/L but are generally less than 300 IU/L and alkaline phosphatase may rise to twice the normal values. Both direct and indirect bilirubin values may rise to 4 mg/dL and serum amylase and lipase may rise to 5 times normal.

Non-pharmacologic interventions include avoiding nausea inducing triggers, such as odours from perfume, smoke, cooking foods, and chemicals. Low fat, frequent, small meals may help to improve symptoms. Multivitamin use at the time of conception has also proved successful, so any patient with a history of hyperemesis in earlier pregnancies should be encouraged to start taking multivitamins prior to conception.

Vitamin B6 in a dose of 10 to 25 mg 4 times a day (QID) is the initial treatment of choice. Its use in conjunction with doxylamine (12.5 mg qid) has demonstrated great success. Promethazine 12.5 mg orally or rectally every 4 hours or diphenhydramine, 50 to 100 mg orally or rectally every 4 to 6 hours can be used in unresponsive patients. In the absence of dehydration, metoclopramide 5 to 10 mg intramuscular (IM)/orally thrice a day; promethazine 12.5 to 25 mg IM/orally/rectally every 4 hours can be added. If dehydration is present, intravenous (IV) fluids should be started, as well as either dimenhydrinate 50 mg intravenously every 4 to 6 hours, metoclopramide 5 to 10 mg intravenously thrice a day, or promethazine 12.5 to 25 mg intravenously every 4 hours. If all these agents fail, methylprednisolone 16 mg thrice a day per orally (PO)/IV for 3 days followed by a 2 week taper or ondansetron 8 mg intravenously twice a day can be added. Methyl-prednisolone has demonstrated an association with oral clefts when used in the first 10 weeks of gestation, and therefore, should be used with great caution.

Minor maternal complications can occur viz. acid-base and electrolyte disturbances. Serious complications viz. oesophageal rupture, retinal haemorrhage, pneumothorax, renal damage, and Wernicke's encephalopathy are rare. Foetal outcomes are similar to those in the general population, except in severe cases wherein mean birth weight is reportedly lower.

ACUTE FATTY LIVER OF PREGNANCY (AFLP)

The prevalence is 1 per 10,000 to 15,000 pregnancies. AFLP develops in second half of the pregnancy (27 to 40 weeks of gestation), usually close to term, but it may be diagnosed even in the post-partum period. The differential diagnosis includes fulminant viral hepatitis, drug-induced hepatic toxicity, idiopathic cholestasis of pregnancy, adult-onset Reye syndrome, and haemolysis, elevated liver enzymes and low platelets (HELLP) syndrome.

Aetiology

AFLP is in the family of microvesicular fat diseases, along with Reye syndrome and valproate toxicity. No clear geographical or racial predisposition exists. Risk factors include older maternal age, primiparity, multiple gestations, pre-eclampsia, male foetus, being underweight and a history of AFLP. Studies have revealed a higher incidence of AFLP in women with (i) genetic mutation that affects their mitochondrial fatty acid oxidation pathway, and (ii) a foetus with a long-chain 3-hydroxyacyl-coenzyme A dehydrogenase (LCHAD) deficiency.

Symptoms

Symptoms develop over several days to weeks and include nausea, vomiting, anorexia, lethargy, abdominal pain, ascites, and progressive jaundice. Transient polyuria and polydipsia may occur due to transient diabetes insipidus. Acute renal failure occurs in 50% patients, hepatic encephalopathy in 60%. Approximately 50% have hypertension, proteinuria, and oedema suggestive of pre-eclampsia.

Diagnosis

In AFLP, serum aminotransferase levels are moderately elevated (typically 300 to 500 U/L), bilirubin is <5 mg/dL except in severe cases. Other typical abnormalities include hypoglycaemia, elevated ammonia levels, thrombocytopaenia, neutrophilia, coagulopathy and renal dysfunction.

Computed tomography (CT) may demonstrate diffuse low-density signals in the liver and ascites. However, ultrasonography (USG) is normal in view of microvesicular fat deposits. Liver biopsy is definitive (microvesicular steatosis), but rarely performed because of the need for prompt therapy as well as the presence of coagulopathy.

Treatment

Patient requires admission, as the disease is progressive and can have sudden deterioration. Continuous foetal monitoring should be initiated. Supportive measures are required in the form of glucose infusion, adequate hydration and blood products, wherever indicated. The primary treatment is prompt delivery of the foetus. Recovery before delivery is not seen. Patients start improving 48 to 72 hours after delivery, but those with evidence of coagulopathy, encephalopathy, or hypoglycaemia on admission, often require continued intensive care level monitoring and possible transfer to centres capable of liver transplants.

Prognosis

Liver function normalises within a week but is delayed for months in severe cases. The maternal mortality has declined from 70% to 7% to 18%. Maternal complications include post-partum haemorrhage, renal failure, hypoglycaemia, disseminated intravascular clotting, pancreatitis, and pulmonary oedema. Perinatal mortality rates have also decreased from 85% to 9% to 23%. Because of the urgent need for immediate delivery, 75% of deliveries are pre-term (average gestational age at delivery is 34 weeks).

INTRA-HEPATIC CHOLESTASIS OF PREGNANCY

Intra-hepatic cholestasis of pregnancy is a common disorder manifesting in the third trimester; symptoms resolve after delivery. The differential diagnosis includes viral hepatitis, autoimmune hepatitis, primary biliary cirrhosis, and cholelithiasis.

Aetiology

The aetiology is multifactorial, including genetic, hormonal, and exogenous factors. Intra-hepatic cholestasis of pregnancy is due to abnormal biliary transport resulting in saturation of the hepatic transport system. Recurrent familial intra-hepatic cholestasis of pregnancy has been described as a heritable defect in the multidrug resistance 3 (MDR3) gene, which encodes for a canalicular phospholipid translocator involved in bile duct secretion of phospholipids.

Risk factors include advanced maternal age, multiparity, personal or family history of the disease, and a history of cholestasis while taking oral contraceptives. Female sex hormones play an important role, as almost all cases are seen in the third trimester, when estrogen levels are rising. Exogenous progesterone is also implicated.

Symptoms

Predominant symptom is generalised pruritus that begins in the periphery, often worse on the palms and soles, and moves to the trunk and face. The pruritus progresses as pregnancy continues and resolves within 48 hours of delivery. Approximately 10% to 25% of patients develop jaundice, usually 1 to 4 weeks after the onset of pruritus. No rash is associated with intra-hepatic cholestasis of pregnancy. Constitutional symptoms and diarrhoea or steatorrhoea have been reported.

Diagnosis

Intra-hepatic cholestasis of pregnancy can be diagnosed based on clinical symptoms, bilirubin is usually < 6 mg/dL, and transaminases are elevated from a minimal rise to 20 times normal. Elevated serum bile acids, may be the first or only abnormality and is confirmatory. Bile acid levels are > 10 µmol/L and may be 100 folds normal. Laboratory abnormalities resolve within 2 to 8 weeks of delivery.

Treatment

Patients should be treated at centres capable of treating premature infants, since ICP is associated with prematurity and stillbirth. Management includes symptomatic treatment of the patient as well as close monitoring and possibly early delivery of the foetus. The medical treatment of choice is ursodeoxycholic acid (UDCA), with doses of 1 g per day. UDCA improves pruritus and liver enzymes and enables delivery to occur closer to term. Cholestyramine also reduces pruritus in total divided doses of 10 to 12 g per day, but it is less effective than UDCA and has more side-effects. Foetal mortality in patients with ICP has been recorded to be as high as 11%, and the cause of mortality is still unknown.

Prognosis

Maternal outcome is good, with symptom resolution after delivery. ICP recurs in 45% to 70% of subsequent pregnancies. Perinatal mortality is upto 3.5%. Rates of stillbirth increase after 37 weeks gestation, thus supporting active management of delivery at 37 weeks.

HAEMOLYSIS, ELEVATED LIVER ENZYMES AND LOW PLATELETS SYNDROME (HELLP)

HELLP syndrome usually presents as a complication of pre-eclampsia, but can occur independently. The HELLP syndrome affects 1 to 6 per 1,000 pregnancies and 4% to 12% of patients with severe pre-eclampsia. Pre-eclampsia is characterised by hypertension, proteinuria, and oedema with onset in the second or third trimester and affects 5% to 7% of pregnancies. Seventy percent of patients with HELLP syndrome present before delivery, and the remaining in the post-partum period.

The differential diagnosis includes hepatitis, pancreatitis, peptic ulcer, appendicitis, cholelithiasis, liver haematoma, acute fatty liver of pregnancy, immune thrombocytopaenic purpura, thrombotic thrombocytopaenic purpura, haemolytic uraemic syndrome, and systemic lupus erythematosus.

Risk factors

Risk factors include white, multiparous, and older patients. As most patients who develop HELLP syndrome have pre-eclampsia, it too is a risk factor.

Aetiology

The initial source of the insult is unknown, but all patients have evidence of endothelial injury with fibrin deposit that causes a microangiopathic haemolytic anaemia and platelet activation and consumption, leading to thrombocytopaenia. The fibrin deposits cause obstruction in the hepatic sinusoids, which leads to areas of haemorrhage and eventual necrosis in the liver, causing elevated liver enzymes. Haemorrhage can develop into large haematomas and cause liver capsule tears.

Symptoms

Patients with HELLP syndrome often present with right upper quadrant or epigastric pain, nausea, vomiting, malaise, and non-specific viral-like symptoms. Some patients also experience headache (30% to 60%), and fewer experience visual symptoms (17%).

Diagnosis

Physical examination findings include right upper quadrant or epigastrium tenderness and generalised oedema. Hypertension and proteinuria are common, as most of the patients have pre-eclampsia. Hypertension is absent in up to 20%, and proteinuria in up to 13%, of the patients.

Laboratory abnormalities assist in confirming the diagnosis of HELLP syndrome, but currently no standardised diagnostic laboratory criteria exists. However, commonly used laboratory values include platelet count of less than 100,000, serum aspartate aminotransferase (AST) greater than 70 U/L, and serum lactic dehydrogenase greater than 600 U/L. A peripheral blood smear may also assist in the diagnosis and often demonstrates schistocytes, burr cells and echinocytes.

Studies have demonstrated that about 50% of patients diagnosed with HELLP syndrome do not have all diagnostic criteria. Those that have all diagnostic criteria, exhibit more severe disease with increased rates of blood transfusions and disseminated intravascular coagulation (DIC).

Treatment

HELLP syndrome is progressive and can sometimes have sudden and severe advancement, eventually compromising maternal and foetal outcome. Even if the diagnosis is in doubt, good blood pressure control should be achieved. IV hydralazine or labetalol may be used to maintain systolic blood pressure less than 160 mmHg and diastolic blood pressure less than 105 mm Hg. Stable patients should be transferred to tertiary care facilities for both maternal and possible neonatal treatment. Delivery is the definitive treatment for HELLP syndrome. In patients with HELLP syndrome at less than 34 weeks gestation and with a reassuring foetal and maternal status, delivery may be delayed for a steroid course of betamethasone 12 mg IM every 24 hours for 2 doses, with delivery 24 hours after the last dose. Delivery is indicated for women with HELLP syndrome at greater than 34 weeks gestation. During labour and for 24 hours post-partum, patients should receive IV magnesium sulphate for seizure prophylaxis, usually with a 4 g loading dose, followed by 2 g per hour. If the patient is already in labour, a vaginal delivery may proceed, as long as no evidence exists of foetal distress or DIC. Any evidence of the above, multiorgan dysfunction, renal failure, or abruption should prompt immediate delivery, usually by caesarean section. Induction of labour is not indicated in these patients, as the induction process can take several hours to days and places the life of patient and the neonate in danger.

Platelets are generally transfused when the platelet count is less than 20,000/mm^3, if less than 50,000/mm^3 and cesarean delivery necessary, or with any significant bleeding. Multiple platelet transfusions are generally unnecessary without significant bleeding, as delivery eventually leads to improvement in thrombocytopaenia.

Patients should be monitored very carefully for at least 48 hours in the post-partum period for evidence of pulmonary oedema due to fluid shifts or renal or hepatic dysfunction. Laboratory abnormalities usually tend to nadir 24 hours post-partum and begin to recover 48 hours post-partum.

Prognosis

HELLP syndrome is associated with increased maternal and foetal morbidity and mortality. The risk of maternal death is approximately 1%. Multiple maternal complications are associated with HELLP syndrome, including pulmonary oedema, acute renal failure, DIC, abruptio placenta, liver haemorrhage or failure, acute respiratory distress syndrome and stroke. Patients with HELLP syndrome also require higher rates of blood transfusion.

The rate of perinatal death has been demonstrated to range from 7.4% to 20.4% and is largely dependent upon gestational age and any additional complicating factors to the pregnancy or delivery. The highest morbidity and mortality rates are associated with the earlier gestations (< 28 weeks), and studies have demonstrated that the rates are not any higher than those found at the same gestational age in women diagnosed only with pre-eclampsia. Most perinatal morbidity is due to pre-maturity with common complications, including respiratory distress syndrome, bronchopulmonary dysplasia, intra-cerebral haemorrhage and necrotising enterocolitis.

LIVER RUPTURE/HAEMATOMA

Subcapsular haematoma formation and liver capsular rupture is an uncommon complication (usually of pre-eclamsia/eclampsia and HELLP syndrome), but carries a very high maternal and perinatal mortality. The differential diagnosis includes trauma, hepatic adenoma, haemangioma, AFLP, cocaine use, and hepato-cellular carcinoma.

Initial insult in the cascade of events leading to haematoma formation is believed to be endothelial injury, which causes vasospasm. In addition to vasospasm, fibrin deposits cause vascular congestion, sinusoidal obstruction with increased pressure ultimately causing hepatic necrosis, and intra-hepatic haemorrhage. Haematomas can affect the right lobe (75%), left lobe (11%) or can be bilateral (14%).

Symptoms

Severe right upper quadrant or epigastric pain, nausea, vomiting, shoulder pain, abdominal distension with hepatomegaly, peritoneal signs, hypotension and even hypovolaemic shock may be observed.

Diagnosis

Abnormal laboratory values include severe anaemia, elevated transaminases, thrombocytopaenia, and abnormal coagulation values. Patients that are haemodynamically unstable are often diagnosed at the time of laparoscopy and/or laparotomy. Sonography, CT, magnetic resonance imaging, selective angiography, and technetium-99^m scan are helpful for haemodynamically stable patients. CT with contrast is the best imaging modality for detecting hepatic haematomas, as they can efficiently and accurately detect acute haemorrhage.

Treatment

Liver haematomas without capsule rupture require conservative management. Additional management includes blood, plasma,

and platelet transfusions as needed, close haemodynamic monitoring, often in an intensive care unit. Some patients may also be candidates for hepatic artery embolisation, which is a good option for patients with multiple intra-hepatic hematomas who are poor surgical candidates. Any sign of haemodynamic instability, continued bleeding, expanding haematoma, or infection are indications to proceed with surgery. Death may occur in 12% of the patients. Most patients who survive the event have complete resolution, with normal CT approximately 4 to 6 months later.

VIRAL HEPATITIS

The incidence of viral hepatitis A, B and C is the same in pregnancy as it is for the general population, but the incidence of hepatitis E is much higher.

In hepatitis A, presentation is similar and maternal/foetal morbidity and mortality is not increased.

All pregnant women should be screened for hepatitis B by testing for HBsAg in the first trimester. Patients who test positive should be counselled about modes of transmission, prevention of hepatitis B, neonatal concerns, and all household contacts should be immunised. No specific treatment exists for acute hepatitis B. The risk of perinatal transmission from mothers who are HBsAg positive is 10% to 20% in the absence of neonatal immunoprophylaxis. In the presence of HBeAg, the neonatal transmission risk without neonatal prophylaxis is 90%. The risk also depends upon when the infection occurred during pregnancy. The risk of perinatal transmission is greatest during the third trimester, (90% as against 10% in the second trimester). To decrease this risk, lamivudine 100 mg per day can be given from the start of the third trimester.

Chronic hepatitis C infection does not seem to alter the course of pregnancy and does not place the mother at increased risk of pre-term labour, pre-eclampsia, or gestational diabetes. Screening all pregnant women for hepatitis C is not recommended. No vaccine for hepatitis C exists and primary prevention is necessary in order to avoid infection. Treatment of hepatitis C with ribavirin and α-interferon is contraindicated in pregnancy, as ribavirin is teratogenic and α-interferon causes severe neurotoxicity under the age of 2 years. The risk of neonatal transmission is as high as 4.3% and HCV infection should not influence the method of delivery. Breastfeeding is not contraindicated.

Hepatitis E has a higher incidence, higher rate of fulminant hepatitis and higher mortality in pregnancy (up to 25% *versus* 2.8% in general population). Increased rates of abortion, stillbirths and neonatal deaths are reported. Perinatal transmission occurs, but rates are still unknown. Transmission does not differ depending on route of delivery as long as no signs of acute maternal disease are present. Post-exposure or pre-exposure anti-HEV immunoglobulins have no benefit. Although anti-HEV antibodies and HEV RNA are found in colostrum of mothers, breastfeeding is not contraindicated.

14.18 Liver in Systemic Disease

Premashis Kar, Rajiv Singla

INTRODUCTION

Liver is frequently involved in systemic disorders which are primarily not hepatic in origin (**Table 1**). The involvement may not be clinically apparent but may change the course of the disease. Therefore, the understanding of liver involvement in systemic diseases is important for making accurate diagnosis and managing underlying disease as well as its hepatic complication.

Table 1: Systemic Diseases with Involvement of the Liver

Cardiac Diseases
Congestive hepatomegaly
Ischaemic hepatitis
Haematological Disorders
Hemolytic anaemias
Myeloproliferative and myelodysplastic disorders
Haematological malignancies
Infections

Bacteremias
Fungal infections
Human immunodeficiency virus
Pulmonary Diseases
Chronic obstructive airway disease
Interstitial lung disease
Immune System and Connective Tissue Diseases
Systemic lupus erythematosus
Rheumatoid arthritis
Sjogren's syndrome
Amyloidosis
Sarcoidosis
Scleroderma
Endocrine and Metabolic Disorders
Diabetes mellitus
Porphyrias
Glycogen storage diseases
Thyroid disorders
Cushing's syndrome

CARDIAC DISEASES

Congestive heart failure leads to painful enlargement of liver and jaundice along with transaminasemia. Congestive hepatomegaly can be differentiated from primary liver disease by observing raised pressure in internal jugular vein. Cardiac cirrhosis can occur in long-standing congestive hepatomegaly, if the underlying cardiac disease does not improve.

Sudden reduction in blood pressure, irrespective of aetiology, can result in necrosis of hepatocytes. Clinically, this ischaemic hepatitis presents as jaundice and there is marked rise in transaminases levels. Characteristic feature of ischaemic hepatitis is rapid resolution of transaminasemia, provided hypotension is corrected.

HAEMATOLOGICAL DISORDERS

Haematological Malignancies

The liver contains multipotent cells that can differentiate into reticulo-endothelial, myeloid and erythroid cells. These can be affected by malignant disease, usually in association with systemic diseases.

Leukaemia

Liver is involved in more than 95% cases of acute lymphocytic leukaemia and nearly 75% of those with acute myeloid leukaemia. Almost all patients with chronic lymphocytic leukaemia have hepatic involvement. In myeloid leukaemia, the liver is enlarged, smooth and may show pale nodules on cut-section. Microscopically, portal tracts and sinusoids are infiltrated with myeloid cells. In lymphoid leukaemia, liver is moderately enlarged with leukaemic infiltration involving only the portal tracts and sparing of the sinusoids. Pre-sinusoidal portal hypertension may occur due to hepatic or portal involvement.

Lymphoma

Hepatic involvement occurs in about 70% of cases and implies stage IV disease. In Hodgkin's disease, hepatic involvement is seen in around half of the patients. The infiltration spreads out from the portal tracts and includes mononuclear cells and occasionally Reed-Sternberg cells. In non-Hodgkin's disease, portal zones are involved and gamma-glutamyl transpeptidase and transaminase levels are often moderately increased. Focal lesions can be seen on imaging studies. Liver biopsy with immunotyping for malignant cells may be helpful.

Multiple Myeloma

The liver may be involved in up to 50% of patients with myeloma. Portal tracts and sinusoids are filled with plasma cells. The patients may have jaundice, ascites and portal hypertension. About 10% of patients also have amyloid deposits in the space of Disse.

Haemolytic Anaemias

In sickle cell disease (SCD), liver may be involved either by sickling crisis that present with right upper quadrant pain, fever and jaundice, or with intra-hepatic cholestasis. In some patients, sickle cell crisis is precipitated by Salmonella infection or by folic acid deficiency. In 10% cases, the crisis selectively affects the liver and lasts for about 2 to 3 weeks. It is difficult to differentiate sickle crises from viral hepatitis. Hepatic histology classically shows intra-sinusoidal sickling, erythrophagocytosis by Kupffer cells and ischaemic necrosis. Bile plugs are prominent and fatty change may occur. Even asymptomatic patients with SCD commonly have raised serum transaminases and hepatomegaly. Repeated blood transfusions may lead to hepatitis B and C and iron overload.

INFECTIONS

Human Immunodeficiency Virus (HIV) Infection

With increased life-expectancy of patients infected with HIV due to the use of highly active antiretroviral therapy, liver disease has assumed greater importance in these patients as a cause of morbidity and mortality. Most HIV-infected patients with IV drug abuse have hepatitis C virus (HCV) co-infection. Though HIV infection accelerates the progression of HCV related liver disease and HCV infection increases the risk of hepatotoxicity due to antiretroviral medications, interferon based therapy for HCV appear to be as effective in HIV-infected subjects as in those without HIV infection. Severely immunosuppressed HIV-infected patients almost uniformly have abnormalities of liver enzymes. Marked liver enzyme elevation accompanied by right upper-quardrant pain, fever, jaundice, or hepatic decompensation in HIV infected person need evaluation using endoscopic retrograde cholangio-pancreatography or liver biopsy, for diagnosis of biliary tract or hepatic parenchymal diseases, respectively.

Tuberculosis

Liver involvement in tuberculosis (TB) can occur either due to granulomatous hepatitis or as a result of hepatotoxicity of anti-tuberculosis drugs. Granulomatous hepatitis most frequently presents with hepatomegaly, elevated serum alkaline phosphatase levels, fever, weight loss, and abdominal pain. A moderate or marked increase in the serum levels of alkaline phosphatase, along with normal or mildly increased serum bilirubin, is highly suggestive of granulomatous hepatitis. Histopathology of liver biopsy in these patients usually consist of granulomas (95.8%), caseation (83.3%), fatty changes (42%), portal fibrosis (20%), acid-fast bacilli in association with granulomas (9%) and mononuclear cell infiltrates. Conventional anti-tuberculosis drugs, except pyrazinamide, can be given in granulomatous hepatitis with close supervision of transaminases. Hepatotoxicity due to anti-tuberculosis drugs is a relatively common phenomenon, with almost all of the first-line drugs having significant hepatotoxicity. Clinical presentation varies from a transitory asymptomatic rise in transaminases to acute liver failure and the frequency of hepatotoxicity in different countries varies widely from 2% to 39%. Hepatotoxicity is most common in period from third week to third month from start of anti-tuberculosis drugs. Anti-tuberculosis drugs should be withheld if clinical jaundice appears or transaminases are raised more than 3 times. Reintroduction of same drugs is possible after remission of jaundice and/or transaminasemia.

PULMONARY DISEASES

Serum bilirubin, alanine transferase, γ-glutamyl transpeptidase (GGT) and alkaline phosphatase may be elevated in patients with chronic pulmonary disease or status asthmatics, and these liver abnormalities may be associated with cor-pulmonale.

IMMUNE SYSTEM AND CONNECTIVE TISSUE DISEASES

Systemic Lupus Erythematosus

Sub-clinical liver injury is seen in about 25% of patients with systemic lupus erythematosus (SLE), but may not be related to the disease itself. Liver biopsy usually shows no significant lesion; rarely, chronic hepatitis or granulomatous hepatitis may be seen. Jaundice is usually haemolytic in origin.

Rheumatoid Arthritis

In rheumatoid arthritis, elevated serum alkaline phosphatase levels may occur in up to 10% to 15% of patients and hepatomegaly in 10% of patients. However, clinical signs of liver disease are usually absent. Liver may have histological changes like fatty change, Kupffer cell hyperplasia, mild mononuclear cell infiltration of portal areas, and rare foci of hepatocyte necrosis.

Amyloidosis

Hepatic involvement is common in patients with systemic amyloidosis. Hepatomegaly is seen in 50% of cases; the liver is smooth and non-tender. Generally, liver function tests (LFT) are mildly deranged. Three patterns of hepatic amyloid deposition are seen: sinusoidal or parenchymal, periportal and mixed. Sinusoidal variety is the most common. Liver biopsy, though diagnostic in more than 95% of cases, is seldom indicated since other involved tissues may be easier and safer to biopsy. Thus, abdominal fat pad aspiration and rectal biopsy are useful alternative modalities. Hepatic involvement generally does not influence the disease prognosis or necessitate any specific management.

Sarcoidosis

Sarcoidosis is characterised by widespread granulomatous lesions involving several body organs. Liver involvement is frequent though mostly asymptomatic. Hepatomegaly is seen in 20% of patients. Overt hepatic insufficiency is rare. Liver biopsy is confirmatory in about 60% of patients, but is indicated only if another accessible tissue is not available. Histologically, small well-formed granulomas in the same stage of development are common. Rarely, asteroid bodies and Schaumann bodies are also seen. Serum immunoglobulin (Ig)G and alkaline phosphatase levels, often raised and serum angiotensin converting enzyme levels are often increased. The prognosis is usually good, except in those with widespread hepatic involvement. Corticosteroids are generally not of much help.

ENDOCRINE AND METABOLIC DISORDERS

Porphyrias

This group of diseases is caused by defects in various enzymatic steps in biosynthesis of haem. Principal clinical manifestations include photosensitivity, cutaneous lesions, neurological dysfunction, and structural liver disease. Increased urine porphobilinogen may suggest the diagnosis. In porphyria cutanea tarda, the liver damage may be due to metabolic abnormality or to additional factors; such as alcoholism and HCV infection. Phlebotomy is the first-line of therapy. In protoporphyria, protoporphyrin may have a direct toxic effect on the liver. Liver transplantation has been used successfully; however, protoporphyrin-induced damage can recur in the transplanted liver.

Diabetes Mellitus (DM)

Liver is an important site of glycogen storage and gluconeogenesis. Thus, hepatic involvement in diabetes is common. Severe, uncontrolled insulin-dependent diabetes mellitus (IDDM) can lead to significant hepatic enlargement. The liver is firm and smooth; and may have a tender edge. The enlargement is due to

glycogen deposition, fat deposition and water retention in hepatocytes secondary to acidosis. In non-insulin-dependent diabetes mellitus (NIDDM), liver may be enlarged though it is usually non-tender. Nearly 80% of diabetics with liver involvement have elevation of liver enzymes. In fact, DM and obesity are among the most common causes of non-alcoholic steato-hepatitis.

Glycogenoses

Several forms of glycogenoses with different enzymatic and structural defects are known. Most of these affect the liver except types V and VII. Hepatic forms are usually diagnosed in infancy or early childhood and are characterised by hypoglycaemia, massive hepatomegaly, poor physical growth, a tendency for increased fat deposition particularly in the cheeks, and biochemical abnormalities.

Type I (von Gierke's Disease)

This autosomal recessive condition, caused by the deficiency of glucose-6-phosphatase, affects the liver and kidney but not muscle and heart. Presentation is with massive hepatomegaly in early childhood, at age of around 2 years. The liver is enlarged, smooth and brown. Splenomegaly is not seen, as opposed to lipodioses, cirrhosis and congential hepatic fibrosis. The liver cells and nuclei are laden with glycogen and fat. Cirrhosis does not develop but occasionally, hepato-cellular adenomas and rarely carcinomas develop. Liver biopsy examination for histology, immunohistochemistry, quantitative glycogen analysis and enzyme analysis is confirmatory. Treatment is aimed at preventing hypoglycaemia; liver transplantation may be useful.

Other Forms of Glycogenoses

In Pompe's disease (type II), all organs including the liver show vacuolated cells due to lysosomal glycogen deposition. In Cori's disease (type III), serum transaminases are usually increased. Periportal fibrosis occurs but cirrhosis is rare. In Andersen's disease (type IV), cirrhosis develops which may be associated with many giant cells. The child develops hepatosplenomegaly, ascites and finally liver cell failure. In Her's disease, only liver is involved and growth retardation and hepatomegaly are the usual manifestations.

Thyroid Disease

Patients with hyperthyroidism frequently experience liver injury. Liver injury can be either cholestatic or hepato-cellular. Up to 64% of these patients show elevated serum alkaline phosphatase test (ALP) and up to 35% show elevated ALT. Interestingly, only 17% of these patients show elevated GGT and most of the increased ALP may be bone-derived. In contrast to hyperthyroidism, liver biochemistry abnormalities are less prominent in patients with hypothyroidism. However, modest elevations in serum AST and ALT have been reported in 84% and 60%, respectively, of patients with hypothyroidism. Thionamides, used for the treatment of hyperthyroidism, are also known to cause serious hepatotoxicity; rarely acute liver failure.

14.19 Tumours of the Liver

Kaushal Madan, Pankaj Tyagi

INTRODUCTION

Tumours of the liver arise either from the hepatocytes, supporting mesenchymal tissue or bile duct epithelium. Although metastasis from other primary tumours are the most common liver tumours, hepato-cellular carcinoma (HCC, hepatoma) is the most common primary malignant tumour and haemangioma is the most common benign tumour of the liver. Conclusive diagnosis of a focal hepatic lesion is essential because it may represent a malignancy or may be benign and carry specific risks, such as rupture, bleed or malignant transformations. Here we would be discussing the most frequently encountered and clinically most significant liver masses.

BENIGN LIVER TUMOURS

Benign focal lesions of the liver are usually found incidentally. In most cases, patients with benign hepatic lesions have no pre-existing liver disease.

HAEMANGIOMA

Haemangiomas are the most common benign solid lesions of the liver. They are congenital vascular malformations, most often found incidentally, have a female predominance (female to male ratio is 6:1) and have no major clinical implications.

Pathology

On gross examination, haemangiomas appear as a dark purple compressible spongy lesion with microscopic appearance of multiple vascular spaces of varying sizes which are lined by single layer of endothelial cells and are separated by fibrous septa. Biopsy may be associated with significant morbidity because of bleeding.

Clinical Features

In most cases, haemangiomas are small and asymptomatic. Haemangiomas larger than 4 cms in size have been referred to as giant haemangiomas. Physical examination findings are usually unremarkable. Hepatic biochemical tests are usually normal.

IMAGING

Typical ultrasonography (USG) appearance of a haemangioma is of echogenic, homogenous lesion with well defined borders. Almost all hepatic hemangiomas of > 2 cm are detected on hepatic triphasic computed tomography (CT) with typical appearance of well defined hypodense lesion on non-contrast image with serial images in triple phase, showing the lesions getting filled from periphery to the centre, with persistence of contrast in the delayed state. Findings similar to CT are seen on a T1, contrast MRI and contrast enhanced USG.

Management

As most haemangiomas are asymptomatic, rarely they enlarge in size or rupture but have no malignant potential, thus surgical intervention is rarely indicated. Surgical resection remains the main definitive treatment of symptomatic haemangiomas. Other less effective options, such as transarterial embolization had been used for symptomatic lesions, acute bleeding and consumption coagulopathy. Hepatic artery ligation, radiation therapy, radiofrequency (RF) ablation and liver transplantation are used on rare occasions for unresectable giant haemangiomas.

FOCAL NODULAR HYPERPLASIA (FNH)

FNH is a benign tumour of unclear aetiology. It is the second most common benign solid mass of liver with a female predominance (female to male ratio is 8:1).

Pathology

FNH is solitary in most cases with most of them smaller than 5 cm. Typical macroscopic appearance is of a firm nodular mass with dense central stellate scar and radiating fibrous septae and microscopically consists of normal looking hepatocytes arranged abnormally.

Clinical Features

In most cases, FNH is asymptomatic and detected incidentally. Hepatic biochemical tests and α-fetoprotein are typically normal.

Radiological Diagnosis

The characteristic central scar may be seen on imaging. The picture on triple phase CT scan, dynamic contrast enhanced MRI and contrast enhanced USG, characteristically shows early filling central arteriole with spread of contrast towards periphery of the lesion. FNH needs to be differentiated from adenoma (**Table 1**). There is no evidence of FNH progressing to malignancy.

Table 1: Differentiating Features between FNH and Hepatic Adenoma

	FNH	Adenoma
Size	Usually <5 cm	More than 5 cm
Use of oral contraceptives	No	Yes
Central scar on imaging	Yes	No
^{99}Tc Sulphur colloid scintigraphy	Hot lesion	Cold lesion
Symptoms	Usually asymptomatic	Usually symptomatic
Management	Serial observation of lesion	Surgical removal

Management

The recommended treatment for asymptomatic FNH is observation. However, if the lesion is enlarging, or is clearly symptomatic, then surgical intervention in the form of wedge resection or enucleation is generally recommended.

HEPATO-CELLULAR ADENOMA (HA)

Hepato-cellular adenoma or hepatic adenoma (HA) is a benign tumour occuring mainly in women of childbearing age and in contrast to FNH and haemangioma. HA has very strong association with oral contraceptive pills (OCPs) use. Prolonged use of OCPs (>5 years) and age over 30 years are risk factors for development of HA. Androgenic and anabolic steroids, diabetes mellitus and glycogen storage diseases type I & III are also associated with development of HA.

Pathology

HA is usually large, well-circumscribed, solitary mass and arises in an otherwise normal liver. Microscopically, cells closely resemble normal hepatocytes with absence of Kupffer cells. A percutaneous needle biopsy carries the risk of bleeding.

Clinical Features

In most series, patients present with upper abdominal pain or discomfort. Hepatic adenomas can be complicated by rupture and/or haemorrhoage. Malignant transformation is rare but does occur. Differences between HA and HCC are given in **Table 2**.

Table 2: Differentiating Features Between a Hepatic Adenoma and an HCC

	Hepatic adenoma	HCC
Predilection for (sex)	Females	Males
Cirrhosis	Absent	Present
Alanine aminotranferase	Normal	High
Use of oral contraceptives	Present	Absent
Alpha-fetoprotein	Normal	High
Portal vein thrombosis	Absent	May present

Radiological Features

USG shows a well-demarcated mass and variable echogenicity. Multiphasic contrast enhanced CT scan shows homogenous enhancement in the arterial phase and isoattenuation in relation to the normal liver on the portal venous phase. 99Tc sulfur colloid scintigraphy typically shows no uptake of colloid because of absence of Kupffer cells.

Management

Generally, surgical treatment is recommended because of the risk of rupture, haemorrhage, and malignant transformation. Surgical approaches for HA includes enucleation, resection and liver transplantation.

MALIGNANT TUMOURS OF THE LIVER

Hepato-Cellular Carcinoma

Hepato-cellular carcinoma (HCC) is the 5th most common cancer worldwide and the third leading cause of cancer-related death. In India, the incidence of HCC has been reported to be about 1.6% among prospectively followed-up cirrhotics to about 2.7% in population-based cancer registries. Risk factors for HCC are given in **Table 3**. Men are generally more susceptible than women to develop HCC. In India, HBV is the most common risk factor (50% to 60%) for HCC followed by HCV (11% to 15%) and alcohol (6% to 14%).

Clinical Features

The symptoms and signs may be those of co-existing cirrhosis or among patient with well-compensated liver disease, HCC may present with pain abdomen, abdominal mass, fever, weight loss or anorexia. HCC development may present as recent decompensation of a previously well-compensated liver disease. **Table 4** presents the frequency of symptoms and sign in a large series of 324 patients from India.

Table 3: Risk Factors for HCC

Major risk factors
- Chronic hepatitis B
- Chronic hepatitis C
- Cirrhosis
- Dietary exposure to aflatoxin B1

Minor risk factors
- Oral contraceptive steroids
- Cigarette smoking
- Hereditary haemochromatosis
- Wilson's disease
- α-1-antitrypsin deficiency
- Type 1 hereditary tyrosinemia
- Type 1 and 2 glycogen storage disease
- Hypercitrullinemia
- Ataxia telangiectasia
- Membranous obstruction of inferior vena cava

Table 4: Symptoms and Signs in Patients with HCC

Symptoms	Frequency (%)	Sign	Frequency (%)
Abdominal pain	59-95	Hepatomegaly	54-98
Weight loss	34-71	Ascites	35-61
Weakness	22-53	Splenomegaly	27-42
Abdominal swelling	28-43	Jaundice	4-35
Jaundice	5-26	Wasting	25-41
Non-specific features	25-28	Fever	11-54

Diagnosis

A number of tumour markers have been used for the diagnosis of HCC. Among these three commonly used are alpha-fetoprotein, PIVKA II or des gamma carboxyprothrombin and alpha-L-fucosidase. The alpha-fetoprotein (AFP) has been the most frequently used, a value of 400 ng/mL is used as a diagnostic level because levels below this value may be found in patients with a variety of acute and chronic benign liver diseases, such as acute and chronic hepatitis and cirrhosis. False-positive results also may occur in patients with tumours of endodermal origin and non-seminomatous germ cell tumours. However, a normal AFP level does not exclude the presence of HCC.

On USG, HCC may appear hypoechoic, hyperechoic or isoechoic to the surrounding cirrhotic liver. Although USG is sensitive in picking up HCC's, but in the presence of altered echotexture of cirrhotic liver, the sensitivity of USG is markedly reduced.

Triple phase helical CT and contrast enhanced MRI are the imaging techniques of choice. The tumour appears hypervascular during the hepatic arterial phase and relatively hypodense in the delayed phase.

Management

Symptomatic hepato-cellular carcinoma carries a grave prognosis. The main reasons for the poor outcome are the extent of tumour

burden when the patient is first seen and the frequent presence of coexisting cirrhosis and hepatic dysfunction. Treatment of HCC is difficult because you have to treat not only tumour but also the complications of cirrhosis as well as the aetiological agent of cirrhosis. Although a number of staging systems are available for staging HCC, the Barcelona Clinic Liver Cancer (BCLC) classification has emerged during recent years as the standard classification because it incorporates all the above parameters and guides therapy according to the stage (**Figure 1**). In our country, about 45% to 55% of tumours have portal vein invasion at the time of diagnosis as reported in 2 large series from tertiary care centres and a large majority of them are BCLC stage C or D.

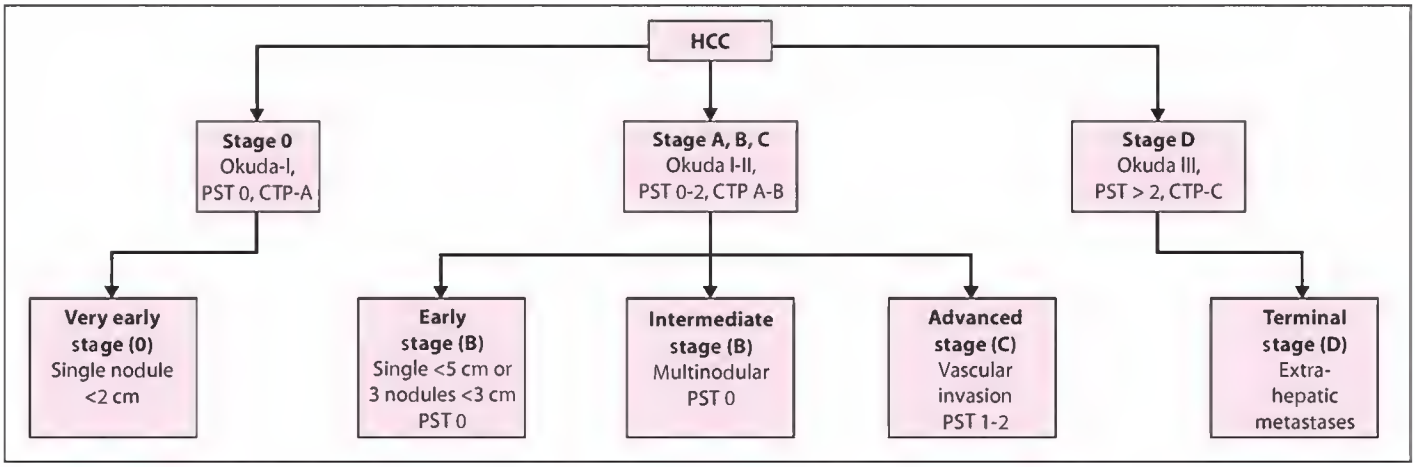

Figure 1: Barcelona Clinic Liver Cancer staging classification.

PST = Performance status; CTP = Child Turcotte Pugh classification.

Curative forms of therapy for HCC include, Liver resection (surgical removal of a part of the liver involved by the tumour), percutaneous ablative therapies [burning the tumour with either radiofrequency (RF) current (RF ablation) or with injection of 100% alcohol or with injection of 50% acetic acid] or liver transplantation. Palliative therapies include transarterial chemoembolisation or systemic chemotherapy. As mentioned earlier, BCLC staging system guides therapy as follows: Patients with very early HCC (stage 0) are optimal candidates for resection. Patients with early HCC (stage A) should be considered for radical curative therapies [resection, liver transplantation, or local ablation *via* percutaneous ethanol injection (PEI) or RF ablation]. Patients with intermediate HCC (stage B) have been found to benefit from transarterial chemoembolization (TACE). Patients with advanced HCC, defined as the presence of macroscopic vascular invasion, extra-hepatic spread, or cancer-related symptoms (ECOG performance status 1 or 2) (stage C), have only systemic chemotherapy as the option. Patients with end-stage disease (stage D) can only receive symptomatic treatment, because any form of therapy for the liver cancer is not only ineffective at this stage, but also detrimental for the already poor liver functional reserve. Recently, for patients in BCLC stage D, a new form of biological therapy, with multikinase inhibitor, sorafenib, has been shown to be associated with improved survival.

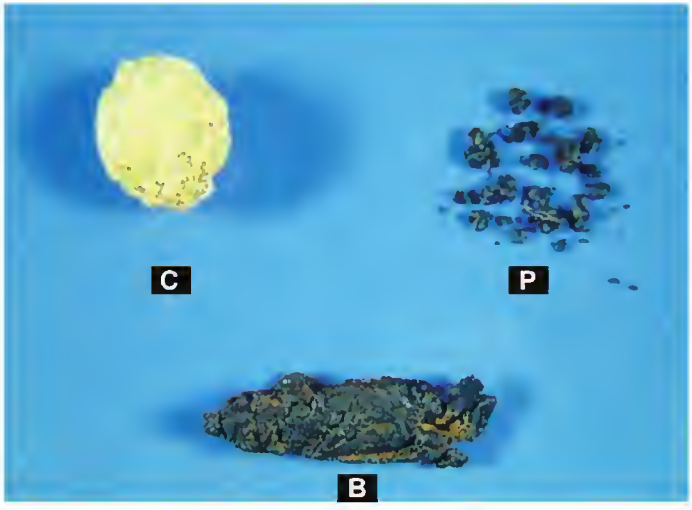
14.20 Diseases of Gall Bladder and Biliary Tract

Rakesh Tandon

GALL BLADDER STONES

The prevalence of gall bladder stones varies widely in different parts of the world. In India, it is estimated to be around 4%, whereas in the western world it is about 10%. In certain ethnic groups like Pima Indians and Taiwan Chinese, the frequency is extremely high; about 60% of Pima Indian women develop gallstones by 25 years of age.



Gallstones cause substantial morbidity and mortality, although only 20% of people harbouring gallstones ever become symptomatic. The cardinal symptom of gallstones is biliary colic. It is a sharp pain appearing suddenly in the right upper or mid abdomen and is possibly caused by transient blockage of the gall bladder outlet by a stone. If the stone does not move out soon and gets lodged in the cystic duct, the patient will develop acute cholecystitis, mucocoele or pyocoele of the gall bladder. Blockage of the common bile duct by a stone results in obstructive jaundice. On the other hand, transient blockage of the ampulla of Vater by a migrating stone may induce acute pancreatitis. Finally, dyspepsia is not considered a manifestation of gallstones.

Risk Factors

At the population level, specific risk factors have been shown to predict gallstone formation. These are older age, female gender, obesity, weight loss, total parenteral nutrition, pregnancy, hypertriglyceridaemia, genetic predisposition and use of certain drugs like clofibrate, oral contraceptives, ceftriaxone and octreotide.

Types of Gallstones

By their gross appearance gallstones have been divided traditionally as cholesterol, mixed and pigment stones (**Figure 1**). The cholesterol and mixed stones contain more than 50% of their dry weight as cholesterol, and are therefore, now together referred as cholesterol gallstones. They are the predominant type and form about 80% to 90% of all gallstones in northern India. Pigment gallstones, on the other hand, contain < 20% of dry weight as cholesterol. The pathogenesis and clinical manifestations of these 2 types of pigment stones differ widely (*vide infra*).

Figures 1A to D: Photograph showing various types of gallstones: Cholesterol (C), pigment (P) and earthy brown (B).

Mechanisms of Gallstone Formation

Cholesterol which is insoluble in water is solubilised in bile by two biliary lipids, viz. bile salts and phospholipids through micelle formation. An excess of cholesterol or a deficiency of either or both of the biliary lipids in bile can result in cholesterol supersaturation and subsequent precipitation of cholesterol out of the soluble phase of bile. However, additional factors must however exist for gallstone formation since many persons have supersaturation of bile with cholesterol but only some develop gallstones. Two such factors are gall bladder hypomotility and a nucleating agent, such as mucin. Some pro-nucleating and anti-nucleating proteins have been recognised in the bile. Their excess or deficiency, respectively, promotes gallstone formation. Often a combination of these factors is operative.

The commonest cause of cholesterol supersaturation in bile is excess cholesterol secretion. Indeed, that is seen classically in obese patients with gallstones. Several hormonal, enzymatic and dietary factors influence cholesterol secretion by controlling the amount of cholesterol delivered to the liver, the amount that is synthesised in the liver through HMG CoA reductase activity and the amount that is converted into bile acids through 7-alpha hydroxylase activity and the amount that is converted into cholesterol esters by acyl cholesterol: lecithin transferase (ACAT) activity.

Genetic polymorphisms in several genes, such as Apo E, Apo B, Apo A-1, low density lipoprotein (LDL) receptor, cholesteryl ester transfer protein and LDL receptor-associated protein genes have been shown to confer susceptibility to gallstone formation. They do so by increasing the hepatic cholesterol secretion either by bringing more cholesterol to the liver or by channelling an increased proportion of cholesterol into bile. By contrast, three active bile acid transporters at the canalicular membrane, viz. bile salt excretory protein, multi-drug receptor 2 and multi-drug receptor 3 have been shown to be downregulated in cholesterol gallstone patients with certain genetic polymorphisms.

Pigment Gallstone Formation

Pigment gallstones are of two types: black-pigment stones found in the gall bladder and the earthy-brown pigment stones found in the intra-hepatic bile ducts (**Figure 1**). Black pigment stones are associated with an excess of unconjugated bilirubin in the bile. The unconjugated bilirubin gets

precipitated as an insoluble highly cross-linked polymer of bilirubin tetrapyrroles in various states of oxidation. These polymers are then bound together by mucous glycoproteins. Other biliary constituents, such as calcium carbonate may also get trapped in these stones.

Diagnosis

As 75% of gall bladder stones are radiolucent, plain film of the abdomen is of little use. The best method available today to detect gall bladder stones is abdominal ultrasonography (USG) (sensitivity > 95%; specificity 99%). Gallstones are seen as areas of echogenicity in the gall bladder with posterior acoustic shadowing (**Figure 2A**). Even stones in the common bile duct (CBD) can be seen (**Figure 2B**); CBD is identified as lying above the portal vein on ultrasound (USG) doppler. The time-honoured oral cholecystography can also be done to visualise radiolucent stones in the gall bladder. Opacification of gall bladder following oral contrast administration also indicates patency of cystic duct, an important pre-requisite for treating gallstones with oral bile acids or lithotripsy. Computed tomography (CT) helps further in knowing the density of the stones but does not detect any stones missed by other tests. For demonstrating stones in the CBD, endoscopic retrograde cholangio-pancreatography (ERCP) is the gold standard but magnetic resonance cholangiopancreatiography (MRCP) is a good non-invasive alternative. Endoscopic ultrasonography, however, appears to be the most sensitive technique for detection of these stones, and can pick up small calculi in the gall bladder as well as the bile duct .

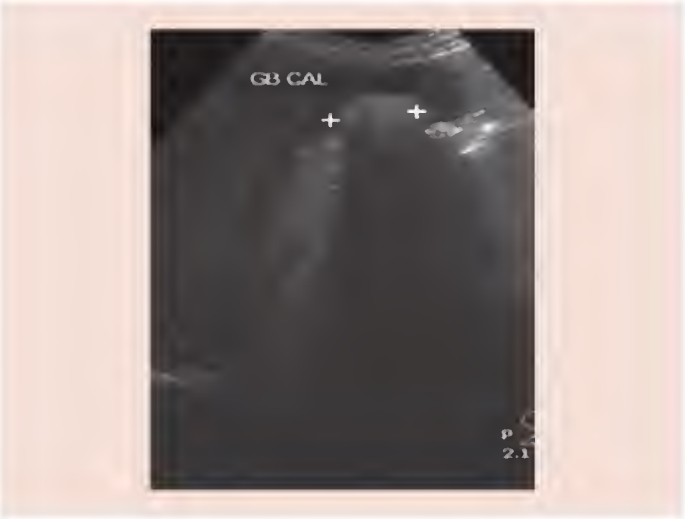


Figure 2A: A single calculus in the gall bladder seen with acoutic shadowing.

Treatment

Asymptomatic gallstones are best left alone and treated expectantly except in special circumstances such as in the case of astronauts or people residing in places that lack medical facilities. The symptomatic patients (10% to 15%) should, on the other hand, be treated effectively as they tend to have recurrence of symptoms or may develop acute cholecystitis, acute pancreatitis or other complications. Surgical removal of the diseased gall bladder (cholecystectomy) appears to be the best treatment option at present, since it provides protection against reformation of gallstones as well as development of carcinoma of the gall bladder.

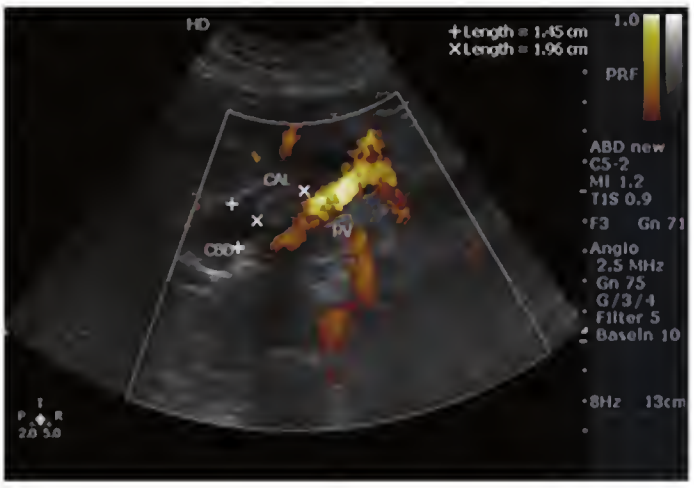

Figure 2B: Stone seen in dilated common bile duct (CBD). Below and parallel to CBD it is seen portal vein.

However, for those who are averse to surgery or those who carry a high surgical risk because of associated coronary artery disease or advanced lung disease, several non-surgical treatment options are available. Both surgical and non-surgical modes of therapy are briefly discussed below.

Surgical treatment

Cholecystectomy is curative and is relatively safe with an overall mortality of 0.1% to 0.6% and a morbidity of 10% to 30%. Both these proportions increase with age, presence of concomitant disease or when the procedure is accompanied by CBD exploration because of a suspected stone in the bile duct. Conventional cholecystectomy through laparotomy has been almost universally replaced by laparoscopic cholecystectomy. The latter has advantages of reduced post-operative pain and shorter hospital stay, as compared with conventional cholecystectomy.

In patients with a history of obstructive jaundice or with a demonstrated CBD stone, the prevailing treatment approach is to clear the CBD by performing an endoscopic sphincterotomy and basket removal of stones, and to then perform the laparoscopic cholecystectomy rather than doing a conventional surgery for both the gall bladder and CBD stones.

Non-surgical treatment

Non-surgical treatment modalities include oral bile acid therapy (OBT), extra-corporeal shock wave lithotripsy (ESWL) and contact dissolution with methyl-1-tert-butyl-1-ether (MTBE). The most popular of these and the one with which substantial experience is available is OBT with chenodeoxycholic acid (CDCA) or its 3-beta epimer ursodeoxycholic acid (UDCA). For bile acid therapy as well as ESWL, it is essential that the cystic duct is patent as established by visualisation of gall bladder on oral cholecystography. Cystic duct patency is required to allow drugs like UDCA to enter and concentrate in the gall bladder as also to let stone fragments pass out of the gall bladder. For OBT, the gallstones should not be >1.5 cm in size, should be radiolucent and preferably have a density of <100 Hounsefield units on CT. On the other hand for ESWL, the stones should be between 1 and 3 in number, 1.0 to 3.0 cm in diameter and preferably radiolucent but may have a few specks or a thin rim of calcification. Whilst OBT works slowly, ESWL is able to remove

the stones fairly fast. There are three methods of shockwave generation: underwater electrostatic spark-gap discharge, electromagnetic generation and piezo-electric generation; of these, the spark-gap lithotripsy is still the most popular and effective.

INTRA-HEPATIC BILIARY DUCTAL STONES

Intra-hepatic ductal stones, also referred to as liver stones or hepatolithiasis, are a common problem in South-east Asia including China, Korea, Japan, Thailand, Malaysia and Indonesia, where the prevalence of this condition is 5% to 10 % in contrast to 1% in the Western world. Two major aetiological factors considered have been infestation with *Clonorchis sinensis* and an intra-hepatic ductal stricture, more often in the left hepatic duct, resulting in bile stasis and bacterial infection. A bacterial enzyme, beta-glucuronidase, is believed to deconjugate bilirubin glucuronide, the water soluble form of bilirubin in the bile, resulting in the formation of free unconjugated bilirubin which is not soluble in water. This free bilirubin precipitates or combines with ionized-calcium to form calcium bilirubinate, which is the main constituent of intra-hepatic brown-pigment stones. A similar deconjugation of fatty acids occurs accounting for the presence of fatty acids in these stones. Intra-hepatic stones grow silently and may then present with recurrent pain, fever and jaundice. These may be associated with a mild rise in serum transaminases and a substantial rise in serum alkaline phosphatase. USG is the best non-invasive imaging technique to demonstrate these stones though cholangio-graphy (percutaneous or endoscopic retrograde) remains the 'gold standard'. Treatment is difficult and frustrating, and is aimed at surgical removal of the stones or of a segment of the liver which is heavily laden with intrahepatic stones. Percutaneous cholangioscopic removal of stones can be done at specialised centres. Despite complete surgical removal of such stones, recurrence rate is high and 4% of patients will develop cholangiocarcinoma.

SPHINCTER OF ODDI DYSFUNCTION

Sphincter of oddi dysfunction (SOD) is defined as a benign, non-calculous disorder with functional obstruction at the level of the SOD that causes pancreatobiliary-type pain, cholestasis and/or pancreatitis. The SOD may be a part of a generalised motility disorder of the upper gastrointestinal (GI) tract. Such cases are associated with a variable combination of abnormally high amplitude oesophageal contractions, gastroparesis, and duodenal and jejunal dysmotility.

The normal sphincter of oddi has a basal pressure of 3 to 5 mmHg with 2 to 6 contractions per minute with an amplitude of 95 to 195 mmHg. Most of the contractions proceed in an antegrade direction in normal persons and cholecystokinin administration leads to a relaxation of the sphincter of oddi.

The SOD can occur from a primary motor disturbance (dyskinesia) or a structural alteration (stenosis). The typical patients with SOD are middle-aged females who present for evaluation of recurrent right upper quadrant pain after cholecystectomy. Findings suggestive of SOD include biliary-type pain, dilatation of CBD >12 mm, delayed drainage of the CBD >45 minutes and abnormalities in serum liver function tests (LFT). Definitive diagnosis of SOD requires tests of biliary tract motility. Manometric findings in SOD include one or more of the following: elevated basal pressure >40 mmHg, more than 7 contractions per minute, retrograde progression in >50% of the contractions, and contractions of the sphincter as a response to cholecystokinin. The management of SOD is based on the Geenen-Hogan classification (**Table 1**). Group I patients mainly have sphincter of Oddi stenosis and can safely undergo endoscopic sphincterotomy without first performing SOD manometry, thus avoiding the risk of pancreatitis due to manometry. Group II patients may have stenosis or dyskinesia, and manometric findings should guide further management. Patients with elevated basal pressure may be treated with endoscopic sphincterotomy or a trial of long-acting nitrates or calcium channel blockers. Group III patients may have a non-biliary cause for pain, and therefore, common causes of abdominal pain must be ruled out.

Table 1: Geenen-Hogan Classification of Sphincter of Oddi Dysfunction

Group 1	Group 2	Group 3
Biliary pain + All of the following criteria	Biliary pain + 1 or 2 of the following criteria	Biliary pain + None of the following criteria
Delayed drainage of the common bile duct (>45 min.)		
Dilatation of the common bile duct (>12 mm) on USG		
Elevation of serum aspartate aminotransferase or alkaline phosphates to >2 times normal on 2 or more occasions		

BILIARY TRACT MALIGNANCIES

Biliary tract carcinomas are locally invasive adenocarcinomas which usually manifest as painless jaundice and biliary obstruction. These include gall bladder carcinoma, cholangio-carcinoma and intra-hepatic biliary malignancies (cholangio-cellular carcinoma) or carcinoma at the lower end of bile duct (peri-ampullary carcinoma). In the absence of treatment, most patients die of cholangitis, cachexia or hepatic failure within 3 to 6 months of diagnosis.

Gall bladder Carcinoma

Presence of gallstones has been proposed as a risk factor for cancers of the gall bladder and the extra-hepatic bile ducts. Other predisposing factors include anomalous junction of the pancreatic and biliary ductal systems, K-ras codon 12 mutation, blood groups A and AB, and *Salmonella typhi* carrier state. Gall bladder carcinoma usually presents at an advanced stage with abdominal pain and cholestatic jaundice. A hard gall bladder mass is often palpable along with hepatomegaly. Prognosis in such patients is poor. In some patients, the tumour is found incidentally after simple cholecystectomy, at gross or microscopic examination of the excised gall bladder.

Conventional surgery is being gradually replaced by aggressive extensive surgical resection procedures, such as extended cholecystectomy which includes wedge resection of the hepatic gall bladder-bed and regional lymphadenectomy. In patients with unresectable tumours, palliation may be possible through endoscopic stent placement.

Cholangiocarcinoma

Hilar cholangiocarcinomas are characterised by a slow growth rate and a low propensity to metastasise. Papillary cholangio-

carcinomas have the best survival rate but are infrequent. Pre-operative diagnosis of cholangiocarcinoma may be established by a combination of brush cytology and forceps biopsy from the bile duct lesion. The established criteria for non-resectability of cholangiocarcinoma are: bilobar extensive intra-hepatic bile duct spread, involvement of the main portal vein, bilobar involvement of hepatic arterial or portal venous branches or both, and a combination of unilobar hepatic involvement with cholangiographic evidence of extensive contralateral ductal spread.

In unresectable tumours, palliation may be possible by restoring bile flow, in order to relieve jaundice and prevent or treat complications like pruritus and sepsis. This is accomplished by endoscopic or percutaneous stenting across the obstructing lesion, or a surgical biliary enteric bypass. Combined external beam radiation and brachytherapy with intracavitary iridium seeds have been used. However, this combined therapy has not been shown to provide a definite survival advantage. Hence, the preferred mode of therapy, if feasible, is curative resection.

Cancer of the Ampulla of Vater

This tumour has a higher resectability rate and a better prognosis than other biliary cancers. This is mainly because these tumours present early with features of obstructive jaundice. USG shows a dilatation of the biliary system and/or the pancreatic duct. Diagnosis is established by an ampullary biopsy taken through a side viewing endoscope. In case the tumour is located submucosally, endoscopic USG guided fine needle aspiration may be helpful in getting the tumour tissue. The best treatment option for these patients is pancreato-duodenectomy (Whipple's procedure). If the tumour is unresectable or pre-operative biliary drainage is needed, a biliary stent can be placed across the papilla endoscopically.

INTRODUCTION

Healthy individuals require adequate production of blood cells on a daily basis to maintain normal function. This process needs to be tightly regulated and balanced to maintain homeostasis. Additionally, during this process, adequate haematopoietic stem cells (HSC) also have to be generated to maintain the pool of HSC. HSC and haematopoietic progenitor cells (HPC) are retained within the bone marrow by numerous ligands and cytokine gradients which are also important in regulation of differentiation and proliferation. The process of haematopoiesis is closely linked and regulated by the haematopoietic micro-environment in the bone marrow which includes mesenchymal derived stromal cells such as endothelial cells, fibroblasts, osteoblasts and adipocytes, cells of non-mesenchymal origin such as cells of the monocyte macrophage system and the extra-cellular matrix. Abnormalities at different stages in this process can result in various haematological disorders, such as aplastic anaemia, cytopaenias, leukaemia and myeloproliferative disorders. Haematopoiesis broadly consists of HSC proliferation and regulation, granulocytopoiesis, thrombopoiesis and erythropoiesis. Once HPC differentiate into mature blood elements, they leave the bone marrow by a still poorly understood mechanism.

DEFINITION

Haematopoiesis is a complex process by which HSC can both self replicate to maintain a pool of HSC and also differentiate into myeloid and lymphoid lineage committed HPC. These HPC can further terminally differentiate to produce all the cellular elements of the blood.

ONTOGENY OF HAEMATOPOIETIC TISSUES

Currently, it is believed that haematopoiesis originates as early as the third week of conception, both from the aorto-gonadal-mesonephros (AGM) region and from the extra-embryonic mesoderm in the yolk sac. Data from mice suggest that HSC arise in the AGM from a haemangioblast which can give rise to HSC and endothelial cells. In humans, HSC that arise from these regions colonise the foetal liver at 5 weeks of gestation and foetal liver haematopoiesis becomes active by 6 weeks and remains the dominant haematopoietic organ in foetal life. HSC seed the bone marrow by 8 weeks of gestation. In contrast to the foetal liver where haematopoiesis is predominantly erythroid, haematopoiesis occurring in the bone marrow is predominantly myeloid in foetal life. HSC also colonises the spleen by 12 weeks of gestation and the thymic rudiment by 8 weeks of gestation and these organs contribute to haematopoiesis in the foetal life (**Figure 1**).

During foetal life and immediately after birth a large number of HSC and HPC are found in circulation. However, within 24 to 48 hours after birth circulating progenitors disappear from the circulation. In adults, haematopoiesis shifts almost entirely into the bone marrow. *In utero* and at birth, the entire bone marrow is involved in haematopoiesis while with increasing age haematopoiesis is limited to the flat bones such as the pelvic bones, skull and ribs, the proximal ends of long bones and the vertebrae. In post-natal life the bone marrow is normally the only site of haematopoiesis, however, at times of extreme need the liver, spleen and other reticulo-endothelial tissue can contribute to extra-medullary haematopoiesis.

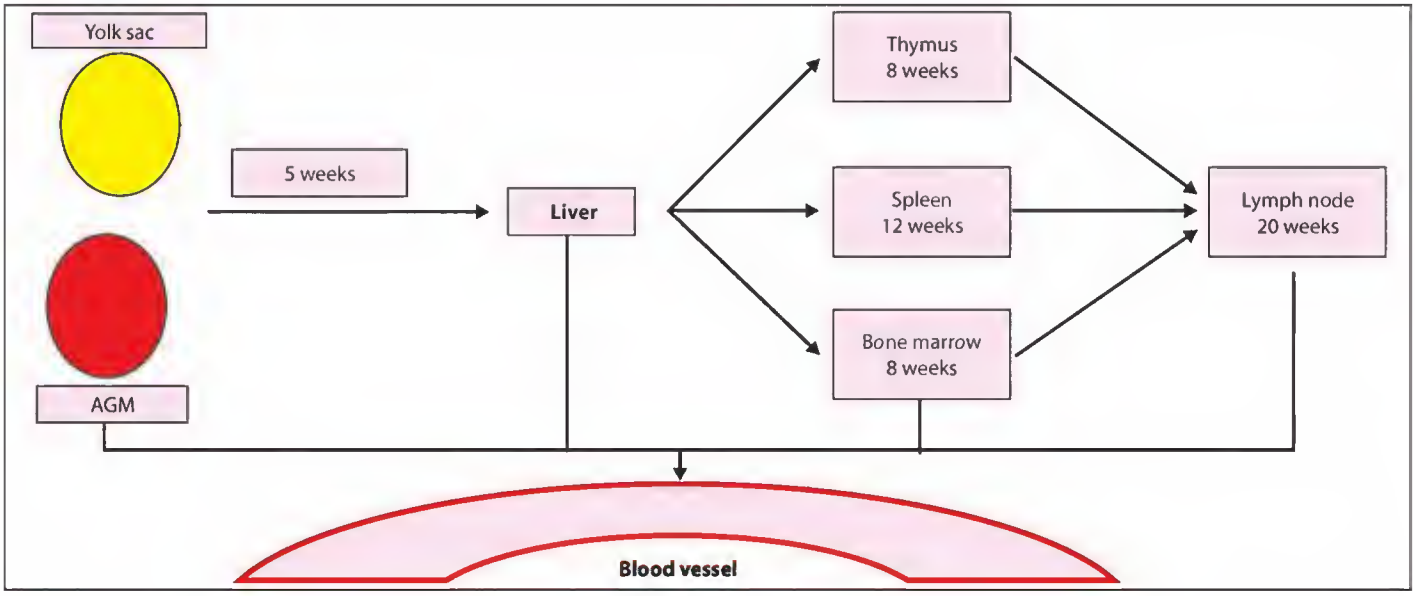

Figure 1: Ontogeny of human haematopoiesis. HSC migrate and colonise different organs. After birth they are found mainly in the bone marrow. The HSC is believed to arise from the AGM and/or extra-embryonic yolk sac at different time periods in gestation, as illustrated above.

AGM = Aorto-gonadal-mesonephros; HSC = Haematopoietic stem cell.

HAEMATOPOIETIC STEM CELLS AND STEM CELL NICHES

Haematopoietic Stem Cells

HSC has been defined functionally by their ability to reconstitute both the lymphoid and myeloid haematopoiesis when transplanted into a recipient. Immunological characteristic of HSC has been the absence of lineage specific antigens (Lin^-), in mice expression of specific antigens such as Sca1 and Thy1 and in humans expression of CD34 antigen. Another property that has been used to study stem cell populations is the ability of these cells to extrude a deoxyribonucleic acid (DNA) binding dye Hoechst 33342 which in turn is based on the property of these cells to often express drug efflux proteins. Based on this technique, a population of Lin^- and CD34 negative cells have been identified which has the capability for long-term reconstitution following a transplant, suggesting that these cells are a subset of HSC, even though they are CD34 negative.

The factors that regulate HSC proliferation and differentiation including commitment remain poorly defined. There are two major theories of HSCs renewal *versus* differentiation and these are the Stochastic model and the haematopoietic inductive microenvironment. In the Stochastic model stem cell renewal *versus* differentiation is based on probability residing within the HSCs while in the inductive micro-environment theory it is linked to probability of the extrinsic environmental signals that it is exposed to. **Figure 2** summarises the pathways of haematopoiesis starting from the HSC.

Haematopoietic Stem Cells Niche

Stem cell niche is a specific site in adult tissues where stem cells reside and undergo self renewal and produce large numbers of progeny (differentiation). The concept of a HSC niche was first proposed by Schofield in 1978 to describe the physiologically limited micro-environment in which stem cells reside. Mesenchymal stromal cell derived osteoblasts are increasingly being found to play a very important role in the HSC niche formation (*osteoblastic niche*). These osteoblastic niches have been shown to provide the structural surface on which HSC reside and also provide important signals that regulate HSC proliferation and differentiation. Thus, osteoblast cells play an important role not only in skeletal development but also in haematopoiesis. Experimental animal models have demonstrated that conditional ablation of osteoblasts leads to depletion of HSC and increasing the number of osteoblasts by the administration of parathyroid hormone has been shown to enhance HSC self renewal and engraftment. The need for physical interaction in the HSC niche probably is important to regulate the number of HSC in the stem cell pool. This physical interaction could also be important in deciding on symmetrical (proliferation) *versus* asymmetrical (differentiation). As illustrated in **Figure 3**, a daughter cell that divides with the division plane perpendicular to the niche plane has the potential to have both daughter cells remain in contact with the niche cell and retain stem cell-ness, while a cell that has its

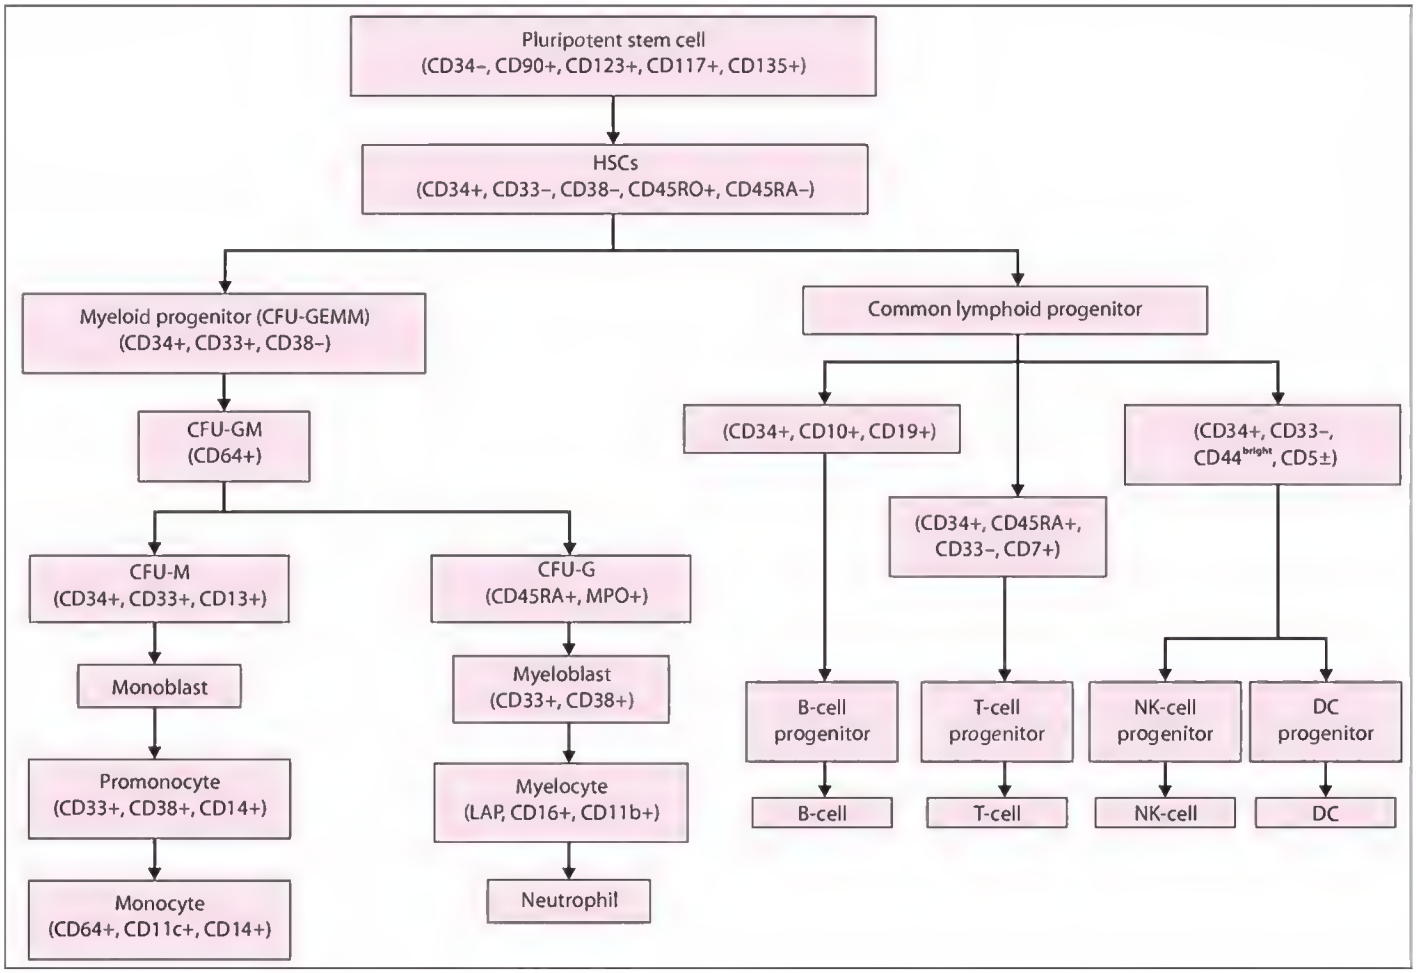

Figure 2: Model of the pathways of haematopoiesis (excluding erythropoiesis) and significant surface antigen expression at each stage.

CFU-GEMM = Colony forming unit gronulocyte/erythroid/mocrophoge/megakoryocyte; CFU-GM = Colony forming unit gronulocyte/mocrophoge; CFU-M = Colony forming unit macrophoge; CFU-G = Colony forming unit gronulocyte; MPO = Myeloperoxidose; NK Cell = Noturol killer cell; DC = Dendritic cell; LAP = Leucocyte alkaline phosphote.

division plane parallel to the niche plane will give rise to a daughter cell that will not be in contact with the niche surface and has the potential to differentiate.

The bone marrow microenvironment is very vascular with numerous sinusoidal vessels. It has been demonstrated that HSC even physiologically frequently leave the confines of the bone marrow and enter the systemic circulation (mobilisation) and also such mobilised HSC return to the bone marrow directed by various homing signals (homing). The regions adjacent to these sinusoidal vessels often house HSC and HPC and also function like a niche (*vascular niche*). The vascular niche may play an important role in mobilisation and in homing. It also appears to play a role in HSC proliferation and differentiation.

Multiple signalling and adhesion molecules are involved in the stem cell maintenance. The main signalling pathway that is involved in this process includes stem cell factor (SCF), which is a cytokine that interacts with c-kit, a receptor that is present in the stem cells and progenitors. C-kit signalling is important for promotion of cell survival, proliferation, and migration. Flt3 signalling pathway is important differentiation of cell types. Thrombopoietin (TPO) and its receptor c-Mpl constitute a pathway that is important for the cell cycle regulation of haematopoietic stem cells. Interestingly, gain of function alleles of c-kit, Flt-3 and c-Mpl it were identified as participants in leukaemia or other cancers. For example, v-kit is a constitutively active kinase that was identified in a feline sarcoma virus. In addition, point mutations or amplifications that result in constitutively active signalling have been found in several types of solid tumours and in acute myeloid leukaemia (AML). For example, Flt-3 activating mutations are found in 30% of human AML cases, and v-Mpl is a constitutively active form of the TPO receptor that was identified in a mouse myeloproliferation inducing retrovirus. Tie-2 is another tyrosine kinase receptor, bound by angiopoietin, plays an important role in steady state haematopoiesis. Tie-2/Ang signalling has been proposed to be important for maintaining quiescence within the bone marrow niche, rather than promoting expansion and proliferation. Several pathways previously known to be essential for embryogenesis also play important roles during the maintenance of HSC. These include Wnt (wingless/Int-1), Hh (hedgehog) and phosphoinositide-3 kinase signalling pathways. The pattern and level of expression of these signalling and adhesive molecules in daughter cells probably plays a role in deciding the fate of the cell.

ERYTHROPOIESIS

The mature red cell is the final product in the long process of erythropoiesis that starts from a HSC that is committed to erythroid differentiation, this process is tightly regulated. Erythroid progenitors are sparse and difficult to isolate. The first recognisable class of progenitors is the burst forming unit – erythroid (BFU-E), named for their ability to generate multi-clustered colonies of (erythroid bursts) haemoglobin containing cells. BFU-E represents the earliest progenitor cell committed exclusively to erythroid differentiation. This is a quiescent reserve of cells (only 10% to 20%) are in only cell cycle. However, once stimulated with the appropriate cytokines these

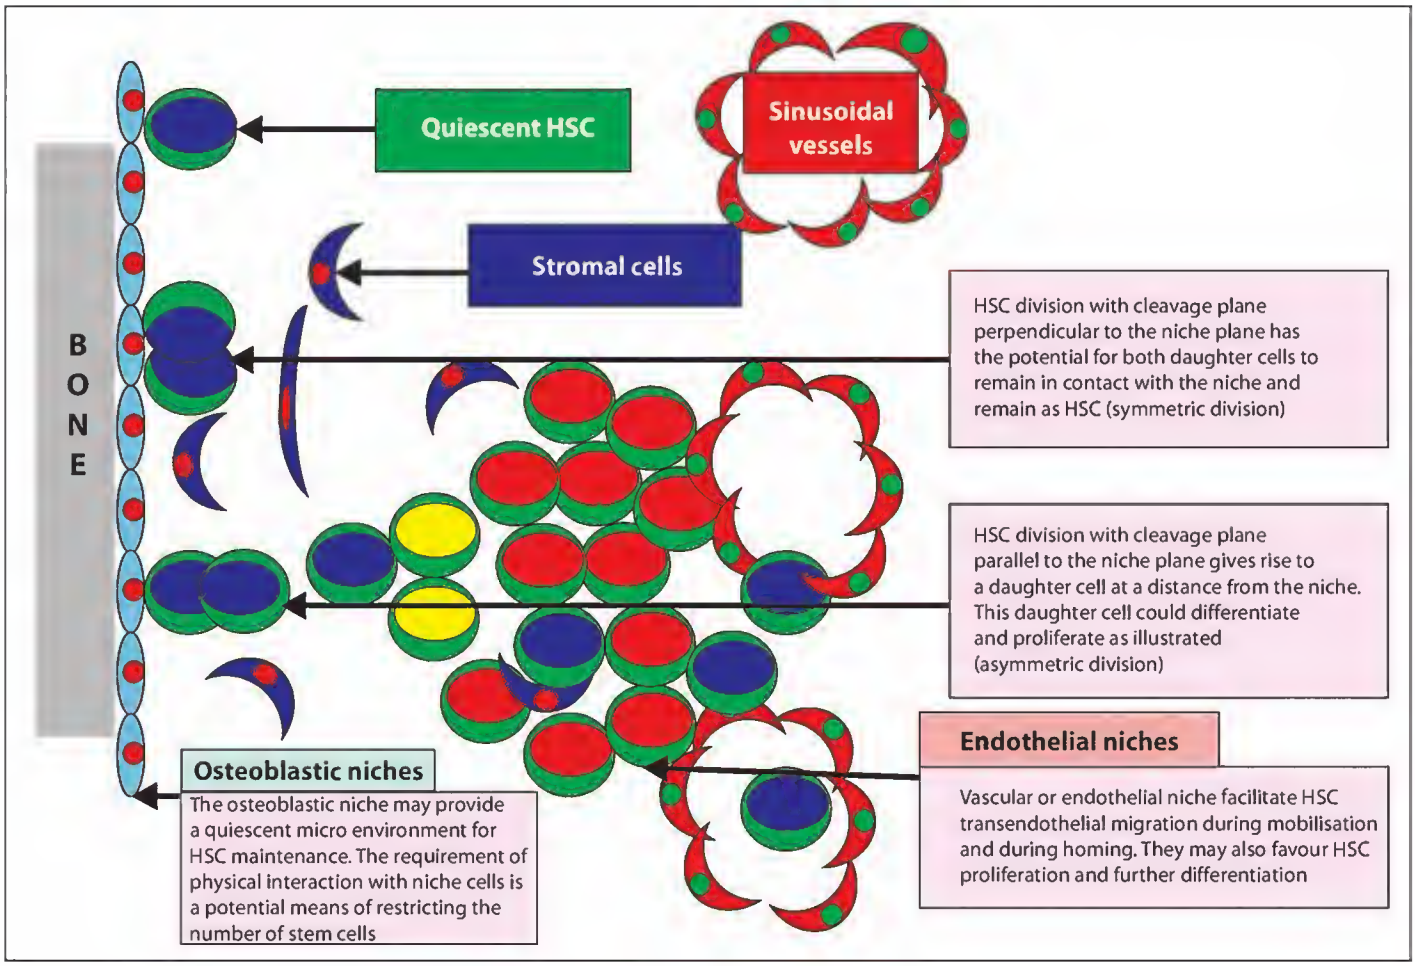

Figure 3: Haematopoietic stem cell (HSC) niches.

demonstrate significant proliferative capacity (≥30 to 40,000 colonies *in vitro*) in 2 to 4 weeks. A second more differentiated progenitor cell is the colony forming unit—erythroid (CFU-E). In contrast to BFU-E majority of these cells are in cycle, and hence, on exposure to appropriate cytokines rapidly proliferate, peaking within 7 days. It is important to understand that these cells are identified retrospectively and *in vitro* by their ability to form specific haemoglobin containing cell colonies in semisolid media (methylcellulose) with appropriate cytokines. It would not be possible with currently available techniques to identify these cells individually by their morphology and immunophenotype as being distinct from other progenitors with commitment to other lineages.

The earliest recognisable erythroid cell is the proerythroblast, it is 12 to 19 µm in diameter with a large oval nucleus which stains homogenously with indistinct nucleoli, and the cytoplasm is darkly basophilic. The basophilic normoblast follows with a diameter of 12 to 17 µm, nuclear chromatin shows coarse clumping which is often described as a cartwheel appearance, nucleoli are generally not seen. The polychromatic normoblast is about the same size as its precursor the basophilic normoblast but is distinguished by the less basophilic cytoplasm due to the increased accumulation of haemoglobin; the nucleus is also further condensed and is almost black on staining. The last nucleated erythroid precursor is the orthochromatic normoblast, this cell approaches the diameter of a reticulocyte (8 to 12 µm), the eosinophilic staining cytoplasm contains nearly the full amount of haemoglobin, the nucleus is fully condensed and pyknotic. Extrusion of the nucleus results in it becoming a reticulocyte. The reticulocyte is characterised by the presence of fine granular or reticular network of ribosomal ribonucleic acid (RNA) observed with supravital stains, such as brilliant cresyl violet or methylene blue. Reticulocytes are normally found in small numbers in the peripheral blood. Reticulocytes gradually lose their cytoplasmic RNA and mature into erythrocytes which are biconcave, relatively flat and non-nucleated disks of 7 to 8 µm in size. Normal erythrocytes survive for 100 to 120 days in the peripheral circulation.

Regulation of Erythropoiesis

The process of erythropoiesis is mainly regulated by erythropoietin (EPO) which is a cytokine produced in the kidney in the peri-tubular cells. Regulation of EPO mRNA and protein is primarily at the transcriptional level. In the setting of hypoxia, these cells are stimulated to secrete EPO by the hypoxia-inducible transcription factor (HIF); this in turn acts on cells that have EPO receptors (BFU-E, CFU-E, etc.) and promotes their survival and proliferation and this activity is thought to be the primary regulatory mechanism for maintaining the homeostasis of red cell mass. A drop in red cell numbers causes tissue hypoxia, leading to increased EPO synthesis and the survival of more CFU-E that can rapidly mature into erythrocytes. Several other cytokines have been shown to synergise with EPO to enhance erythroid differentiation, including interleukin (IL) 6, IL3 and SCF. SCF receptor, c-kit is expressed by CFU-E and BFU-E.

Lineage specific transcriptional factors are responsible for regulating the expression of erythroid genes in the course of erythroid differentiation. Two important transcription factors that are involved in the erythropoiesis are GATA-1 and EKLF (KLF1). GATA-1 forms complexes with multiple other proteins to up-regulate the expression of erythroid specific genes. Disruption of GATA-1 gene leads to block of primitive erythropoiesis resulting in embryonic lethality. FOG-1 (Friend of GATA) binds to GATA-1 and this association is required for many of the functions of GATA-1. The significance of this association is exemplified by the finding in individuals with severe congenital dyserythropoietic anaemia of GATA-1 mutations that disrupts its physical contact with FOG-1. GATA-1 also associates with CREB binding protein (CBP) which is a protein that acetylates histones suggesting that GATA-1 is involved in transcriptional activation of erythroid genes. Other proteins that are associated with GATA-1 are transcription factors stem cell leukaemia gene (SCL, TAL-1), LBD1 and LMO2. Distinct protein complexes of GATA-1 are required for activation of genes in primitive and definitive erythropoiesis.

Several members of the Kruppel-like transcriptional factor (KLF) family are known to activate erythroid specific genes. KLF1 (EKLF) is expressed in both primitive and definitive erythropoiesis. This protein associates with SWI/SNF related chromatin remodelling complex suggesting that its activity in erythroid cells may in part be related to altering the configuration of chromatin. Activation of EKLF is regulated by GATA-1 illustrating the complex transcriptional regulatory mechanisms involved in both primitive and definitive erythropoiesis. KLF2 and KLF4 are required for the expression of genes in the embryonic stage.

The continued identification of interacting transcription factors and their downstream targets will provide a better understanding of erythroid cell maturation and will facilitate the construction of increasingly complex models of the genetic regulatory networks that exist in erythroid cells. More recently micro-RNAs, small RNA molecules that target messenger RNAs in a sequence specific manner to modulate their stability or their ability to undergo translation, have been shown to play roles in erythropoiesis.

Though several studies have been carried-out to unravel the molecules and mechanisms involved in erythropoiesis, it is not yet clear how the signalling pathways, micro-RNAs and transcription factors act together in regulating erythropoiesis.

Haemoglobin synthesis

Production of haemoglobin requires the co-ordinated production of haem and globin. Haem is the prosthetic group that mediates reversible binding of oxygen by haemoglobin. Globin is the protein that surrounds and protects the haem molecule.

Haem synthesis

Haem is synthesised in a complex series of steps involving enzymes in the mitochondria and in the cytosol of the cell. The first step in haem synthesis takes place in the mitochondria, with the condensation of succinyl CoA and glycine by 5-aminolevulinic acid (ALA) synthase to form 5-ALA. This molecule is transported to the cytosol where a series of reactions produce a ring structure called coproporphyrinogen III. This molecule returns to the mitochondria where an additional reaction produces protoporphyrin IX. The enzyme ferrochelatase inserts iron into the ring structure of protoporphyrin IX to produce haem. Deranged production of haem results in a variety of anaemias (porphyrias). Iron deficiency, the world's most common cause of anaemia, impairs haem synthesis thereby producing anaemia. A number of drugs and toxins directly inhibit haem production by interfering with enzymes involved in haem biosynthesis. Lead commonly produces substantial anaemia by inhibiting haem synthesis, particularly in children.

Types of haemoglobin synthesis

Haemoglobin molecules are tetrameric proteins with two distinct types of globin chains. In humans, there are 5 different types of haemoglobins which are produced at different stages of the development. The genes that produce different types of globin chains are present as clusters in chromosomes 11 and 16 with the genes present in the order in which they are expressed during development. In adults, haemoglobin (HbA) contains two α globin and two β globin chains ($\alpha_2\beta_2$). The predominant haemoglobin produced at the embryonic stage is Hb Gower 1 and foetal stage is $\alpha_2\beta_2$ (HbF; foetal haemoglobin). **Table 1** summarises the haemoglobins seen in humans in different stages of development.

Disorders that affect the synthesis rate of the globin chains cause thalassaemias which are the most common genetic diseases in humans. There are around 400 different reported mutations that can cause α and β thalassaemia. Other types of mutations in the globin genes that affect the structure of haemoglobins (not the quantity) are broadly classified as haemoglobinopathies which include sickle cell anaemia a common genetic disease in most populations.

Table1: Normal Haemoglobin (Hb) seen at Different Stages of Development

Embryonic Hb		Foetal Hb		Adult Hb	
Gower 1	$\xi_2\varepsilon_2$	HbF	$\alpha_2\gamma_2$	HbA2	$\alpha_2\delta_2$
Gower 2	$\alpha_2\varepsilon_2$			HbA	$\alpha_2\gamma_2$
Portland	$\xi_2\gamma_2$				

A better understanding of the mechanisms regulating the activation and silencing of the embryonic, foetal and adult globin genes has important clinical implications for the treatment and cure of patients with haemoglobinopathies, particularly sickle cell disease and the thalassaemia syndromes. GATA-1 and EKLF are two major transcription factors that have been found to be playing key functions in the activation of adult globin genes responsible for the transcriptional regulation of globin genes. Recent studies have identified a key regulator protein, BCL11A, which plays a role in stage specific expression of globin genes. This protein represses foetal globin gene expression in adults. Mutations in the BCL11A gene cause increased expression of foetal haemoglobin (HbF) in normal adults and in patients with thalassaemia and sickle cell disease. Such increases HbF in these conditions could ameliorate the phenotype of these diseases and hence manipulating this proteins levels in patients with sickle cell disease and homozygous β thalassaemia has the potential to be a therapeutic option for these diseases.

GRANULOPOIESIS AND MONOCYTOPOIESIS

Granulopoiesis

The earliest identifiable cell of the myeloid lineage is the myeloblast. This cell is approximately 12 to 14 μm in diameter with a round or oval nucleus and basophilic cytoplasm. Nuclear chromatin is fine and 1 to 5 nucleoli are easily visible. The next cell in the differentiation process is the promyelocyte which is the largest cell in this differentiation series. Promyelocytes have variable nuclear morphology with less prominent nucleoli; the cytoplasm is deeply basophilic and contains variable number of peroxidase positive granules. Myelocytes are characterised by round to oval nucleoli with a characteristic nuclear indentation and coarse chromatin structure. The cytoplasm is pale pink-brown and has numerous specific granules covering the nucleus and throughout the cytoplasm except at the nuclear indentation (centrosphere), which represents the Golgi apparatus. The myelocyte is also the first cell in differentiation in which specific granules appear and the last cell that is capable of cell division during myeloid differentiation. The metamyelocyte exhibits a characteristic bean shaped nucleus, the band form a band shaped or 'S' shaped nucleus without a definite nuclear constriction and the segmented neutrophil characterised by typical nuclear segmentation. The cytoplasm in all these cells is similar to that of a myelocyte except for the absence of a centrosphere. Maturation of eosinophils and basophils follows the same morphologic steps as that of a neutrophil until the appearance of specific granules. The eosinophil exhibits a bilobed nucleus, and the basophilic cytoplasm is filled with prominent orange-red granules. Basophils exhibit less segmentation of the nucleus and the cytoplasm is filled with deeply staining blue to purple metachromatic granules. The granules often obscure the nucleus and cytoplasm which stains pink to reddish pink.

Monocytopoiesis

The earliest cell of the monocyte/macrophage series is the monoblast which can be difficult to distinguish from a myeloblast. The cell is 12-18 μm in diameter, with a round or oval nucleus which is frequently convoluted. The chromatin is fine and the nucleoli are sometimes present. The cytoplasm is basophilic and devoid of granules. The promonocyte is a large cell with an indented nucleus, exhibiting fine chromatin and a single nucleolus. The cytoplasm stains light blue. The monocyte is the largest cell with a diameter of 13-20 μm, the nucleus is large, lobulated, or bean shaped, with coarse chromatin and lacks a nucleolus. The cytoplasm has a characteristic light blue appearance. Egress of monocytes from the blood into the tissues is associated with increased cell size and larger and more lightly staining nucleus. These cells, termed macrophages or histiocytes, are phagocytic and mobile.

Lineage Commitment and Transcriptional Control of Granulopoiesis and Monocytopoiesis

The mechanisms of lineage commitment remain poorly understood. *In vitro* studies of murine embryonic stem cells reveal a coordinated expression of growth factor receptor genes during cell maturation. Certain genes are expressed constitutively during development of these cells, such as the c-kit and the α sub-units of the growth factor receptor genes. Expression of the common β sub-unit of these growth factor receptor genes (IL-3, IL-5, GM-CSF, SCF) are induced early. In contrast c-fms, G-CSFR and CD34 are induced later, at an intermediate stage of development, reflecting the initiation of myeloid commitment. At later stages, when a limited number of cytokine receptors are expressed or dominate in a progenitor cell, cytokines such as GM-CSF and G-CSF become important for neutrophil maturation, M-CSF and GM-CSF for macrophage development, IL-5 for eosinophil development and SCF, nerve growth factor and IL-3 for basophil and mast cell growth. The extent to which these growth factors and their receptor expression determine commitment remains unclear. Transcriptional factors such as PU-1 and EGR-1 play a role in macrophage development while genes such as fes and MZF-1 appear to be important in modulating granulocytic precursor proliferation.

THROMBOCYTOPOIESIS

The morphologic features of platelet forming cells are distinctly different from erythroid or leucocyte cell lineages. Distinct differentiation and morphologic changes do not occur. These processes are instead replaced by a process of polyploidisation. In this process, successive nuclear divisions without concomitant nuclear divisions lead to megakaryocytes with 1-32 nucleoli. The first identifiable cell in this lineage is the megakaryoblast, a distinctly large cell with a high nuclear/cytoplasmic ratio. The nuclear shape varies but frequently displays convolutions and deep furrows. The cytoplasm stains basophilic, does not contain granules and may exhibit fraying of the cytoplasmic membrane. Some megakaryoblasts may contain multiple nuclei. The pro-megakaryocyte exhibits a lobulated nuclear structure without nucleoli. The cytoplasm is basophilic, with azurophilic granules adjacent to the nucleus and formed platelets can be seen on the cytoplasmic surface. Mature megakaryocytes are the largest haematopoietic cell in the bone marrow. The nucleus is lobulated and exhibits coarse and clumped chromatin. Nuclear number varies from 4 to 8. Platelets can be seen in the periphery of the cytoplasm and are attached to the cell membrane. Platelets are believed to form by cytoplasmic budding from the megakaryocytes.

Regulation of Thrombocytopoiesis

Thrombopoietin (TPO) is a putative lineage specific regulator of platelet production. Data suggests the TPO production is regulated inversely by the platelet mass in the body. TPO is constitutively produced in the liver, kidney and probably the spleen and marrow as well.

LYMPHOCYTES

Lymphocytes and plasma cells are components of the immune system which also arise from HSC. Lymphocytes broadly include natural killer cells (NK cells), a component of the innate immune system, and T-cells and B-cells which are involved in adaptive immunity. Primary lymphoid organs where lymphopoiesis occurs include the bone marrow and thymus, while secondary lymphoid organs such as lymph nodes, spleen, mucosal and cutaneous associated are involved predominantly in immune sensitisation and selection.

B-Cells

B lymphocytes like all blood cells are the progeny of HSC. Once commitment to lymphoid development has occurred, a further bifurcation to T-cell and B-cell development occurs. The defining features of these commitment steps and their regulation remain poorly understood. Once committed to B-cell development there is less confusion as to precursor—progeny relationship and an orderly evolution from a precursor B-cell to a mature plasma cell occurs, antigen expression through these phases are unique and help identify the cells. This antigenic expression profile is summarised in **Table 2**.

The end result of B-cell development is generation of plasma cells that are capable of secreting immunoglobulins. These immunoglobulins are composed of heavy and light chains; these chains undergo re-arrangement of their V, D and J loci on the gene giving rise to antigen binding specificity and an immunoglobulin repertoire. These immunoglobulins are expressed on the surface of the B-cell, if the newly produced B-cell does not encounter an antigen, it undergoes apoptosis

Table 2: Antigenic Expression During the Stages of Development of T-cells and B-cells

B-cells

Antigen	Pro B-cell	Pre B-cell	Immature B-cell	Mature B-cell
CD34	+	±	–	–
CD10	–	+	±	–
CD19	+	+	+	+
CD20	–	–	+	+
CD21	–	±	+	+
CD22	–	–	±	±
CD24	±	–	±	±
CD38	+	–	–	–
CD45	±	+	+	+
Cyt Ig	–	+	+	+
SmIg	–	–	±	+

T-cells

Antigen	Prothymocyte	Early Thymocyte	Late Thymocyte	Mature T-cell
CD1	–	+	–	–
CD2	+	+	+	+
CD3	–	–	+	+ (either CD4/CD8+)
CD4	–	+	+	+
CD5	–	–	+	+
CD6	–	–	+	+
CD7	+	+	+	+
CD8	–	+	–	+ (either CD4/CD8+)
CD38	+	–	–	–
TCR	–	–	+	+

while those that encounter an antigen recognised by the re-arranged immunoglobulin molecule undergo blast transformation and proliferate.

T-Cells

These cells again arise from HSCs. They are released and home to the thymus where they must receive signals provided by the thymic stromal cells (processed antigen) for them to survive and undergo maturation into mature T-cells. Within the thymus these T-cells up-regulate CD25 (IL-2 receptor) and are now called pro-T-cells. They then go through stages of early and late pre-T-cell development and eventually mature following commitment into either CD4 positive helper T-cells or CD8 positive cytotoxic T-cells.

CONCLUSION

Haematopoiesis is a complex process involving the HSCs, osteoblasts, and components of the bone marrow micro-environment, receptors and cytokines. While attempts are made to compartmentalise the process for the sake of understanding, this does not truly represent the physiological state and does gross injustice to the complexity involved. Many of the processes and regulatory elements are poorly understood or are still in the process of being described. Abnormalities that affect this process can lead to life-threatening complications such as aplastic anaemia or myeloproliferative disorders. Additionally, better understanding of the basic science of haematopoiesis has already translated into new therapeutic tools as evidenced by the numerous cytokines that are available in the market.

15.2 Anaemia—A Clinical Approach

Renu Saxena, M Mahapatra

DEFINITION

Anaemia is functionally defined as an insufficient red blood cells (RBC) mass to adequately deliver oxygen to peripheral tissues. It may be due to increased RBC clearance, decreased RBC production, or both and caused by intrinsic or extrinsic causes. According to WHO, haemoglobin (Hb) of less than 13.0 g/dL in adult male, less than 12.0 g/dL in adult non-pregnant female and less than 11.0 g/dL in pregnant female should be considered as evidence of anaemia.

KINETIC CLASSIFICATION

Although, there are many classification schemes for anaemia based on aetiology, red cell morphology, etc. kinetic classification of anaemia based on reticulocyte production index (RPI) is most relevant clinically. Anaemias can be categorised as either hypoproliferative or haemolytic (hyperproliferative) and thereafter investigated appropriately.

Hypoproliferative anaemias are due to impaired RBC production and result from acquired nutritional deficiencies or systemic diseases. These are characterised by inadequate reticulocyte production (RPI <2.5) in response to anaemia.

Haemolytic anaemias (RPI >2.5) may be either congenital (membrane, enzyme or globin chain defects) or acquired (immune, microangiopathic, PNH, etc.) the former being more common in children and the latter in adults. In acute or chronic blood loss, increased RBC production occurs, provided that adequate nutrients are present.

EPIDEMIOLOGY

Nutritional deficiencies are the commonest cause of hypoproliferative anaemia in our country and affect both adults and children. Other common causes include the anaemia of acute or chronic inflammation and the anaemia of renal disease (due to low erythropoietin). Haematologic malignancies and solid tumours infiltrating the bone marrow (myelophthisis) are encountered mainly in adults. Haemoglobinopathies are more prevalent in certain geographical regions in our country like Hb-D in Punjab, Hb-E in Bihar, Bengal, Assam, North-Eastern states and Hb-S in Orissa and Maharashtra. Acquired and congenital RBC hypoplastic disorders are encountered more frequently in children. Here, we will restrict our discussion to approach of anaemia in adult patients.

CLINICAL PRESENTATION

Anaemia is not a disease, but it is a manifestation of an underlying pathology. It is never normal to be anaemic. The clinical presentations are related to anaemia itself or to the disorders causing anaemia. The signs and symptoms of anaemia will depend on how rapidly it appears, its severity, and the age of the patient. Patients with anaemia usually seek medical attention because of decreased work or exercise tolerance, shortness of breath, palpitation or fatiguability. When the haemoglobin falls below 7 g/dL, exercise capacity is markedly reduced. Older individuals with cardiovascular disease can develop angina and heart failure. Heart systolic murmurs are a common cardiac sign associated with anaemia and best heard in the pulmonary area. Pallor of skin and mucous membranes is a sign of anaemia. In the hands, the skin of the palms first becomes pale, but the creases may retain their usual pink colour until the haemoglobin concentration is less than 7 g/dL. Certain people routinely have pale-appearing skin without being anaemic. Patients with myxoedema may manifest pallor without anaemia. Skin and mucosal changes especially in nails and hairs are very common with anaemia. Thinning, loss of lustre and greying of hair may occur, the last especially with pernicious anaemia. The nails may lose their lustre, become brittle and break easily. This finding is commonly noticed in chronic iron deficiency anaemia. Headache, faintness, lack of mental concentration, tinnitus, and vertigo are common symptoms of severe anaemia.

APPROACH TO EVALUATION OF ANAEMIA

The correct diagnosis of anaemia requires a thorough history and physical examination along with complete blood cell count (CBC), reticulocyte count, and peripheral blood smear.

History and Physical Examination

A careful history and physical examination will provide clues to the potential cause as well as underlying systemic disorder (like renal failure, diabetes mellitus) or malignancy. Dietary history is very important, particularly in the young with food-fads and the elderly with anaemia. Pure vegetarian diet lacks B12 whereas insufficient green-leafy vegetables and overcooked food lacks folic acid. A detailed drug history is necessary to rule out drug induced bone marrow depression or autoimmune haemolytic anaemia. A past history of gastrectomy or ileal resection may point towards B12 deficiency anaemia. Menstrual and reproductive history is important to assess the iron status. Occupational history may be relevant in patients exposed to welding, paints and dyes resulting in exposure to lead or other potentially marrow toxic agents. A family history of anaemia, jaundice, gall stones or splenectomy may hint towards inherited haemolytic anaemia. Similarly, ethnicity of the patient helps in analysis of patients with suspected haemoglobinopathies.

On examination, pallor may be accompanied by angular cheilitis (cracking at the edges of the lips) and koilonychia (spooning of the nails) in iron deficiency anaemia and hyperpigmentation of knuckles in megaloblastic anaemia. Presence of jaundice alongwith pallor would suggest the possibility of haemolytic anaemia. Splenomegaly in adults may indicate an acquired disorder, such as autoimmune haemolytic anaemia; infections like kala-azar; venous congestion; lymphoproliferative or myeloproliferative disorder. In young adults, it may be even due to a congenital haemolytic anaemia, such as thalassaemia intermedia, hereditary spherocytosis or even congenital

dyserythropoietic anaemia. There may be exquisite tenderness over bones, especially over sternum suggesting acute leukaemia. Presence of petechiae and purpurae in addition to pallor would indicate marrow aplasia or infiltrative disease (leukaemia, lymphoma, myeloma, metastasis); these may be seen in megaloblastic anaemia also. The patients (especially pure vegetarians) presenting with neurological findings such as loss of vibration or position sense in the extremities should be investigated for early changes of megaloblastic anaemia even in absence of marked reduction of haemoglobin. Although, anaemia itself may result in systolic cardiac murmurs, the finding of an increased murmur in an anaemic patient with a prosthetic cardiac valve may be due to perivalvular leak resulting in microangiopathic change (schistocytes) on peripheral smear.

Reticulocyte Count

The reticulocyte count provides important information about the kinetics of the red cell production in response to anaemia and helps in classification and directing the initial investigations of anaemia. Reticulocyte count can be done manually using supravital stains (like brilliant cresyl blue or new methylene blue) or more accurately by automated cell counters and flow cytometers using fluorescent dyes like thiazole orange that bind to the residual ribonucleic acid present in these newly released red cells. Automated reticulocyte counting also allows the evaluation of other parameters, such as reticulocyte haemoglobin content and the proportion of immature reticulocytes (immature reticulocyte fraction). The various parameters derived from reticulocyte count are given below. RPI cut-off of 2.5 is used to differentiate hypoproliferative and hyperproliferative anaemias (**Table 1**).

Table 1: Kinetic Classification of Anaemia

Hypoproliferative anaemias (RPI <2.5) or (ARC <75000/µL)
- Anaemia of chronic disease
- Anaemia of renal disease
- Aplastic anaemia
- Pure red cell aplasia (PRCA)
- Congenital dyserythropoietic anaemia (CDA)
- Endocrine anaemias
- Marrow replacement

Maturation abnormalities (Ineffective erythropoiesis) (RPI <2.5) or (ARC <75000/µL)
- Vitamin B12 deficiency
- Iron deficiency anaemia
- Folate deficiency
- Sideroblastic anaemia
- Thalassaemia

Haemolytic anaemias (RPI >2.5) or (ARC >100,000/µL)
- Haemoglobinopathies
- Immune haemolytic anaemias
- Infectious causes of haemolysis
- Membrane abnormalities
- Metabolic abnormalities (enzymopathies)
- Mechanical haemolysis

Reticulocyte count = % reticulocytes in RBCs population

Corrected reticulocyte count = % reticulocytes × (patient Hct/45)

Reticulocyte production index = Corrected reticulocyte count × maturation time in peripheral blood in days* (Normal values of all of above 0.5-1.5%)

Absolute reticulocyte count (ARC) = % reticulocytes × RBC count/L (Normal values for ARC are from 25000 to 75000/mL; values <75000/mL indicate an inappropriately low erythropoietic response whereas an ARC >100,000/mL is indicative of hemolysis or an appropriate erythropoietic response. ARC between 75,000 and 100,000/mL require interpretation in the context of other clinical data.

*Hct = Haematocrit; *Reticulocyte maturation time = 1 day for Hct 40%; 1.5 days for Hct 30-40%; 2.0 days for Hct 20-30%; 2.5 days for Hct <20%.*

Red Cell Indices

Automated cell counters provide detailed information regarding the size, shape, and haemoglobin content of RBCs. The two parameters most useful in classifying anaemia are the mean corpuscular volume (MCV) in femtolitres (fL) and the red blood cell (RBC) distribution width (RDW). RDW reflects the variation in RBC size and shape (anisopoikilocytosis). These parameters are useful because relatively reproducible changes in the MCV and RDW are associated with certain types of anaemia (**Table 2**). Particularly when combined with the reticulocyte count, the MCV and RDW can significantly narrow the differential diagnosis (**Table 3**).

Table 2: Usefulness of the MCV and RDW in the Diagnosis of Anaemia

	Low MCV (< 80 fL)	Normal MCV (80-99 fL)	High MCV (>100 fL)
Normal RDW	Anaemia of chronic disease	Acute blood loss	Aplastic anaemia
	α- or β-thalassaemia trait	Anaemia of chronic disease	Chronic liver disease
	Haemoglobin E trait	Anaemia of renal disease	Chemotherapy/ antivirals/alcohol
Elevated RDW	Iron deficiency	Early iron, folate, or vitamin B12 deficiency	Folate or vitamin B12 deficiency
	Sickle cell-β-thalassaemia	Dimorphic anaemia (for example, iron + folate deficiency)	Immune haemolytic anaemia
		Sickle cell disease	Cytotoxic chemotherapy
		Chronic liver disease	Chronic liver disease
		Myelodysplasia	Myelodysplasia

MCV = Mean corpuscular volume; RDW = Red blood cell distribution width.

Table 3: Combining Reticulocyte Count and Red Blood Cell Parameters for Diagnosis of Anaemia

MCV, RDW	Reticulocyte Count <75,000/µL	Reticulocyte Count >100,000/µL
Low, Normal	Anaemia of chronic disease	
Normal, Normal	Anaemia of chronic disease	
High, Normal	Chemotherapy/antivirals/ alcohol, aplastic anaemia	Chronic liver disease
Low, High	Iron deficiency anaemia	Sickle cell-β thalassaemia
Normal, High	Early iron deficiency, folate, vitamin B12 deficiency	Sickle cell anaemia
	Myelodysplasia	Sickle cell disease
High, High	Folate or vitamin B12 deficiency	Immune haemolytic anaemia
	Myelodysplasia	Chronic liver disease

MCV = Mean corpuscular volume; RDW = Red blood cell distribution width.

Peripheral Blood Smear

Despite the availability of automated cell counters and sophisticated diagnostic testing, review of a well-made peripheral blood smear remains one of the most informative and rewarding diagnostic procedures. The finding of hypersegmented neutrophils suggests a megaloblastic process, and this morphologic abnormality can be seen in the blood

smear before there are significant changes in the haemoglobin or MCV. Also, only the blood smear reveals the unique morphologic changes occurring with various haemolytic disorders.

There are many commonly encountered findings in RBCs on the peripheral smear (**Table 4, Figures 1 to 4**). Microcytic, hypochromic red cells are suggestive of iron deficiency anaemia or thalassaemia; whereas macrocytic red cells with ovalocytes are suggestive of megaloblastic anaemias. Some findings reflect organ dysfunction, such as echinocytes (burr cells) in uraemia, or acanthocytes (spur cells) in severe liver disease and abetalipoproteinaemia. Target cells may be seen in cases of liver disease as well as in haemoglobinopathies, including sickle cell disease or thalassaemia. The presence of schistocytes or RBC fragmentation often reflects systemic disease, such as disseminated intravascular coagulation (DIC), thrombotic thrombocytopaenic purpura (TTP), or the haemolytic uraemic syndrome (HUS). Finding spherocytes on a smear is suggestive of autoimmune haemolytic anaemia or hereditary spherocytosis. Peripheral smear examination, especially thick blood smear, also helps in detecting haemoparasites like malaria, filaria and even leishmania. Some of the new automated cell counters have the technology to flag the sample in presence of haemoparasites based on their light scatter properties.

Table 4: Features of the Peripheral Blood Smear

RBC Morphology	Definition and Cause	Interpretation
Schistocytes	Fragmented cells; shearing force	Microangiopathic haemolytic anaemias DIC, TTP, HUS, prosthetic valves
Spherocytes	Small cells without central pallor; loss of membrane	HS, AIHA, burns, bacterial infection, G6PD
Teardrop cells	Pear-shaped erythrocytes; mechanical stress during release from bone marrow or passage through spleen	Myelophthisis (marrow replacement), thalassaemia, megaloblastic anaemia
Burr cells (Echinocytes)	Regular small projections circumferentially; shrinkage	Uraemia, PK deficiency, EDTA storage artefact
Spur cells (Acanthocytes)	Few irregular projections; abnormal lipid composition of membrane	Liver disease, Abetalipoproteinemia, Mcleod phenotype
Polychromasia	Large, bluish red blood cells; residual ribonucleic acid	Elevated reticulocyte count; haemolytic anaemia
Basophilic stippling	Many small bluish dots; clustered polyribosomes	Haemolytic anaemias, lead poisoning (lead inhibits pyrimidine 5′-nucleotidase)
Pappenheimer bodies	Several greyish, irregular inclusions; aggregates of ribosomes and ferritin	Sideroblastic and megaloblastic anaemia, haemoglobinopathies
Heinz bodies (Bite cells on routine staining)	Greyish inclusions on supravital or metachromatic stain; denatured Hb	Oxidative injury in G6PD deficiency, unstable Hb
Howell-Jolly bodies	Purplish inclusions; residual nuclear fragments	Splenectomy/splenic hypofunction

DIC = Disseminated intravascular coagulation; TTP = Thrombotic thrombocytopaenic purpura; HUS = Haemolytic uraemic syndrome; HS = Hereditary spherocytosis; AIHA = Autoimmune haemolytic anaemia; G6PD = Glucose-6-phosphate dehydrogenase; PK = Pyruvate kinase; Hb = Haemoglobin.

Bone Marrow Examination

Bone marrow aspiration and biopsy permit evaluation of cellular morphology and marrow architecture, respectively. It is generally avoided in the initial work-up of anaemia because

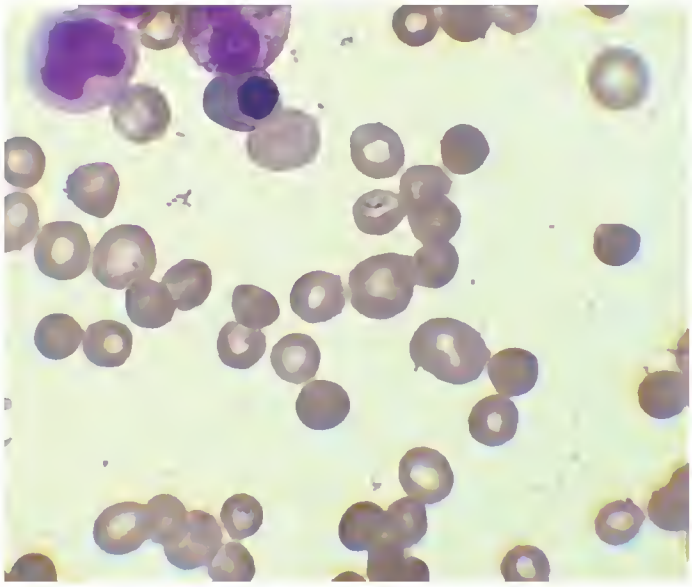

Figure 1: Peripheral smear showing spherocytes without central pallor, and nucleated RBCs.

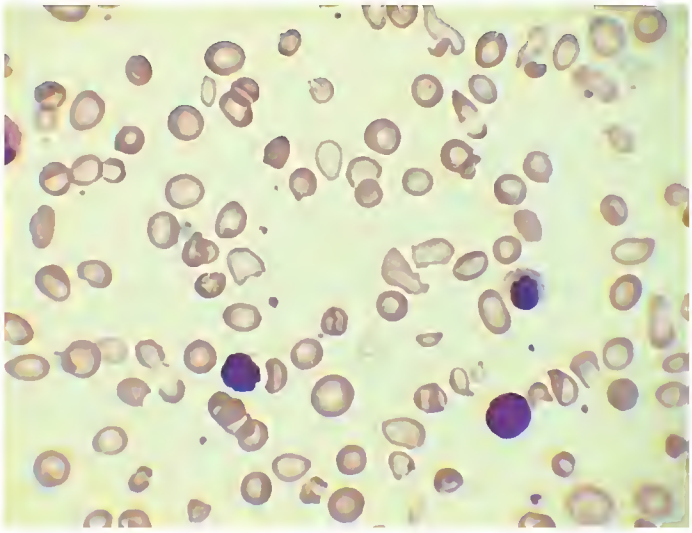

Figure 2: Peripheral smear showing fragmented RBCs with spicules (schistocytes) in a case of TTP.

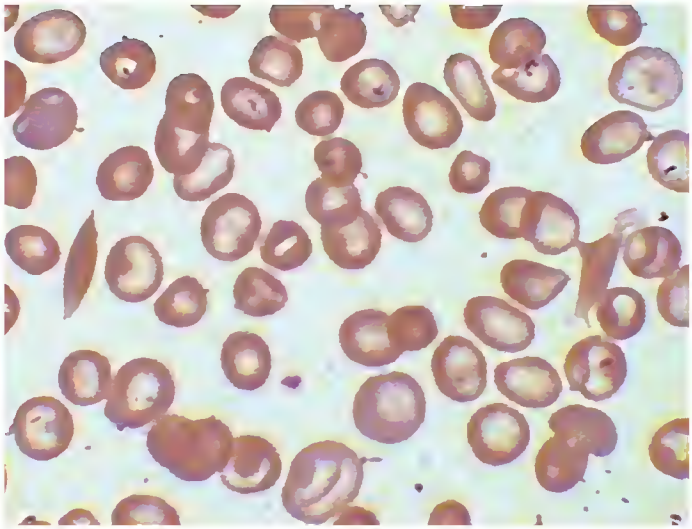

Figure 3: Peripheral smear from a patient of thalassaemia major with anisopoikilocytosis and microcytic hypochromic cells.

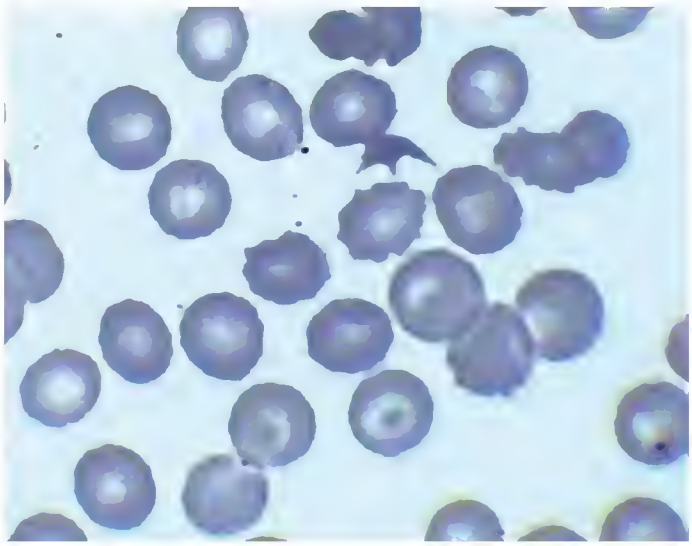

Figure 4: Peripheral smear showing sickle cells.

of the discomfort involved in the procedure and minimal additional useful information. However, it becomes necessary in cases where the possibility of myelodysplasia, leukaemia, or lymphoma is being considered. In such cases, samples of anticoagulated aspirate should be simultaneously collected for cytogenetics (heparinised tube) and flow cytometry (Heparin/EDTA) in addition to morphology and sent for the appropriate test, based on the morphology review.

Diagnostic uncertainty in the setting of hypoproliferative anaemia is an indication for bone marrow biopsy to rule out aplastic anaemia. A variety of infiltrative (myelophthisic) processes including granulomatous and metastatic deposits may be uncovered with bone marrow biopsy. Bone marrow biopsy touch preparation provides important diagnostic material especially in cases with diluted aspirate and must always accompany the bone marrow aspirate, biopsy and peripheral smear of the patient.

Other Tests in Work-up of Anaemia

Haemolytic work-up

Cation exchange Hb-HPLC (High performance liquid chromatography)/Hb Electrophoresis, sickling test, Coomb's test, test for cold agglutinins, osmotic red cell fragility and estimation of various red cell enzymes (at least G6PD screening) would be needed in suspected case of haemolytic anaemia. Raised plasma haemoglobin will indicate intravascular haemolysis.

Iron, vitamin B12, folic acid

Serum iron, iron-binding capacity, transferrin saturation, serum ferritin, marrow iron and serum transferrin receptors help in differentiating iron deficiency and anaemia due to chronic disorders. Serum vitamin B12 and folate levels may be estimated along with the metabolites like homocysteine and methylmalonic acid in suspected megaloblastic anaemia.

Urine and stool examination

Urine examination for proteins, pus cells, red cells, urobilinogen and haemosiderin can provide explanation for anaemia. Stool examination for ova, cyst and occult blood should be done in iron deficiency anaemia especially if refractory to treatment.

Other ancillary tests like upper and lower gastrointestinal endoscopy may be required in iron deficient patients to rule out bleeding ulcer or underlying gastrointestinal malignancy especially in the elderly.

TREATMENT

While it is very essential to evaluate a patient of anaemia for a definitive diagnosis, it is equally important to start any definite treatment. When anaemia is acute or so severe to threaten the patient's survival, immediate steps must be taken to guarantee oxygen delivery to tissues. Hypovolaemia can be managed with appropriate infusions of electrolytes and colloid solutions. Tissue hypoxia can be prevented by giving RBC transfusions and oxygen. If anaemia is less severe, red blood transfusion should be withheld till a proper diagnosis is made. Once the cause for anaemia is established, specific treatment should be initiated.

PREVENTION

A proper dietary guidance and balanced diet is the most important factor in preventing the occurrence of nutritional anaemias in all age groups. In addition, routine antenatal screening (e.g. Hb-HPLC, NESTROFT) and detection (DNA based) programmes should be in place to reduce the burden of thalassaemia major and other haemoglobinopathies in the society.

To conclude, a systematic approach to the evaluation of anaemia that includes a detailed history, complete blood count, and peripheral smear examination, facilitates an efficient diagnosis and minimises unnecessary testing.

15.3 Splenomegaly—A Clinical Approach

Lalit Kumar, Anuj Kumar Bansal

INTRODUCTION

The spleen is normally not palpable. It has to be enlarged 2 to 3 times before it becomes palpable. A palpable spleen was reported in 3% of asymptomatic male, college students which was still palpable at 3 years follow-up in 30% of them and there was no evidence of lymphoid malignancies at 10-year follow-up. Higher incidence of palpable spleen without evidence of disease has been reported from some tropical countries (e.g. New Guinea); no such data is available from India. A pathologically enlarged spleen is often firm, it may have an abnormal surface and it is frequently associated with signs and symptoms of the underlying disease. When the tip of the spleen is enlarged, more than 1 to 2 cm below the costal margin, further evaluation should be considered.

CAUSES OF ENLARGED SPLEEN

Splenomegaly is often the result of some other condition and not the result of a primary pathologic state (**Table 1**). Spleen size is not always a reliable guide to splenic function because palpable spleen is not always pathologic and abnormal spleen is not always palpable. Common causes of enlarged spleen according to size of spleen are given in **Table 1**. It must be understood that the classical causes of moderate and massive splenomegaly can also cause mild splenic enlargement in the early stages.

Table 1: Causes of Splenomegaly According to Size of Spleen

Massive	Moderate	Mild
Non-malignant	**Non-malignant**	**Infections**
Tropical splenomegaly	Portal hypertension with congestive splenomegaly	*Bacterial*
Chronic malaria	Chronic haemolytic anaemias	Salmonella, tuberculosis, Sub-acute bacterial endocarditis
Kala-azar	Sarcoidosis	*Viral*
Polycythaemia vera	Essential thrombocythaemia	Infectious mononucleosis, viral hepatitis, CMV, AIDS
Gaucher's disease		*Fungal*
Thalassaemia major		Parasite: Malaria, Leishmaniasis
Malignant	**Malignant**	Megaloblastic anaemia
Chronic myeloid leukaemia	Lymphomas	SLE
Idiopathic myelofibrosis with myeloid metaplasia	Chronic myeloid leukaemia	
Hairy cell leukaemia	Chronic lymphocytic leukaemia	
Lymphomas	Acute leukaemias	
	Amyloidosis	

Note: All the diseases which cause moderate or massive splenomegaly may cause mild splenomegaly at an early stage of disease.
CMV = Cytomegalovirus; AIDS = Acquired immunodeficiency syndrome; SLE = Systemic lupus erythematosus.

CLINICAL PRESENTATION

Mild splenomegaly may be asymptomatic. The most common symptoms produced by enlarged spleen are pain and a heavy sensation in the left upper quadrant; massive splenomegaly may cause early satiety. Occasionally, patient may present with severe pain in left hypochondrium or lower left chest due to rapid or acute enlargement of spleen resulting in stretching of the spleen with stretching of the capsule, infarction or inflammation of the capsule. Enlargement of spleen can be made on palpation in supine position or right lateral decubitus position, if the spleen is mildly enlarged. Enlargement of spleen more than 8 cm beneath left subcostal margin is called as massive splenomegaly. Radiological investigations are rarely necessary to see the enlargement of spleen. If needed, presence of an enlarged spleen can be more precisely determined by ultrasonography (USG). An USG can confirm the presence of the enlarged spleen or space-occupying lesions (e.g. cyst, abscess), provide accurate dimensions and help in distinguishing between splenic enlargement and other causes of a left sub-chondral mass (e.g. kidney). Collateral blood vessels develop secondary to portal hypertension and reversal of portal vein blood flow direction may be visualised with Doppler ultrasonography. Changes in spleen structure, such as mass lesions, infarcts, inhomogeneous infiltrates and cysts, are more readily assessed by computed tomography, magnetic resonance imaging or USG. However, none of these techniques are very reliable in the detection of patchy infiltration (e.g. Hodgkin's disease).

EVALUATION

A detailed history and good physical examination coupled with complete haemogram and liver function tests can give a clue to the cause of splenomegaly in most cases. Massive splenomegaly (≥8 cm or >1000 g) occurs in few conditions, e.g. myeloproliferative disorders (e.g. chronic myelogenous leukaemia, myelofibrosis, polycythemia vera), hairy cell leukaemia, lymphomas (splenic villous lymphoma), chronic lymphocytic leukaemia, Gaucher's disease, autoimmune haemolytic anaemia and chronic malaria. Presence of pallor (anaemia) may indicate haemolysis, bone marrow infiltration and hypersplenism. Petechiae/purpura due to thrombocytopaenia is seen in conditions, e.g. bone marrow failure (e.g. leukaemia), autoimmune disorders and hypersplenism. Presence of fever or rigors is indicative of

infections such as malaria, infectious mononucleosis or bacterial endocarditis. Presence of icterus may suggest haemolytic anaemia or liver disease as possible cause of splenomegaly. Skin rash may occur in acute and chronic infective states, Systemic lupus erythematosus (SLE), infective endocarditis and rheumatoid arthritis. Cloudy cornea and cherry-red retinal spots in children may be suggestive of metabolic storage disorders, e.g. mucopolysaccharidoses. Presence of respiratory and cardiac symptoms may be secondary to congestive heart failure, severe anaemia or a new murmur may be clue to infective endocarditis as cause of mild splenomegaly. Presence of prominent veins over abdominal wall, ascites, enlarged or shrunken liver may be indicative of portal hypertension and liver pathology as possible cause of splenomegaly. History of joint pains (rheumatoid arthritis, SLE) or bone pains (e.g. leukaemia) may be an important clue to diagnosis of splenomegaly. Splenomegaly may be seen in congenital haemolytic anaemias like beta-thalassaemia, hereditary spherocytosis and sickle cell anaemia in which family history may also be present. Non-cirrhotic portal fibrosis occurs in older children and young adults. Presence of generalised lymph node enlargement may suggest lymphohaemopoietic malignancies as a possible cause of splenomegaly. Primary tumours of spleen are rare except cysts; mostly metastasis from adjacent organs, such as stomach, pancreas and kidney can spread to spleen.

LABORATORY ASSESSMENT

Blood Counts

Complete blood count with differential and peripheral blood smears is the most important test. Pancytopaenia may be present because of bone marrow infiltration. White blood cell (WBC) count may reveal atypical lymphocytes (e.g. due to viral infections), blasts (e.g. in leukaemia), neutropaenia, (e.g. due to viral infections), neutropaenia, or neutrophilia (e.g. due to infection or leukaemia). Haemoglobin concentrations, red blood cell smears and reticulocyte counts may demonstrate anaemia, abnormal erythrocyte morphology, reticulocytosis (e.g. due to haemolysis), or malarial parasites. The platelet count may be high in conditions like myeloproliferative disorders (e.g. cytomegalovirus, primary thrombocythemia, polycythemia vera), may be normal or low in congestive splenomegaly, acute leukaemia, Gaucher's disease and immune thrombocytopaenia. Thrombocytopaenia may be present due to decreased production (e.g. due to bone marrow infiltration), increased destruction (e.g. due to immunologic causes, drug reactions, or viral infections), or sequestration or hypersplenism.

Bone Marrow Examination

It is generally indicated for work-up whenever a malignant haematologic disease is suspected or disseminated infection like kala-azar or tubercular infection is suspected.

Infection Work-up

This should be done as clinically indicated. Smear or antigen test for malaria, kala-azar, cultures from blood, body fluids (for bacterial infection), viral studies (Hepatitis, human immunodeficiency virus) and antibody titers for toxoplasmosis may aid in the diagnosis of infection as cause of splenomegaly.

Evaluation for lymphohaematopoeitic disorders

In myeloproliferative disorders, there may be mild anaemia with elevation WBC count (generally 10,000 to 20,000/mm^3 in myelofibrosis and polycythaemia vera or more than 1,00,000/mm^3 in chronic myeloid leukaemia). On differential count myelocytes, metamyelocytes and basophils may be appreciated. Spleen may be enlarged in a number of lymphoproliferative disorders. Immunophenotyping from peripheral blood or bone marrow may be necessary for definite diagnosis.

Liver disease evaluation

Liver function tests may be abnormal. For portal hypertension, ultrasound and Doppler of portal venous system and endoscopy (if indicated to exclude oesophageal varices) may be considered.

Evaluation for immunological disorders

This may include erythrocyte sedimentation rate, C3, C4, antinuclear antibody, rheumatoid factor, urinalysis, blood urea nitrogen and serum creatinine.

Evaluation for haemolytic disorders

Reticulocyte count, blood smear, serum bilirubin, urinary urobilinogen, Coombs' test, osmotic fragility, haemoglobin electrophoresis and other tests for haemolytic anaemia are performed, if indicated.

15.4 Iron Deficiency Anaemia

Subhash Varma

DEFINITION AND EPIDEMIOLOGY

Though iron is the third most abundant element yet its deficiency is the commonest nutritional deficiency and a major health problem that is estimated to afflict over two billion people globally. More than half of patients with anaemia are assumed to have iron deficiency. Between 30% and 70% population in the developing world is iron deficient. The third national family health survey (NFHS-3) estimates suggest that 56% of women and 70% of children in India have anaemia. Over half of all cases of anaemia are secondary to iron deficiency. Iron deficiency passes through a latent phase to overt iron deficiency anaemia (IDA). IDA is associated with cognitive impairment, reduced work output and is an important contributor to increased maternal and perinatal mortality.

IRON METABOLISM

Body Iron Stores

Average total human body iron is approximately 3 to 4 gm in men (50 mg/kg) and 2.3 gm (40 mg/kg) in women. Though iron is present in all cells and has several vital functions, nearly 70% of the body iron is present in haem compounds, especially haemoglobin and myoglobin; with small amounts being incorporated into enzymes that use iron in electron transfer (cytochromes, peroxidases, catalases and ribonucleotide reductase) and in enzymes containing iron-sulphur clusters (including cytochromes and aconitase). About 30% of iron, which is non-haem, is stored as ferritin or haemosiderin in the bone marrow, spleen and liver. Approximately 0.1% of body iron is in transit in the plasma, bound to the carrier protein, transferrin. The relative iron stores and their turnover are shown in **Figure 1**. Iron metabolism is discussed in details in chapter 5 of section 18.

Iron Cycle and Iron Absorption

Since most of the iron in body is recycled and normally the losses are minimal and limited to those through the epithelial cells of skin, gut and genitourinary tract, the daily loss that needs dietary replenishment is approximately 1 mg in men and post-menopausal women and up to 2 mg in menstruating women. However, it can increase several fold in those with blood loss due to any cause. Since only 10% to 15% of ingested iron is absorbed, the dietary intake has to be higher. It is generally between 12 and 15 mg in normal diet. Iron absorption from the proximal small intestine is tightly regulated and increases in patients with iron deficiency. Several factors affect iron absorption (**Table 1**). Bioavailability of ingested iron in meat containing diets is approximately two to four times compared to a vegetarian diet. Phytates and phosphates present in some foods such as leafy vegetables and tannates in tea also reduce the bioavailability of iron in vegetarian food. Vitamin C enhances the iron absorption. Ingested iron could be in organic (haem) and inorganic form. Inorganic iron is generally in ferric form that needs to be reduced to ferrous form, a function that is accomplished by the gastric acid. Consequently, achlorhydria either due to disease or drugs like proton pump inhibitors reduces iron absorption.

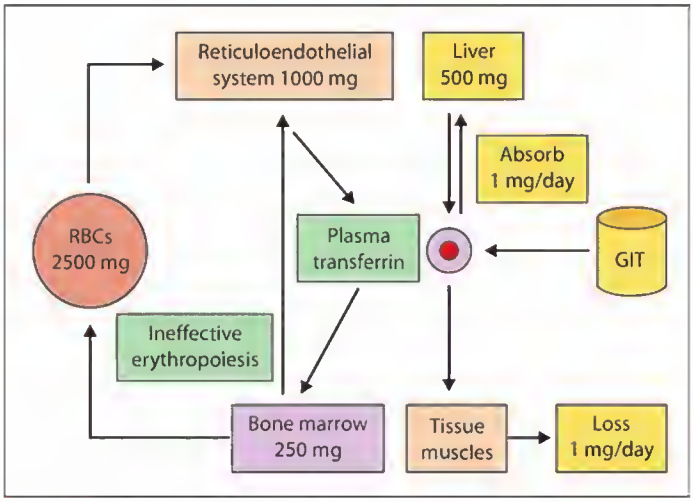

Figure 1: Iron stores and turnover.

RBCs = Red blood cells; GIT = Gastrointestinal tract.

Table 1: Factors Affecting Iron Absorption

Increased Absorption	Decreased Absorption
Dietary factors	
Increased haem-iron	Vegetarian diet
Animal protein	Achlorhydria
Vitamin C	Phytates
	Tannic acid (Tea)
	Alkali intake
Systemic factors	
Iron deficiency	Iron overload
Ineffective erythropoiesis	Inflammatory disorders
Thalassaemia, myelodysplasia	Infection
Increased erythropoiesis	
Haemorrhage (Haemolytic anaemia)	
Hypoxia	

Iron is absorbed in the duodenum and upper jejunum involving different transport mechanisms for haem and non-haem iron. Understanding of molecular mechanisms involving mucosal uptake, transfer to lamina propria, iron transport, storage and release has improved tremendously in recent years. Several key players such as diavalent metal transporter 1 (DMT1), hephaestin, ferroportin and hepcidin act in synchrony to maintain iron homeostasis. Absorbed iron is transported after binding to transferrin to the proerythroblasts for haem synthesis and some is carried to hepatocytes and reticuloendothelial cells (RE cells) for storage. The iron released from the red cells is recycled through the transferrin as well as stored in RE cells. Ferritin is the principal storage protein and ferritin levels correlate with status of body iron store, however, it is an acute phase reactant and the levels can be high in inflammatory diseases even in absence of iron

deficiency. Excess iron is also stored as haemosiderin which is water insoluble protein iron complex.

AETIOPATHOGENESIS

Iron deficiency results when demand outstrips supply and that may occur due to blood or haemoglobin loss, increased physiologic demands as in pregnancy, lactation and adolescence, decreased dietary intake or impaired absorption (**Table 2**). In a person with normal iron stores it passes through a pre-latent stage (iron store depletion) to latent stage (iron deficient erythropoiesis) and then to frank IDA (**Table 3**). With the progressive depletion of iron stores, serum iron levels fall and total iron binding capacity (TIBC) increases. When serum transferrin saturation falls to less than 16%, the supply of iron to marrow becomes sub-optimal. Initially free erythrocyte protoporphyrin levels increase and it finally results in decreased haemoglobin per cell and ultimately typical morphological changes of IDA appear. At times iron deficient erythropoiesis may result from impaired iron utilisation as in anaemia of chronic disease. Similar phenomenon occurs secondary to use of erythropoietin in chronic renal disease that is the result of impaired mobilisation of the large quantities needed for erythropoiesis.

Table 2: Causes of Iron Deficiency Anaemia

Increased Iron Requirements
Blood loss, massive haemorrhage
Gastrointestinal bleeding
- Haemorrhoids
- Duodenal or gastric ulcers or gastritis
- Nonsteroidal anti-inflammatory drugs, including aspirin
- Inflammatory bowel disease
- Diverticulosis
- Malignancy
- Arteriovenous malformation
- Varices
- Meckel's diverticulum
- Milk-induced enteropathy (infants)
- Salicylate use
- Hookworm *(Necator americanus and Ancylostoma duodenale)*
- Schistosomiasis
- Trichuriasis

Alveolar haemorrhage
Haemoglobinuria
Rapid growth in body size between 2 and 36 months of age
Menstruation, pregnancy and lactation

Inadequate Iron Supply
Poor nutritional intake

Malabsorption
- Gastric by-pass surgery for ulcers or obesity
- Achlorhydria from gastritis or drug therapy
- Severe malabsorption: coeliac disease
- Abnormal transferrin function
- Congenital atransferrinaemia
- Auto-antibodies to transferrin receptors
- Duodenal by-pass
- Drugs that increase gastric pH
- Tannins, phytates, bran
- Competing metals

Regular Blood Donation

Factitious Anaemia

Genetic Iron Deficiency Anaemia
Iron-resistant-iron deficiency anaemia
Atransferrinaemia
Acaeruloplasminaemia
Mutations in genes encoding DMT1 and glutaredoxin-5

Table 3: Stages of Iron Deficiency Anaemia

Pre-latent
Reduction in iron stores without reduced serum iron levels
Detected by a low serum ferritin measurement
Hb (N), MCV (N), iron absorption (↑), transferrin saturation (N), serum ferritin (↓), marrow iron (↓)

Latent
Iron stores are exhausted but the blood Hb level remains normal
Hb (N), MCV (N), TIBC (↑), serum ferritin (↓), transferrin saturation (↓), marrow iron (absent)

Iron deficiency anaemia
Blood Hb concentration falls below the lower limit of normal
Hb (↓), MCV (↓), TIBC (↑), serum ferritin (↓), transferrin saturation (↓), marrow iron (absent)

Hb = Haemoglobin; N = Normal; MCV = Mean corpuscular volume; TIBC = Total iron binding capacity; ↓ = Decreased; ↑ = Increased.

CLINICAL FEATURES

Patients with IDA could be incidentally diagnosed on laboratory investigations or may present with symptoms related to anaemia, the underlying cause or those peculiar to iron deficiency.

Anaemia

IDA can result in varying degree of anaemia that may be well tolerated in some persons. Severe IDA may be associated with fatigue, breathlessness, palpitations, dizziness, headache and irritability.

Growth

Iron deficiency impairs growth in infancy. In infants and pre-school children, iron deficiency anaemia affects neurological development by decreasing learning ability and altering motor functions. Iron deficiency even without overt anaemia has been linked to delayed cognitive development in children and adolescents.

Epithelial Tissue Changes

Patients with long-standing iron deficiency may develop a constellation of symptoms and signs characterised by defective structure or function of epithelial tissue. Nails, tongue and mouth are especially affected. Fingernails may become brittle, fragile, or longitudinally ridged and ultimately develop koilonychia. Soreness of tongue, mild papillary atrophy, absence of filiform papillae and angular stomatitis are the most frequent epithelial changes. Some patients may complain of dysphagia secondary to post-cricoid oesophageal web or stricture with gradual onset of dysphagia to solids but not to liquids (Paterson-Kelly syndrome/Plummer-Vinson syndrome).

Other Manifestations

IDA has been associated with impaired immune function and resultant increase in infections. Pica or craving for unusual substances like ice, clay, starch or other unusual food is a well described feature that improves on treatment with iron. Iron deficiency has also been associated with decreased work performance and exercise tolerance. Restless leg syndrome, i.e. an urge to move the legs with or without paraesthesia that worsens at rest and improves transiently with activity, has been associated with iron deficiency, especially in the elderly.

LABORATORY INVESTIGATIONS

IDA is diagnosed by the presence of biochemical indicators of iron deficiency along with characteristic blood and bone

marrow changes. Unfortunately, the classic combination of laboratory findings occurs consistently only when IDA is far advanced, when there are no complicating factors such as infection or malignant neoplasms and when there has been no previous therapy with transfusions or parenteral iron. Various tests and their limitations are listed in **Table 4**.

Table 4: Utility and Limitations of Various Investigations in Iron Deficiency

Test	Comments
Haemoglobin	Non-specific, not affected in early stages
Transferrin saturation	Low cost, widely available Marked diurnal variation in values, increased in ineffective erythropoiesis
MCV	One of the last parameters to be affected, hence low specificity
% hypochromic RBCs	Needs specialised autoanalysers, affected late
Reticulocyte Hb content	Early and sensitive sign False normal in thalassaemia and with increase in MCV
RBCs zinc protoporphyrin	Simple and precise for field surveys No additional information than % hypochromic RBCs Falsely high in lead toxicity, jaundice and haemodialysis patients
Serum ferritin	Widely available, falsely high in inflammation, liver disease, alcoholism, malignancy, chronic infection and haemophagocytic syndrome
Bone marrow iron stain	Not done routinely due to expense, discomfort and technical difficulties like high inter-observer variability
Soluble transferrin receptor	Also elevated in conditions of increased erythropoiesis, chronic haemolytic anaemias

MCV = Meon corpusculor volume; RBCs = Red blood cells.

Blood Parameters

Erythrocytes

IDA is characterised by a decrease in haemoglobin and red blood cell (RBC) counts along with decrease in the mean corpuscular volume (MCV) to less than 80 fL, mean corpuscular haemoglobin (MCH) to less than 28 pg/cell and mean corpuscular haemoglobin concentration (MCHC) to less than 30 g/dL. The content of reticulocyte haemoglobin (CHr) is an early, sensitive indicator of iron deficiency. CHr directly examines the haemoglobin endowment of the youngest circulating erythrocytes, allowing early detection of iron deficiency.

Peripheral smear

It shows characteristic findings in severe IDA. Anisocytosis is an important early sign in iron deficiency and when quantified has differential diagnostic value. An increased red cell distribution (RDW) on automated counter is indicative of anisocytosis. The red cells show microcytosis, hypochromia and poikilocytosis (**Figure 2**). Patients with parasitic diseases may show eosinophilia. Reactive thrombocytosis may be present in 50% to 70% cases, though some cases may have associated thrombocytopaenia.

Biochemical Parameters

Serum ferritin, serum iron and TIBC

Low serum ferritin invariably signifies iron deficiency. It has high negative predictive value although it lacks sensitivity and a normal value does not reliably exclude iron deficiency. In uncomplicated IDA, the serum ferritin level is less than 12 µg/L.

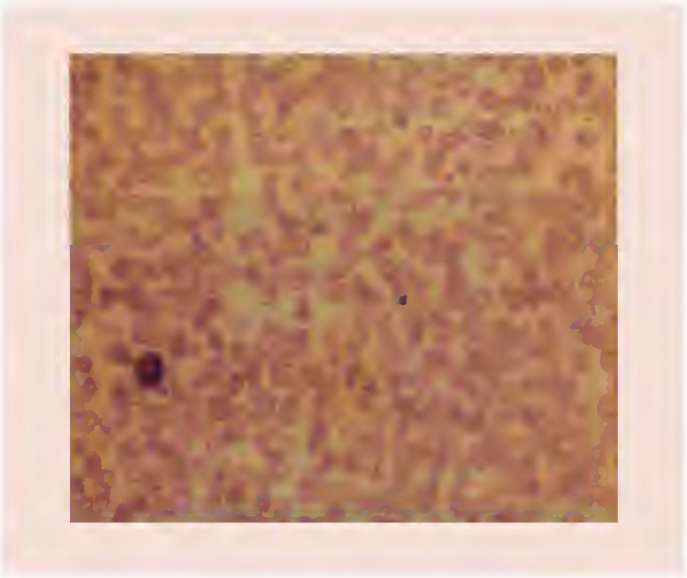

Figure 2: Peripheral smear in iron deficiency anaemia.

However, higher serum levels are the rule in the presence of a complicating infectious or inflammatory disease. Serum iron concentration (normal 30 to 160 µg/dL) is reduced in iron deficiency, and the TIBC (normal 220 to 420 µg/dL) increased. TIBC may be reduced in patients who have hypoalbuminaemia, inflammation, or both. Transferrin saturation is always reduced to less than 16% in iron deficiency.

Serum transferrin receptor (sTFR) fragments

These are measured by immunologic methods, are substantially increased in iron-deficient patients. This is useful in distinguishing iron deficiency from the anaemia of chronic disease (ACD), particularly when analysed as the ratio of sTFR to the log of the ferritin value. When the ratio of sTFR to log ferritin is greater than 1.5, iron deficiency is usually present (with or without other processes); when it is less than 1.5, the patient most likely has impaired iron use due to ACD, without frank iron deficiency.

Erythrocyte ferritin

Erythrocyte ferritin concentration is increased in thalassaemias and sideroblastic anaemias and decreased in iron deficiency. Though opinions differ, it has been suggested that basic red cell ferritin is not influenced by inflammation, and therefore could detect iron deficiency more reliably. However, this test is still not widely available.

Erythrocyte zinc protoporphyrin

Free erythrocyte protoporphyrin (FEP), mainly zinc protoporphyrin, is increased in disorders of haem synthesis, including iron deficiency, lead poisoning and sideroblastic anaemia. FEP is useful in differentiating iron deficiency from thalassaemia in which its value remains normal. This test requires small blood samples, is quite sensitive in the diagnosis of IDA and practical for large-scale screening programmes designed to identify children with either iron deficiency or lead poisoning. In addition, FEP also has a retrospective application as it helps to diagnose iron deficiency anaemia for some time even after the commencement of therapy.

Bone marrow

Hypercellularity with erythroid hyperplasia and presence of micronormoblasts is variable depending on the severity of

anaemia. These morphologic changes are not sufficiently distinctive to be of diagnostic value. However, a decrease or absence of stainable iron in marrow macrophages is characteristic finding of iron deficiency in bone marrow aspirates. Anaemias other than IDA have normal or increased iron stores.

DIFFERENTIAL DIAGNOSIS

Differential diagnoses of IDA includes anaemia with microcytic hypochromic picture like thalassaemia minor and other haemoglobinopathies like Hb E disease, anaemia of chronic disorders and sideroblastic anaemia (**Table 5**). **Table 6** summarises laboratory tests for differentiating IDA from other microcytic hypochromic anaemias.

Table 5: Causes of Microcytic Hypochromic Anaemia

Cause	Body Iron Stores
Iron deficiency anaemia	Decreased
Disordered globin synthesis	Increased
Thalassaemia states	
Microcytic haemoglobinopathies	
Impaired iron utilisation	Increased
Anaemia of chronic disease	
Infections	
Inflammation	
Disorders of haem synthesis	Increased
Sideroblastic anaemias	
Hereditary	
Acquired	

Blood Transfusion

RBC transfusions are rarely indicated because in most instances anaemia responds well to supplementation and is well tolerated. However, elderly with cardiovascular disease and those with excessive loss may need RBC transfusion.

Iron Replacement

Both oral and parenteral forms of iron are available for therapeutic use. Most patients would benefit by oral iron which is cheap, inexpensive and easy to administer. Several salts of iron are currently marketed (**Table 7**). Ferrous sulphate is cheap, inexpensive and effective. Usual adult dose is 150-200 mg of elemental iron per day whereas children are given 3 mg/kg of elemental iron. The absorption is better when iron is taken on empty stomach. Iron absorption is inversely proportional to the level of haemoglobin. Haemoglobin in responsive patients would increase by 2 g/dL at 3 weeks. Most patients would report early subjective improvement and maximum reticulocyte response is noted between 5th to 8th day after the start of treatment. Haemoglobin would return to normal in approximately 2 months. However, the treatment should be continued for 4 to 6 months to replenish the iron stores. The maintenance dose is 60 mg of elemental iron per day.

Some patients may not tolerate oral iron and develop epigastric discomfort, nausea, vomiting, diarrhoea or constipation. In such individuals the dose may be reduced or iron may be administered with meals. Since it would decrease the iron absorption, the treatment period is likely to be prolonged. Costlier formulations and enteric coated preparations that claim

Table 6: Laboratory Investigations for Iron Deficiency Anaemia

Test	Iron Deficiency	Chronic Inflammation	Thalassaemia	Sideroblastic Anaemia
MCV	Decreased	Normal or decreased	Markedly decreased	Decreased
RDW	Increased	Increased or normal	Increased or normal	Increased or normal
Red cell morphology	Microcytic, hypochromic, pencil cells, anisocytosis	Normocytic, normochromic or microcytic, hypochromic	Microcytic, hypochromic, basophilic stippling, target cells, polychromasia	Dimorphic
Red cell count	Decreased	Decreased	Normal	Normal
Serum iron	Decreased	Decreased or normal	Normal or increased	Normal or increased
Total iron binding capacity	Increased	Decreased	Normal	Normal
Per cent saturation	Decreased	Decreased to normal	Normal or increased	Normal or increased
Ferritin	Decreased	Increased or normal	Normal	Normal
Serum transferrin receptor	Increased	Normal	Increased	Normal
Free erythrocyte protoporphyrin	Increased	Increased	Normal	Increased
Haemoglobin pattern on electrophoresis	Normal	Normal	Abnormal (Hb A_2 >3.5%)	Normal
Marrow Iron	Low or absent	Normal or increased	Normal	Ring sideroblasts seen >15%

MCV = Mean corpuscular volume; RDW = Red blood cell distribution width.

TREATMENT OF IRON DEFICIENCY

Treatment of iron deficiency requires not only the correction of anaemia but also to replenish the depleted iron stores. Though iron deficiency is easily corrected by iron administration in most cases, a thorough search for finding and treating the underlying cause of deficiency is essential. Treating hookworm infection empirically is justified in Indian context. However, more sinister causes that result in occult blood loss must be considered and investigated especially in men and non-menstruating women.

Table 7: Oral Iron Salts

Iron Preparation	Elemental Iron (%)
Ferrous sulphate	20
Exsiccated ferrous sulphate	30
Ferrous fumarate	33
Ferrous succinate	23
Ferrous gluconate	12
Ferrous carbonate	16

less side effects are available but are generally not needed in practice.

Parenteral Iron Therapy

Parenteral iron therapy is indicated only in rare instances such as intolerance of oral iron therapy despite changes in dose and time of administration, malabsorption states, excessive continued losses, noncompliance, need for acute replacement as in pregnancy or in conjunction with erythropoietin in patients with renal failure and other causes of qualitative iron deficiency. Various preparations of iron that are available include low and high molecular weight iron dextran complexes, ferric gluconate, iron sucrose and iron sorbital complex (**Table 8**). New parenteral preparation, iron ferumoxytol and iron carboxymaltose have been reported to be safe. Parenteral iron can cause serious and life-threatening reactions such as hypotension, anaphylaxis or serum sickness like illness. Hence, these must always be administered under supervision. Parenteral iron other than iron sucrose can be administered to deliver the total dose that can be calculated as under:

Total iron in mg = Weight in kg x 2.2 x 15 – patients haemoglobin in g/dL) + 1,000 for males/600 for females

The total dose is diluted in 250 to 1,000 mL normal saline. 25 mg is given as test dose over 30 seconds and if no reaction is observed over 15 minutes then the remainder is given over 4 to 6 hours. The rate of rise of haemoglobin is similar to that with oral preparations.

Table 8: Parenteral Iron Preparations

Preparation	Comments
Iron dextran	50 mg/mL, intramuscular and intravenous use Test dose required Total dose infusion possible Potentially severe side-effects
Iron sorbitol citrate	Only intramuscular use, 50 to 100 mg/day Test dose required
Iron sucrose	100 mg in 5 mL Only intravenous use. Maximum single dose 100 mg can be given as slow injection over 5 min or as infusion in 100 ml saline over 30 mins. Test dose not required, reactions very rare.
Ferric gluconate complex in sucrose (Sodium ferric gluconate)	12.5 mg in 10 mL. Slow injection over 10 mins or infusion in 100 mL saline over 1 hour Reactions very rare

IRON REFRACTORY IRON DEFICIENCY

Some patients continue to have iron deficiency despite supplementation (**Figure 3**). In some instances, it may be due to poor compliance, a wrong diagnosis or continuing losses that cannot be corrected. Iron malabsorption due to latent or overt celiac disease, autoimmune gastritis and *Helicobacter pylori* infections have been the commonest demonstrable cause of refractory IDA in adults. In addition inherited forms of IDA affecting iron uptake, transfer and release (due to increased hepcidin levels) have been described in children. A diligent search either for iron loss or iron malabsorption is often rewarding in refractory IDA.

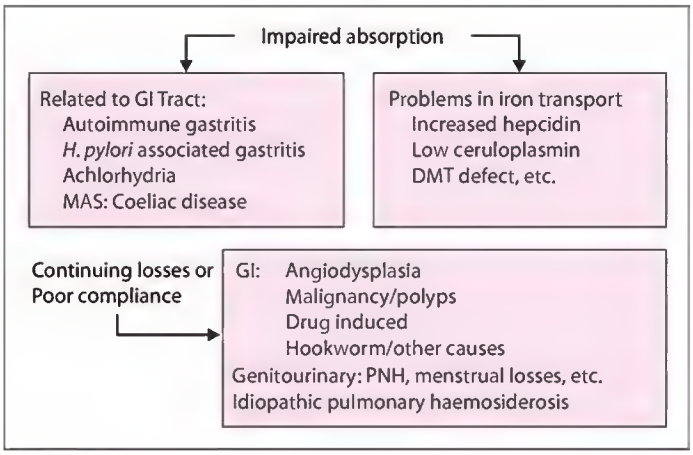

Figure 3: Iron refractory iron deficiency.

GI = Gastrointestinal; DMT = Divalent metal transporter.

CONCLUSIONS

Iron deficiency is the commonest nutritional deficiency and is responsible for more than 50% of anaemia worldwide. Iron deficiency results from an imbalance between the demand and supply of iron. It may occur secondary to decreased intake, increased requirements during pregnancy, lactation or growth spurt, inability to absorb iron from the gastrointestinal (GI) tract or increased losses from the gut, genitourinary tract or into other organs/tissues. Though easily treatable, a cause must be sought for in every case because it may be the harbinger of underlying sinister disorder, such as GI malignancy. Iron deficiency results initially in depletion of iron stores and progresses to the development of characteristic microcytic hypochromic anaemia. The diagnosis is established by biochemical parameters and it must be differentiated from other causes of hypochromic microcytic anaemia. Treatment is directed towards replacement of iron and treating the underlying cause. Oral ferrous sulphate is safe, cheap and effective in treating iron deficiency. In case of inadequate response besides looking at compliance, other reasons, such as continuing losses, co-morbidities, iron malabsorption and concomitant deficiencies should be sought.

15.5 Megaloblastic Anaemia

Tarun Kumar Dutta

INTRODUCTION

A puzzling illness with idiopathic anaemia, debilitation, languor and finally, torpor and death was first described by Addison in 1849. In 1880, Ehrlich identified megaloblasts and proposed them as the precursors of the 'giant blood corpuscles'. These events in course of time heralded the knowledge of disease known as megaloblastic anaemia. Castle described *achylia gastrica* and demonstrated that gastric juice contains an 'intrinsic factor' (IF) that combines with an 'extrinsic factor' in meat and allows it to be absorbed.

Wills, who treated macrocytic anaemia with yeast, defined the need for folate, which was isolated and characterised in 1948.

DEFINITION

The megaloblastic anaemias are disorders caused by impaired deoxyribonucleic acid (DNA) synthesis due to deficiencies of vitamin B12 (cobalamin, i.e. Cbl) or folic acid (FA), which give rise to anaemia and macro-ovalocytic red cells (mean corpuscular volume [MCV] >100 fL) and bone marrow showing intense erythroid hyperplasia and megaloblastic changes. The megaloblast, the morphologic hallmark of the syndrome, is a product of impaired DNA formation due to deficiencies of vitamin B12 or FA.

PATHOGENESIS OF MEGALOBLASTIC ANAEMIA

Megaloblastic anaemia results from abnormal maturation of haematopoietic cells due to impaired DNA synthesis. Cbl (vitamin B12) and FA are two essential vitamins for DNA biosynthesis. Deficiency of either vitamin results in what is called as nucleo-cytoplasmic asynchrony. All proliferating cells will exhibit megaloblastosis; hence changes are evident in the buccal mucosa, tongue, small intestine, cervix, vagina and uterus. In the haematopoietic system this asynchrony results in abnormal nuclear maturation with normal cytoplasmic maturation, apoptosis, ineffective erythropoiesis, intra-medullary haemolysis, pancytopaenia and typical morphological abnormalities in the blood and marrow cells.

AETIOLOGY

Aetiology of megaloblastic anaemia is multifactorial and may result from dietary deficiency, impaired absorption and transport or impaired utilisation of these vitamins in DNA synthesis (**Table 1**). The dietary patterns vary widely across India and studies need to be conducted region-wise to find out the variable aetiology of megaloblastic anaemia.

Table 1: Causes of Cobalamin and Folic Acid Deficiencies in India

Common Causes of Cobalamin Deficiency in India

Nutritional deficiency/inadequate intake
(most important cause in India, including in strict vegans)
Malabsorption
Defective absorption of cobalamin from food
- Gastric achlorhydria
- Partial gastrectomy
- Drugs blocking gastric acid secretion

Inadequate production of intrinsic factor (IF)
- Total gastrectomy

Disorders of terminal ileum
- Tropical and coeliac sprue
- Intestinal resection
- Granulomatous diseases

Competition for cobalamin
- Bacteria (Blind loop syndrome)

Drugs
- Colchicine
- Neomycin

Uncommon Causes of Cobalamin Deficiency in India

Pernicious anaemia
Congenital absence or functional abnormality of IF
Crohn's disease
Selective cobalamin malabsorption: Imerslund-Grasbeck syndrome
Fish tapeworm infestation (*Diphyllobothrium latum*)
Transcobalamin II deficiency

Common Causes of Folic Acid Deficiency in India

Nutritional deficiency
Increased requirements
- Infancy and children
- Pregnancy
- Malignancy
- Chronic haemolytic anaemia
- Chronic exfoliative dermatitis
- Haemodialysis

Malabsorption
- Tropical and non-tropical sprue
- Drugs: Phenytoin, barbiturates

Impaired metabolism
- Inhibitors of dihydrofolate reductase

Methotrexate, pyrimethamine
Alcohol

Uncommon Causes of Folic Acid Deficiency in India

Rare enzyme defect – dihydrofolate reductase
Drugs that impair DNA synthesis
- Purine antagonists: 6-mercaptopurine, azathioprine
- Pyrimidine antagonists: 5-fluorouracil, cytosine arabinoside
- Others: Hydroxyurea, procarbazine, zidovudine, acyclovir

Metabolic disorder
- Lesch Nyhan syndrome, hereditary orotic aciduria

Megaloblastic anaemia of unknown aetiology
Refractory megaloblastic anaemia in myelodysplastic syndrome (MDS)

PREVALENCE AND CAUSATIVE FACTORS

Very few studies have been conducted to study the prevalence of megaloblastic anaemia in the general population. Analysing the western literature, it is found that dietary and pregnancy-related folate deficiencies are probably the most common causes of megaloblastic anaemias. The frequency of pernicious anaemia (PA) is 0.25-0.5 cases per 1,000 persons in their seventh decade of life. However, the frequency of PA is reported to be higher in Sweden, Denmark, and the United Kingdom (100-130 cases per 100,000 population). In a study conducted among North African population, 478 patients with megaloblastic anaemia were studied; 98% of patients had vitamin B12 deficiency. PA accounted for most of these cases, and median age at presentation was 45 years.

In a study conducted in Hong Kong on 84 consecutive Chinese patients with megaloblastic anaemia (48 males and 36 females) median age at presentation was 67 years, and vitamin B12 deficiency was found in all cases and none had folate deficiency.

Indian Scenario

A study reported that 75% of a selected urban population from India, Pune (Maharashtra) had metabolic evidence (hyperhomocysteinaemia and methylmalonic acidaemia) of Cbl deficiency, which could only partly be explained by a vegetarian diet. Folate deficiency has traditionally been linked to poverty, which (by Indian standards) afflicts ~33% of the population of India. In Delhi, a hospital-based study showed that 2.7% of all anaemia was megaloblastic anaemia.

In another study from Puducherry, megaloblastic anaemia was found in 38.4% out of 60 adult patients of macrocytic anaemia. There was a significant male preponderance in the study (65%), and majority were young. The megaloblastic anaemias observed were due to either vitamin B12 deficiency (78.3%) or combined vitamin B12 and folate deficiency (21.7%). None had lone folate deficiency. A significant proportion of non-vegetarians (73.9%) had megaloblastic anaemia.

In a study at Delhi, megaloblastic anaemia was diagnosed in 175 patients with anaemia over a period of 6 months. Assays were done on 120 patients who could be followed-up and results showed Cbl deficiency in 78 patients (65%), combined Cbl and folate deficiency in 20 patients (12%) and pure folate deficiency in 8 patients (6%). The peak incidence of megaloblastic anaemia was in the age group of 10 to 30 years (48%), with female preponderance (71%).

More and more reports from India show vitamin B12 deficiency as a predominant cause for megaloblastic anaemia in contrast to folate deficiency, which was earlier believed to be a major cause. This may be attributed to the routine FA supplementation especially among women.

Western data emphasises on PA as the major cause, but Indian data suggests nutritional deficiency of vitamin B12 and FA as major causes of megaloblastic anaemia. An attempt should always be made to find out the cause and treat accordingly.

COBALAMIN DEFICIENCY

Physiologic Considerations

Animal products (meat and dairy products) provide the only dietary source of Cbl for humans. The minimum daily requirement is 6-9 µg/day. Total body stores of Cbl are 2-5 mg, approximately one-half of which is in the liver. As a result, it takes years to develop vitamin B12 deficiency after absorption of dietary B12 ceases.

Clinical Manifestations of Cobalamin Deficiency

The classic picture of Cbl deficiency due to PA was that of a prematurely graying, mentally sluggish person with a shiny tongue (atrophic glossitis) and a shuffling broad gait. This classic picture of PA is now seen less frequently. It has been replaced by more subtle presentations. Because Cbl is required for all rapidly growing cells, including enteric mucosal cells and epithelial cells of the skin, patients with Cbl deficiency may complain of glossitis, vaginal atrophy, and malabsorption; they often have diffuse hyper-pigmentation particularly increased pigmentation over knuckles (**Figures 1 and 2**). The patient may have neuro-psychiatric problems consisting of paraesthesiae, numbness, weakness, impaired memory and personality changes. Examination reveals haematologic and neurologic abnormalities.

When the anaemia is severe, there may also be thrombocytopaenia and neutropaenia (i.e. pancytopaenia). Thrombocytopaenia occasionally may be associated with frank mucosal bleeding.

Figure 1: Diffuse pigmentation of hand and knuckle hyper-pigmentation in megaloblastic anaemia.

Figure 2: Knuckle hyper-pigmentation in a 55-year-old woman with megaloblastic anaemia due to combined vitamin B12 and folic acid deficiency.

Neurologic Abnormalities

The neurologic problems, when present, consist of the classic picture of sub-acute combined degeneration of the dorsal (posterior) and lateral spinal columns. This lesion, specific for Cbl deficiency, is due to a defect in myelin formation of unknown mechanism. The neuropathy is symmetrical and affects the legs more than the arms. It begins with paraesthesiae and ataxia associated with loss of vibration and position sense, and can progress to severe weakness, spasticity, clonus, paraplegia and even faecal and urinary incontinence.

Other neurologic abnormalities that can be seen are axonal degeneration of peripheral nerves and central nervous system symptoms including memory loss, irritability and dementia. Patients may present with Lhermitte's syndrome, a shock-like sensation that radiates to the feet during neck flexion.

Of great clinical importance, not all patients with neurologic abnormalities secondary to Cbl deficiency are either anaemic or have macrocytic red cell indices. As an example, among 141 consecutive patients with neuro-psychiatric abnormalities due to Cbl deficiency, the haematocrit was normal in 34, the mean red cell volume was normal in 25 and both tests were normal in 19.

FOLIC ACID DEFICIENCY

Physiologic Considerations of Folic Acid

Folate occurs in animal products and in leafy vegetables in the polyglutamate form. Normal daily requirements for unstressed individuals are about 200-400 μg/day; this increases to 500-800 μg/day in pregnancy and lactation.

The most common cause of folate deficiency is nutritional due to poor diet and/or alcoholism. Although folate is plentiful in liver, greens and yeast, it is easily destroyed by heat during cooking. Body stores are small (5-10 mg) and individuals on a folate deficient diet can develop megaloblastosis within 4 to 5 months.

Folate at physiologic levels enters cells by binding to a folate receptor. Once inside the cell, FA is polyglutamated, a form which is biologically active and cannot diffuse back into the plasma.

Causes of Folate Deficiency

Alcohol abuse produces a sharp fall in serum folate within 2 to 4 days by impairing its enterohepatic cycle and inhibiting its absorption. Thus, alcoholics on a low folate intake can develop megaloblastosis within 5 to 10 weeks. This period is shorter than the 4 to 5 months required in normals in part because alcoholics start with lower stores due to previous dietary habits.

Other mechanisms of folate deficiency include increased requirements in pregnancy and in patients with haemolytic anaemias and exfoliative skin disease and drug-induced interference with folate metabolism. Pregnancy and lactation increase the need for FA and the daily requirement increases from 400 μg to 800 μg.

Several drugs interfere with FA metabolism. Trimethoprim is a weak inhibitor of dihydrofolate reductase and in high dose has been implicated in megaloblastic pancytopaenia. Methotrexate can also produce folate deficiency.

Clinical Manifestations

The haematologic manifestations of folate deficiency are similar to those of Cbl deficiency but neurologic abnormalities do not occur.

Another important difference is the time required for deficiency to develop. Because Cbl stores are so large in relation to daily intake, a year of inadequate intake of absorption is required before the onset of symptoms. On the other hand, symptoms of folate deficiency can occur within a few weeks after intake is diminished.

Folate deficiency occurs in patient who abuse alcohol or other drugs and have a very poor dietary intake. Older and depressed patients who live alone and avoid cooking foods that contain folate may become deficient, as can patients with the malabsorption syndrome. Increased folate demands occur in patients with chronic severe haemolytic anaemia and pregnancy.

Hyperhomocysteinaemia

Both Cbl and FA are required for the metabolism of homocysteine to methionine. As a result, deficiencies in these vitamins can lead to elevations in plasma homocysteine levels, which is a risk factor for the development of atherosclerosis and venous thrombosis.

DIAGNOSIS OF MEGALOBLASTIC ANAEMIA

The evaluation of suspected Cbl or folate deficiency generally proceeds in two stages: Documenting the presence of the vitamin deficiency and then determining its cause (e.g. malabsorption, dietary lack or PA).

The diagnosis of deficiency can most often be established by a combination of the following; red blood cell mean corpuscular volume (MCV), evaluation of the peripheral blood smear and bone marrow examination; measurement of the serum Cbl and the red blood cell (or serum) folate concentrations and evaluation of specific metabolites (e.g. methylmalonate and homocysteine).

An elevation of the red blood cell MCV is one of the hallmarks of Cbl and folate deficiency. The degree of elevation of the MCV is often a clue as to whether a vitamin deficiency is present. The major haematologic finding is a macro-ovalocytic anaemia (**Figure 3**) (with elevated serum bilirubin and LDH levels that reflect the increased red cell breakdown due to ineffective erythropoiesis). The absolute reticulocyte count is normal or even distinctly low. The peripheral blood smear shows macro-ovalocytes, occasionally megaloblasts, and hyper-segmented neutrophils (greater than 5% of neutrophils) with 5 or more lobes or 1% with 6 or more lobes. Hypersegmentation is result of an alteration of late granulopoiesis.

When the anaemia is severe, there may also be thrombocytopaenia and neutropaenia (i.e. pancytopaenia). Bone marrow aspiration and biopsy reveal a very hypercellular marrow with megaloblastic erythroid hyperplasia and giant metamyelocytes (**Figure 4**).

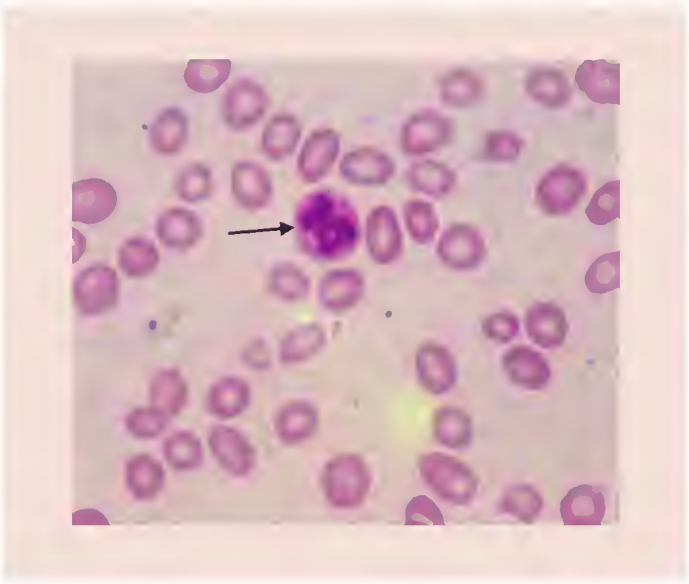

Figure 3: Peripheral smear showing macro-ovalocyte, hypersegmented neutrophil (arrow) and scanty platelets (Leishman's stain × 1000).

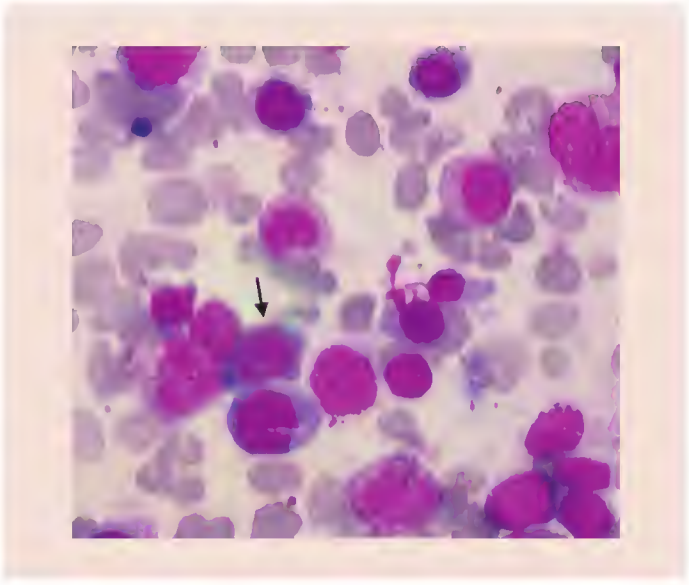

Figure 4: Bone marrow aspirate showing a colony of megaloblastic erythropoiesis with sieve-like chromatin and a giant stab form (Leishman's stain × 1000).

Cobalamin Levels

In general, however, serum Cbl levels can be interpreted, as follows:

- More than 300 pg/mL (normal result); Cbl deficiency is unlikely,
- 200 to 300 pg/mL (borderline result); Cbl deficiency possible,
- Less than 200 pg/mL (low); consistent with Cbl deficiency (specificity of 95% to 100%).

Folate Levels

The red cell folate concentration is theoretically a more reliable indicator of tissue folate adequacy, since it reflects a time-averaged value of FA availability, and is therefore not subject to the short-term fluctuations noted above. As a result, it has been suggested that the less expensive serum folate concentration should be obtained as an initial screening test and that there is no basis for the routine testing of all samples for both serum folate and red cell folate. If the serum folate concentration is more than 4 ng/mL (9.1 nanomol/L), folate deficiency is effectively ruled out.

If the Cbl and folate levels are equivocal, the next step should be evaluation of the metabolites methylmalonic acid (MMA) and total homocysteine. The measurement of the serum concentrations of the metabolities is helpful in clarifying the diagnosis in such a situation.

Measurement of Methylmalonate and Homocysteine

Serum concentrations of homocysteine and methylmalonic acid (MMA) are elevated in Cbl deficiency, due to a decreased rate of metabolism. In comparison, only homocysteine is elevated in folate deficiency, since folate does not participate in MMA metabolism. Hereditary homocysteinaemia can raise serum homocysteine levels. Serum and urinary levels of MMA are elevated in patients with methylmalonic aciduria and in patients with renal insufficiency or hypovolaemia.

If a diagnosis of Cbl and/or folate deficiency has been established through the above testing, the next step is to determine the cause of the deficiency (e.g. PA, diet, malabsorption, drugs).

The presence of anti-intrinsic factor antibodies and positive Schilling test are highly confirmatory for the diagnosis of PA.

Vitamin B12 deficiency, PA, malabsorption, blind-loop syndromes and ileal disease can be reliably and quickly diagnosed using methods other than the Schilling test. Thus, Schilling test is not commonly employed these days.

In the absence of facilities to estimate vitamin levels, a therapeutic algorithmic approach can be followed to find out cause of megaloblastic anaemia, whether due to vitamin B12 or FA deficiency (**Figure 5**).

TREATMENT

Treatment of Cobalamin Deficiency

PA is typically treated with parenteral (i.e. intramuscular) Cbl, in a dose of 1,000 µg (1 mg) every day for one week, followed by 1 mg every week for 4 weeks and then, if the underlying disorder persists, as in PA, 1 mg every month for the remaining life of the patient.

Oral Formulations

An alternative that appears to be as effective as parenteral therapy is based on the premise that there is presence of a second, lower efficiency transport system for Cbl that does not require IF or a functioning terminal ileum. Because of variability in absorption, lower doses are not completely effective in some patients with PA. The dose given in this situation (1-2 mg/day) is more than 200 times higher than the minimum daily requirement for normal subjects, and significantly higher than that available in most standard multivitamins and B12 supplements (100 µg/day). The effectiveness of this form of treatment should be monitored frequently with determinations of serum Cbl and methylmalonate concentrations.

Laboratory Monitoring

Laboratory studies should be monitored after Cbl therapy to document a haematologic and metabolic response: If the

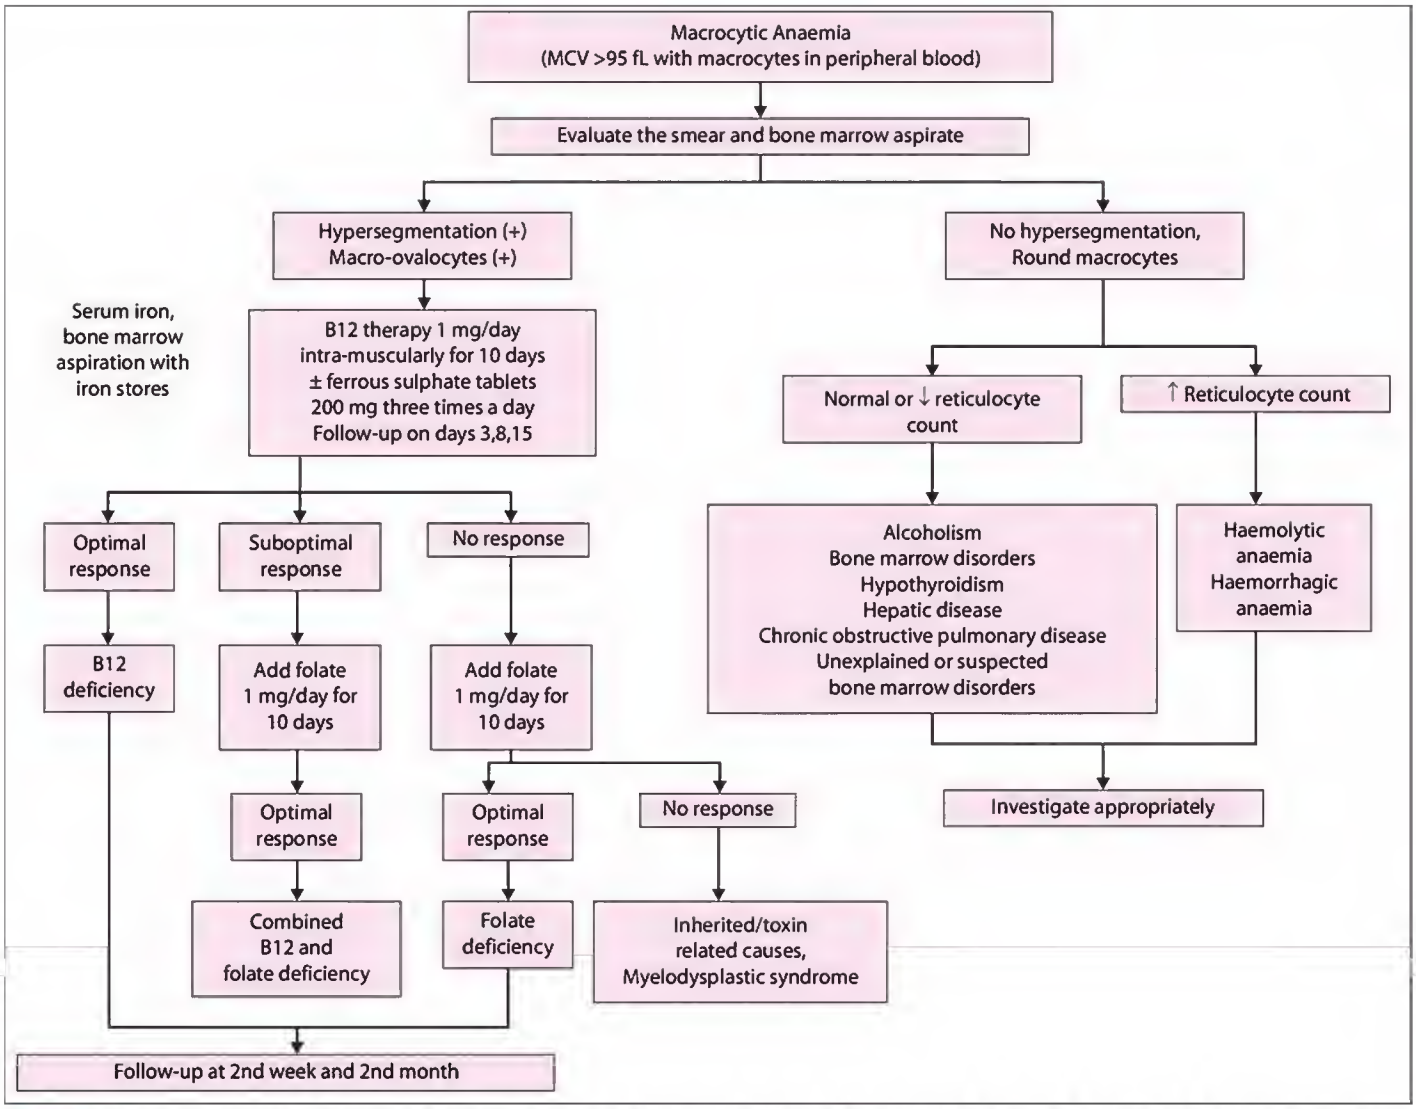

Figure 5: Algorithmic approach to find cause of macrocytic anaemia/megaloblastic anaemia (in the absence of facility for vitamin B12 or folic acid estimation).

patient is anaemic, there will be a reticulocytosis in 3 to 4 days, peaking at days 6 to 7 days, followed by a rise in haemoglobin and a fall in MCV. The haemoglobin concentration begins to rise within 10 days and usually returns to normal within 8 weeks. A delayed response suggests the presence of an additional abnormality (e.g., iron deficiency, infection, hypothyroidism, malignancy). In patients with severe anaemia, serum iron levels fall within 24 hours and the serum LDH levels begin to fall within 2 days. Hyper-segmented neutrophils disappear at 10 to 14 days. Neurologic abnormalities, if present, improve more slowly over six months; the degree of improvement is inversely related to the extent and duration of disease.

Treatment of Folate Deficiency

Folate deficiency is treated with FA (1-5 mg/day) for 1 to 4 months, or until complete haematologic recovery occurs. A dose of 1 mg/day is usually sufficient, even if malabsorption is present. These doses are in excess of those recommended for disease prevention (e.g., recommended daily allowance in normal adults, alcoholics, the elderly, prevention of neural tube defects).

Folic acid can partially reverse some of the haematologic abnormalities of Cbl deficiency, but the neurologic manifestations will progress. Thus, it is important to rule out Cbl deficiency before treating a patient of megaloblastic anaemia with FA. If initiation of treatment is urgently required, blood samples should be obtained for the appropriate assays and the patient should be treated with both FA and vitamin B12 simultaneously until the results are known.

15.6 Hereditary Haemolytic Anaemia

MB Agarwal

Once released from marrow, red cells circulate in blood for 120 days, after which they are removed by macrophages of reticuloendothelial system (RES) in the liver, spleen and marrow. Iron is recycled via transferrin to the marrow while the pigment protoporphyrin is broken down to bilirubin which is conjugated in liver and excreted into the gut where it is converted to stercobilinogen. Most of the stercobilinogen is excreted in faeces but some of it is partially reabsorbed and excreted in urine as urobilinogen and urobilin. A small fraction of protoporphyrin is converted to carbon monoxide and excreted via the lungs. Globin chains are broken into amino acids and are reutilised for general protein synthesis in the body. Normally, there is no intravascular haemolysis. Any haemoglobin released into the plasma binds to a protein called haptoglobin and this complex of haemoglobin and haptoglobin is removed from plasma by the RES.

Haemolysis is characterised by premature removal of circulating red blood cells (RBCs) due to lysis within the circulatory system (intravascular haemolysis) or premature removal by the RES of the spleen, liver and bone marrow (extra-vascular haemolysis). Such accelerated RBC destruction is seen in various hereditary and acquired haemolytic disorders.

Normal marrow has tremendous capacity to become hyperplasic and compensate for haemolysis, and hence, anaemia occurs only when this compensation is not adequate. The erythroid hyperplasia of marrow is reflected in blood as reticulocytosis unless there is ineffective erythropoiesis as in thalassaemia major. Shortened RBC survival can be demonstrated by chromium-labelled red cell survival studies. The site of destruction can also be determined by surface counting over liver and spleen.

HEREDITARY HAEMOLYTIC ANAEMIAS

Haemolytic anaemias can be classified in various ways, e.g. inherited (hereditary) versus acquired, intra-corpuscular versus extra-corpuscular (**Table 1**) and acute versus chronic. Hereditary haemolytic anaemias are usually due to intra-corpuscular or intrinsic red cell defects. **Table 2** gives a simplified aetiological classification of hereditary haemolytic anaemias.

Table 1: Pathophysiologic Classification of Haemolytic Disorders

Intrinsic (intra-corpuscular) defects: usually hereditary
Red blood cell membrane defects
Red blood cell enzyme defects
Haemoglobinopathies
Extrinsic (extra-corpuscular) defects: usually acquired
Immune-mediated haemolysis
Physical damage to red blood cells
Toxins
Thermal injury
Mechanical disruption

Table 2: Aetiological Classification of Hereditary Haemolytic Anaemia

Membrane defects
Hereditary spherocytosis
Hereditary elliptocytosis
Hereditary stomatocytosis
Hereditary acanthocytosis
Enzyme defects (congenital non-spherocytic haemolytic anaemia)
Deficiency of glucose-6-phosphatase dehydrogenase or other enzymes in the pentose phosphate pathway
Deficiency of pyruvate kinase or other enzymes in the Embden-Meyerhof pathway
Associated with abnormalities of nucleotide metabolism
Haemoglobin defects
Thalassaemia syndrome
β-thalassaemia major
Hb-H disease
Others
Haemoglobinopathies
Sickle cell anaemia
Other abnormal haemoglobins (Hb-E, Hb-D, Hb-C, etc.)
Unstable haemoglobin disease
Others

Clinical Features

Clinical findings in a case of hereditary haemolytic anaemia include pallor, icterus (**Figure 1**), splenomegaly, haemolytic facies, ankle ulcer, pigment gall-stones, growth retardation, pathological fractures and various crises, e.g. aplastic crises due to B19 parvovirus and megaloblastic crises due to folic acid (FA) deficiency.

Figure 1: Icterus in a case of haemolytic anaemia.

Laboratory Investigations

Various laboratory investigations to be conducted for the diagnosis of hereditary haemolytic anaemias are presented in **Tables 3, 4 and 5** which can be divided into four groups as given below.

1. Those secondary to excessive red cell destruction, raised indirect serum bilirubin, increased urinary urobilinogen, decreased serum haptoglobin and haemopexin, increased serum lactic dehydrogenase, altered osmotic fragility, auto-haemolysis and shortened red cell survival as shown by chromium labelled studies.
2. Features of increased red cell production which are reticulocytosis, macrocytosis, erythroid hyperplasia of the marrow and radiological changes in the bones (skull and tubular bones).
3. Changes in red cell morphology (**Table 5**).
4. Features of intra-vascular haemolysis are haemoglobinaemia (**Figure 2**), haemoglobinuria (**Figure 3**), haemosiderinuria and methaemalbunaemia.

Table 3: Laboratory Evaluation of Red Blood Cells Production and Breakdown

Bone marrow production	↑ Reticulocyte count, ↑ BM cellularity, ^{59}Fe uptake
Red blood cell destruction	↓ Hb/PCV, ^{51}Cr RBC survival studies
Red blood cell sequestration	^{51}Cr RBC sequestration
Red blood cell breakdown	↓ Haptoglobin, ↑ bilirubin, ↑ LDH, haemoglobinaemia, methemalbumin, ↑ BM iron
Excretion	Haemosiderinuria, haemoglobinuria

BM = Bone marrow; Hb = Haemoglobin; PCV = Packed cell volume; RBC = Red blood cell; LDH = Lactate dehydrogenase.

Table 4: Urine and Serum Testing in Haemolysis

Pigment	Normal Range	Comments
Serum bilirubin	0.5 to 1.0 mg/dL	Limited significance, jaundice seen >3.0 mg/dL
Serum indirect bilirubin	<0.5 mg/dL	↑ in haemolysis, also in hereditary conjugation disorders (Crigler-Najjar syndrome, Gilbert syndrome)
Plasma haemoglobin	<10 mg/dL	Significant above 50 mg/dL, Cherry-red plasma > 150 mg/dL, binds to haptoglobin or albumin
Urine haemoglobin	Absent	Appears after haptoglobin saturation, haematuria and myoglobinuria must be excluded
Methaem albumin	Absent	Qualitative determination by electrophoresis or serum spectrophotometric measurement

Table 5: Morphological Changes in RBCs in Hereditary Haemolytic Disorders

Red Cell Abnormality	Major Diagnostic Possibilities
Permanently sickled cells	Sickle cell disease
Target cells*	Thalassaemia Hb-E, Hb-D, Hb-C disorders
Spherocytes*	Hereditary spherocytosis
Elliptocytes*	Hereditary elliptocytosis
Acanthocytes*	Hereditary acanthocytosis, Spur-cell anaemia
Basophilic stippling*	Pyrimidine 5'-nucleotidase deficiency, thalassaemia trait
Bite cells/ Blister cells	Hereditary non-spherocytic haemolytic anaemia, i.e. RBC enzymopathies (especially precipitated by drugs)

** These can also occur in various acquired conclitions which are not listed here.*

MEMBRANE DEFECTS

Hereditary Spherocytosis

Hereditary spherocytosis is the commonest hereditary haemolytic anaemias secondary to an erythrocyte membrane defect. It is due to defective structural protein (spectrin) of the red cell membrane. The greater the deficiency of spectrin, the more severe is haemolysis. There are different genetic lesions resulting in variable degree of haemolysis (**Table 6**). Hereditary spherocytosis is inherited as an autosomal dominant disorder but the phenotypic expression is variable. Very rarely, it is inherited as an autosomal recessive order.

Loss of membrane is also responsible for the spherical shape of the red cells (**Figure 4**). As the spherical cells are unable to pass through the splenic micro-circulation, these die prematurely.

Figure 2: Haemolysis showing pinkish *vs* normal plasma.

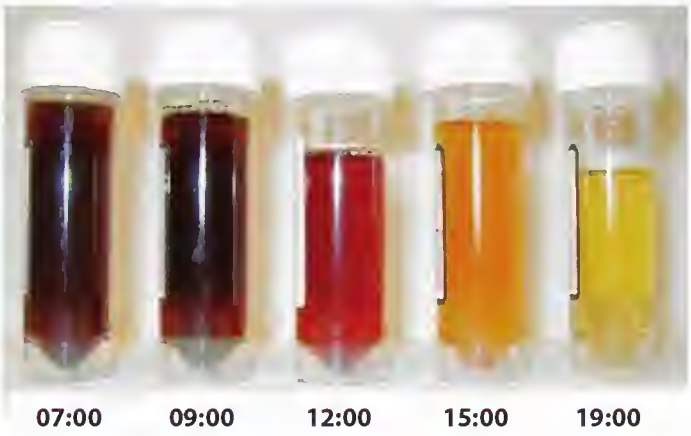

Figure 3: Haemoglobinuria.

Table 6: Heterogeneity of Hereditary Spherocytosis

Protein Defect	Haemolysis	Inheritance Pattern (Autosomal)	Frequency
Spectrin α-chain	Severe	Recessive	Rare
Spectrin β-chain	Mild-to-moderate	Dominant	Common (20 %)
Ankyrin defect	Mild-to-severe	Dominant	Common (60%)
Band 3 defect	Mild-to-moderate	Dominant	Common (20%)
Protein 4.1 defect	Mild	Dominant	Common in N. Africa
Protein 4.2 defect*	Moderate-to-severe	Recessive	Common in Japan

** = No response to splenectomy.*

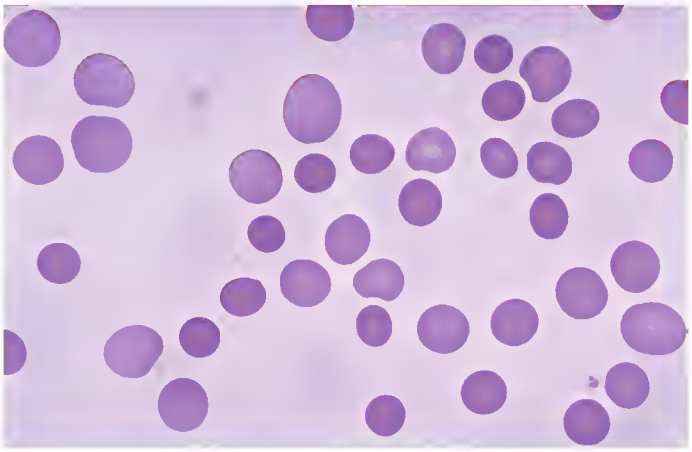

Figure 4: Hereditary spherocytosis.

Clinical Features

Clinical features include moderate anaemia, variable degree of jaundice and splenomegaly. Pigment gall-stones are common and parvovirus B19 induced aplastic crises may cause sudden increase in severity of anaemia. Multiple members from different generations of a given family may be affected. Occasionally, severity of anaemia tends to be different in different members of a given family. Reticulocyte count varies from 10% to 20%. Blood film invariably shows microspherocytes (small dense cells shown in **Figure 4**). Red cell osmotic fragility is increased (**Figure 5**). In some patients, one may need 24-hour incubation at 37°C in order to demonstrate increased osmotic fragility. Auto-haemolysis is increased and is correctable by glucose. Coombs test is negative and radio-labelled chromium studies reveal severity of haemolysis and the dominant role of spleen in the red cell destruction. The treatment is splenectomy which almost always normalises the haemoglobin, even though, microspherocytosis remains. As splenectomy in childhood increases the risk of life-threatening bacterial infections, it is avoided until the age of 5 years or more. Until then, FA should be given regularly. Pneumococcal vaccine is given prior to splenectomy and oral penicillin prophylaxis is given post-splenectomy to avoid sepsis due to encapsulated organisms. Mild cases do not need splenectomy unless gall-stones develop.

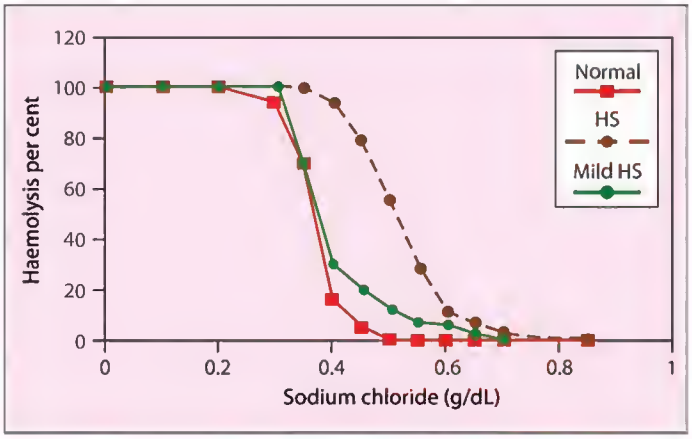

Figure 5: RBC osmotic fragility (Normal, hereditary spherocytosis and mild hereditary spherocytosis).

HS = Hereditary spherocytosis.

Hereditary Elliptocytosis (Ovalocytosis)

Hereditary elliptocytosis has clinical and laboratory features similar to that of hereditary spherocytosis except for the characteristic red cell morphology (**Figure 6**) and overall milder course. Majority of the patients can be left alone. Occasionally, splenectomy is required. Inheritance is autosomal dominant. Occasionally homozygous or doubly heterozygous cases of elliptocytosis may present with a more severe haemolytic anaemia called hereditary pyropoikilocytosis.

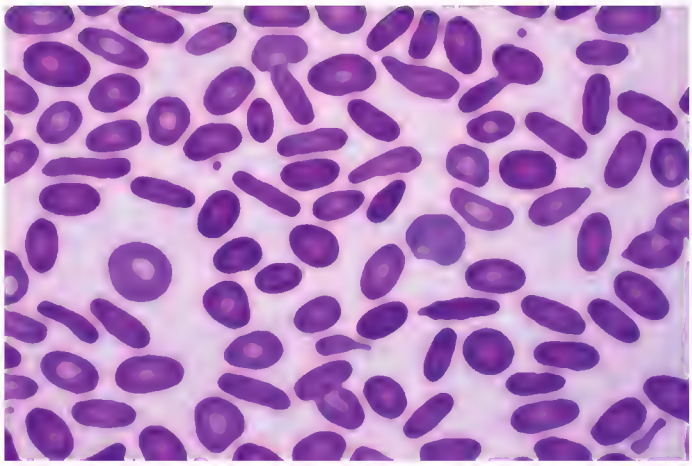

Figure 6: Hereditary elliptocytosis.

Hereditary stomatocytosis (**Figure 7**) and hereditary acanthocytosis (**Figure 8**) are rare RBC membrane disorders.

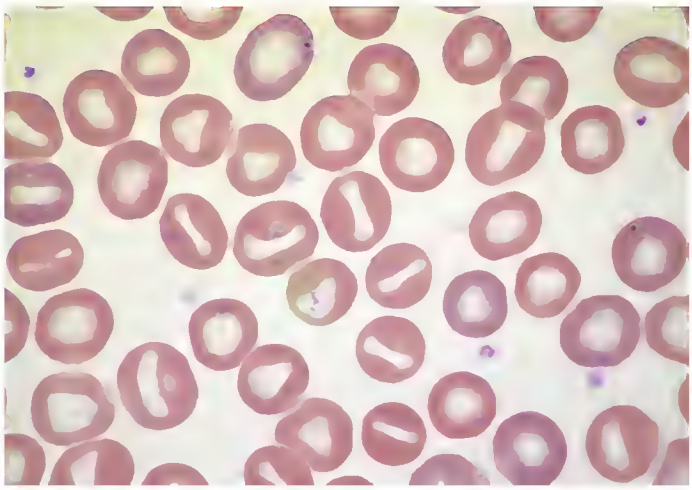

Figure 7: Hereditary stomatocytosis.

ENZYME DEFECTS

G6PD Deficiency

Glucose-6 phosphate dehydrogenase (G6PD) is an enzyme that functions to reduce nicotinamide adenine dinucleotide

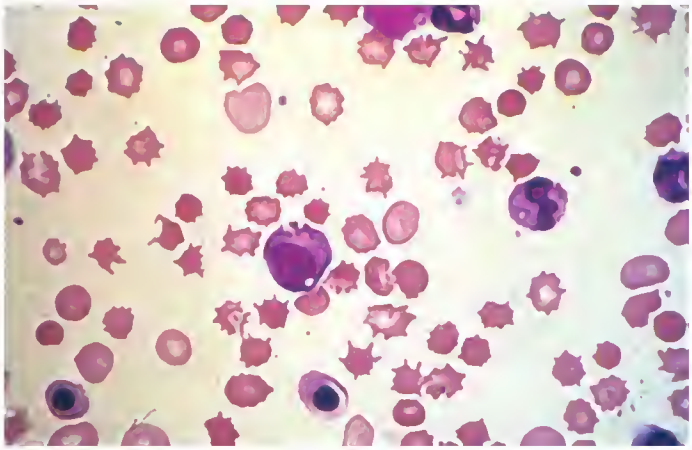

Figure 8: Hereditary acanthocytosis.

phosphate ($NADP^+$) while oxidising glucose-6 phosphate. Various genetic variants of G6PD are known (**Table 7**). The commonest of these are Type A in Africans and B in the rest of the world. In all, over 400 variants of the enzyme have been characterised which show less or more activity than normal. It has been estimated that over 200 million people are deficient in G6PD enzyme. Usually, G6PD deficiency is an asymptomatic entity. The main clinical problems are shown in **Table 8** and they are due to an acute haemolytic crises which occurs in response to an oxidant stress (drugs, infections or fava beans, **Figure 9**). Rarely, neonatal jaundice or even a congenital non-spherocytic haemolytic anaemia can occur.

Table 7: Common G6PD Variants

G6PD Variant	Haemolysis	Prevalence
G6PD A	No: Normal variant	Blacks
G6PD B	No: Normal variant	All
G6PD A-	Yes: Moderate	Blacks
G6PD ^{MED}	Yes: Severe	Whites

Figure 9: Fava beans.

The inheritance is sex-linked. Heterozygote female carriers have approximately half the normal red cell G6PD values and have an advantage of resistance to *Falciparum* malaria. Approximately 1% of Indian males are G6PD deficient. It is more common in Parsees (15%), Bhanushali (11%), Khatri (5%), Punjabi (3%), Kutchi (3%) and Muslims (2.5%). The worldwide distribution shows highest prevalence in the tropical zone chiefly West Africa, the Mediterranean, Middle East and South-East Asia. The deficiency is of variable degree. Most severely affected cases are seen in the Mediterranean countries and in orientals (**Table 7**). Rarely, severe cases also occur in Caucasians. The milder variants have mutations located at the amino-end of the gene, while the severe ones affect the carboxy-end.

Table 8: Clinical Features of G6PD Variants

Clinical Features	G6PD A	G6PD^{MED}
Drug-induced haemolysis	Common	Common
Infection-induced haemolysis	Common	Common
Favism	Non-seen	Common
Neonatal icterus	Rare	Observed
Hereditary non-spherocytic haemolytic anaemia	Not seen	Rare
Degree of anaemia	Moderate	Severe
Chronic haemolysis	Not seen	Rare

Acute haemolytic episodes have sudden onset of severe pallor, icterus and red-coloured urine. Patient may develop renal failure as well as symptoms of hypoxia. Usually, the episodes are self-limiting as the younger red cells have nearly normal G6PD activity. However, in Mediterranean type, the haemolysis may not be self-limiting. It may not be possible to make a definite diagnosis during the acute haemolysis. However, between the crises, the enzyme deficiency can be detected by one of the various screening tests or by direct enzyme assay of red cells. During crisis, the blood film may show contracted and fragmented cells, bite cells and blister cells. Reticulocyte preparation may show Heinz bodies (oxidised denatured haemoglobin, **Figure 10**), particularly if spleen has been removed.

The treatment includes stoppage of the offending drug (**Table 9**), blood transfusion, maintaining high urine output and if required, haemodialysis. If neonatal jaundice is severe, newborns may need phototherapy or even exchange transfusion.

Table 9: Drugs or Chemicals that Cause Haemolysis in Patients with G6PD Deficiency

- Analgesics
  - Acetanilide
- Antimalarials
  - Primaquine
  - Quinine
  - Chloroquine
- Fluoroquinolone
  - Norfloxacin
  - Ciprofloxacin
- Sulphonamides
  - Sulphacetamide
  - Sulphamethoxazole
  - Sulphanilamide
  - Sulphapyridine
  - Sulphasalazine
- Sulphones
  - Dapsone
  - Thiazole sulphone
- Miscellaneous
  - Acetylphenylhydrazine
  - Chloramphenicol
  - Doxorubicin
  - Methylene blue
  - Naldixic acid
  - Napthalene (moth-balls)
  - Niridazole
  - Phenylhydrazine
  - Toluidine blue
  - Trinitrotoluena
  - Vitamin K
  - Vitamin C
  - Nitrofurantoin

Other Red Cell Enzyme Deficiencies

These are listed in **Table 10**. These will not be discussed further because of their rarity.

HAEMOGLOBIN DISORDERS

Thalassaemia Syndrome

The thalassaemia syndrome consists of heterogenous group of inherited anaemias characterised by defective synthesis of one

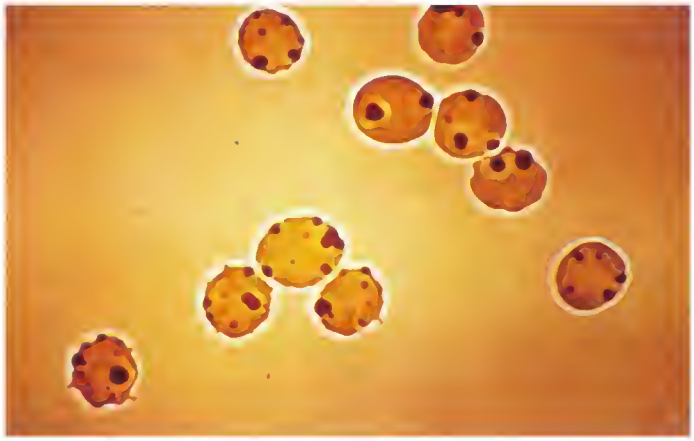

Figure 10: Heinz bodies in G6PD deficiency disorder.

Table 10: Hereditary Haemolytic Anaemias due to Rare Enzymopathies*

Associated with pentose-phosphate pathway deficiencies
Glutathione reductase
γ-glutamyl cysteine synthetase
Glutathione synthetase

Hexokinase
Glucose phosphate isomerase
Phosphofructokinase
Triose phosphate isomerase
Phosphoglycerate kinase aldolase
Associated with abnormalities of nucleotide metabolism
Adenylate kinase deficiency
Pyrimidine 5'-nucleotidase deficiency
Hyperactivity of adenosine deaminase

** Commonest of these is G6PD deficiency which is not listed here.*

or more of the globin-chain subunits of the Hb-tetramer. Taken as a group, the thalassaemia syndrome represents the most common gene disorder known to mankind. These are common in the tropical belt where *Falciparum* malaria has been endemic for Centuries (**Figure 11**). In some parts of the world, these constitute major public health problem. Thalassaemia is a Greek word which means 'the sea (water) in the blood'. Traditionally known as Cooley's anaemia, this disorder was first described in a child of Italian origin by Thomas Cooley, a paediatrician from Philadelphia. It is extremely frequent in the Mediterranean region specially amongst Italians and Greeks. Individual subtypes are named according to the nature of globin chain deficiency. β thalassaemia suggests deficiency of β globin chain, α thalassaemia suggests deficiency of α globin chain and so on. β° thalassaemia suggests total absence of β globin chain products while β^{+} thalassaemia suggests partial reduction. The genes for globin synthesis are located on chromosomes 11 and 16. The abnormalities at chromosomal level range from total deletion, rearrangement to point mutation and over 100 subtypes of molecular defects are known. The thalassaemia belt extends along the shores of the Mediterranean sea and throughout the Arabian Peninsula, Turkey, Iran, India and South-East Asia (**Figure 11**). Gene frequency ranges from 1% to 15%. In India, thalassaemia is prevalent in North-West region, i.e. Punjab, Gujarat, Maharashtra and Karnataka. It is also seen in Bengal and Assam but relatively less common in the Southern states. On an average, 3% of Indians carry the β thalassaemia gene. The highest incidence is found in Lohanas and Sindhis who have migrated from Sindh in Pakistan to many parts of India at the time of partition.

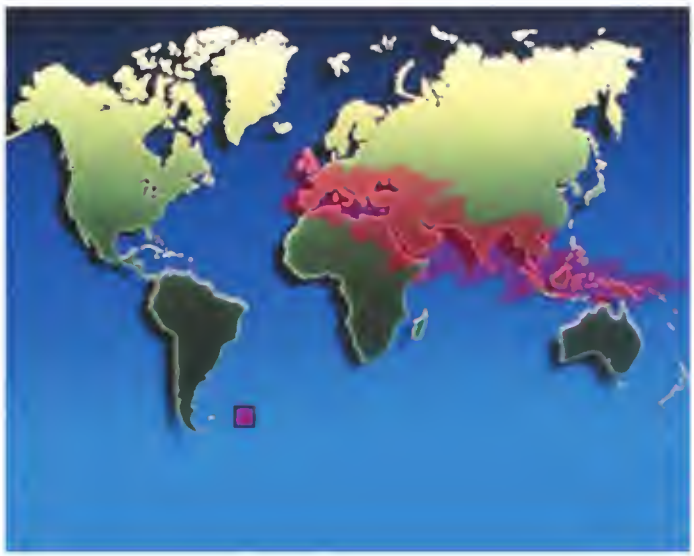

Figure 11: Geographical distribution of thalassaemia and haemoglobinopathies (Pink).

Clinically speaking, three common terms are used which connote the severity of disorder. These terms are thalassaemia major, intermedia and minor. Thalassaemia major is a severe disorder due to inheritance of two β thalassaemic genes (**Figure 12**). Child becomes anaemic within a few months of birth and the anaemia is so severe that regular transfusions are needed for survival. Thalassaemia minor, also known as thalassaemia trait or β thalassaemia heterozygous state is due to a single gene mutation together with a normal β globin gene on the other chromosome. It results in profound hypochromia and microcytosis despite minimal anaemia.

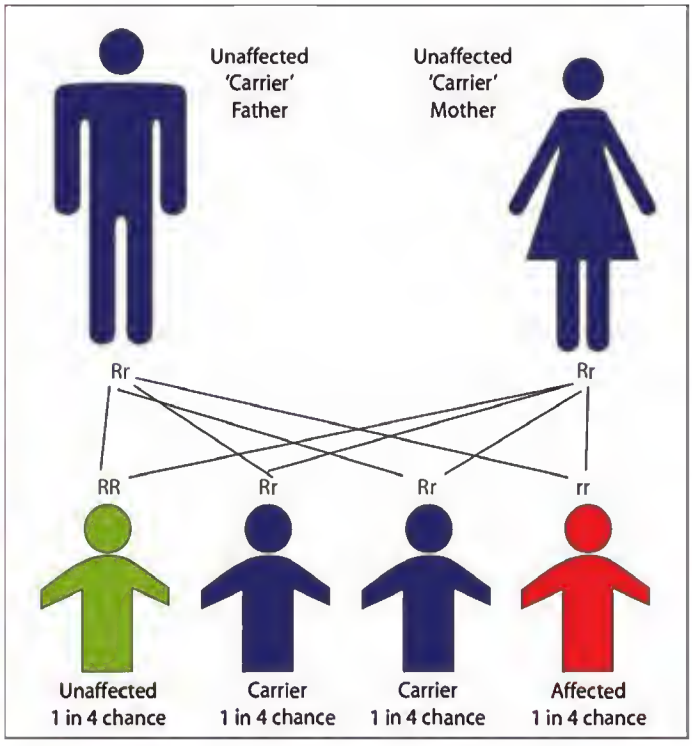

Figure 12: Inheritance of thalassaemia syndrome.

The term thalassaemia intermedia applies to a clinical phenotype where although patient is significantly anaemic, regular periodic blood transfusions are not a must for survival.

Pathophysiologically, the relative excess of the unpaired α globin chains that accumulate produce damage to the membrane of red cells leading to haemolysis. In addition, short-life of RBC precursors in the marrow results in ineffective erythropoiesis.

Clinical Features of Haemoglobin Disorders

Thalassaemia minor is often an incidental diagnosis. It does not produce many symptoms or signs as anaemia is not very significant. There are no overt signs of haemolysis or marrow expansion.

Patients with thalassaemia major develop profound anaemia within first few months of birth (anywhere from the age of 2 months to 2 years). This results in marked anorexia, failure to thrive, frequent infections and growth retardation. This also leads to production of high levels of erythropoietin which in turn causes extensive marrow expansion leading to characteristic chipmunk-facies due to frontal bossing and maxillary marrow hyperplasia. Enlarged spleen and liver lead to protuberant belly. Subsequently, patients develop massive splenomegaly, high output congestive cardiac failure, increased susceptibility to infection and even pathological fractures of long bones and vertebrae due to cortical invasion by erythroid element. Erythropoiesis may be so exuberant that masses of extra-medullary tissues may be formed in the paraspinal region, abdomen, pelvis and even in skull.

Patients of thalassaemia intermedia survive long enough without medication and develop above mentioned features to the maximum extent. Unless transfused, these patients go on to develop hypersplenism, profound increase in the blood requirement, non-healing leg ulcers and gall-stones.

Repeated transfusions in thalassaemia major and enhanced absorption of iron from the gut in thalassaemia intermedia, lead to iron overload with damage to heart, liver, pancreas and other endocrine organs including hypothalamus. Many patients die secondary to iron overload-related cardiomyopathy resulting in cardiac failure or arrhythmia. Absent or delayed puberty, retarded physical growth, diabetes mellitus, hypoparathyroidism and hypothyroidism are the other iron-related problems. Blood transfusions also lead to transmission of viruses and hence chronic liver disease secondary to hepatitis-C or B. Transmission of human immunodeficiency virus (HIV) infection may lead to acquired immune deficiency syndrome (AIDS). Development of RBCs allo-antibodies can lead to difficulty in transfusions.

With the development of modern hypertransfusion therapy and regular chelation, most of the clinical features mentioned above are largely preventable. Nonetheless, in India and many parts of the world, the clinical features mentioned above are common given the irregularity of blood transfusion and high cost of chelation therapy. An untreated child may succumb to anaemia itself during early childhood or even in infancy. Those who receive inadequate chelation, succumb between late second decade and early third decade of life. However, those receiving regular hypertransfusion and effective iron chelation can have near normal survival. Life expectancy and quality of life in thalassaemia minor do not differ from normal individuals. Thalassaemia intermedia on the other hand, has variable severity.

Investigations

Thalassaemia major leads to severe anaemia. Red cell morphology is strikingly abnormal with hypochromia, microcytosis, anisopoikilocytosis, tear drop cells and target cells. Nucleated red cells are abundant, however, reticulocyte count is low (2% to 8%). This is due to severe intra-medullary erythroid destruction. White blood cell count and platelet counts are normal unless hypersplenism develops. Marrow shows marked hypercellularity secondary to normoblastic hyperplasia. The osmotic fragility is significantly reduced, serum iron is increased and iron binding protein is fully saturated.

Normal haemoglobins in healthy adults are shown in **Table 11**. The haemoglobin profile in β° thalassaemia major reveals predominantly Hb-F which is nearly 100%. It may vary from 10% to 90% in β^+ thalassaemia. The red cell survival is diminished as seen with ^{55}Cr tagged studies. RBCs half-life ranges from 6 to 20 days. Radiological changes include striking changes in the skull and facial bones resulting in hot-cross-bun configuration of the skull, widened diploic spaces and the classic hair-on-end appearance. Compression fractures of the vertebrae and marked osteoporosis are common.

Table 11: Normal Haemoglobins in Adults

Haemoglobin Type	Globin Chains	Percentage
Hb-A	$\alpha_2\beta_2$	>95
Hb-A2	$\alpha_2\delta_2$	<3.5
Hb-F	$\alpha_2\gamma_2$	<2.0

Thalassaemia minor is a hypochromic microcytic anaemia where red cell volume distribution width (RDW) is normal and RBC counts are on higher side. Peripheral blood film, besides hypochromia and microcytosis shows target cells (**Figure 13**) and basophilic stippling (**Figure 14**). High performance liquid chromatography (HPLC) and Hb-electrophoresis shows increased HbA_2, usually 3.6% to 7.8%. α thalassaemia (Hb-H) is relatively less common in India. Hb-H disease has clinical features of thalassaemia intermedia. It is characterised by presence of a fast moving Hb-H on electrophoresis and inclusion bodies in red cells as shown in **Figure 15**.

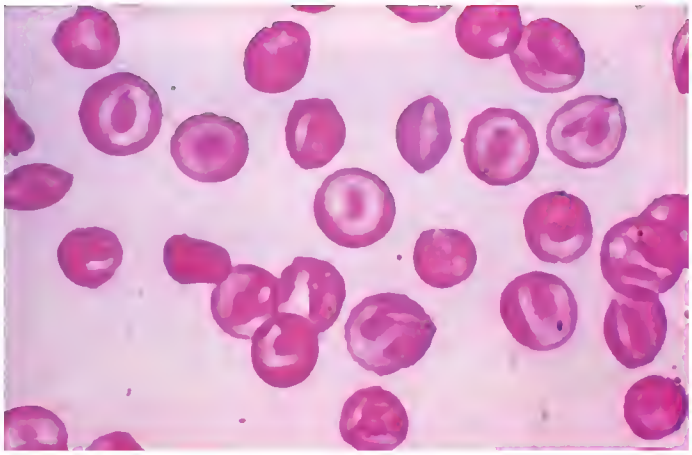

Figure 13: Target cells.

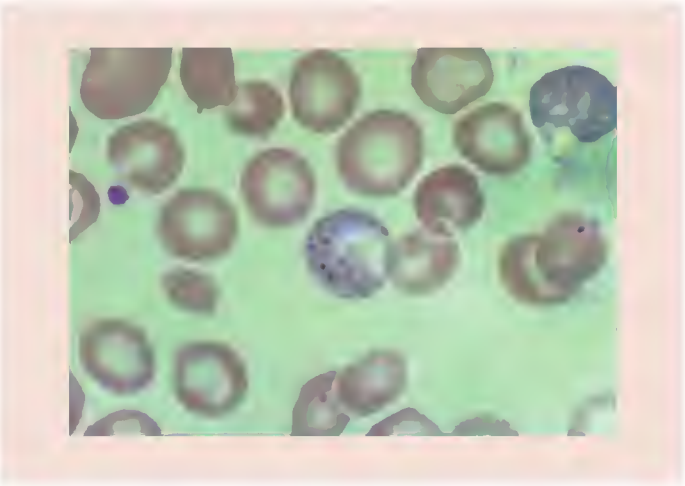

Figure 14: Basophilic stippling.

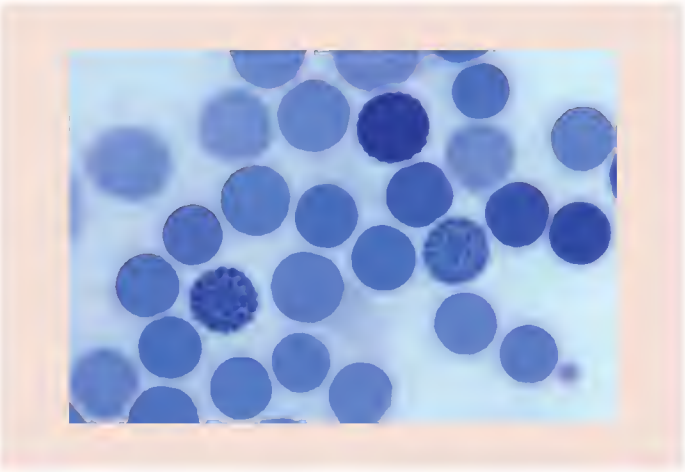

Figure 15: Inclusion bodies in a case of Hb-H disease (α thalassaemia).

Treatment

β thalassaemia major requires treatment with regular transfusions so as to maintain haemoglobin between 10 and 14 g/dL. This relieves symptoms and allows normal growth and development. However, this leads to iron overload (which is inevitable), transmission of viruses (hepatitis-B, hepatitis-C and HIV) and development of RBCs allo-antibodies. Without adequate iron chelation, such patients die during second or third decade of life due to cirrhosis of liver, endocrinopathies (specially diabetes mellitus) and cardiomyopathy. Deferoxamine given subcutaneously using an infusion pump over 8 to 10 hours a day, 5 days a week forms the standard chelation. The dose of deferoxamine is 30-50 mg/kg body weight. This has to be started once 15-20 units of blood transfusions have been given and is continued life-long. It is more effective in removing iron from liver.

Two oral iron chelators already in clinical use are: Deferiprone and Deferasirox. Deferiprone has been around for 2 decades and is superior to deferoxamine in chelating iron from the heart. It is given in the dose of 75 mg/kg per day in divided doses (usually thrice a day). Combination of deferoxamine and deferiprone has also been extensively used. Deferasirox has been recently introduced and it is given in the dose of 20-40 mg/kg per day once daily. It is whole body iron chelator and has slowly replaced the earlier compounds.

Bone marrow transplantation is an alternative. This can cure thalassaemia major provided an human leucocyte antigen-matched donor is available. Umbilical cord stem cell transplantation is another option. Alternative forms of therapy like manipulation of globin gene expression using butyrate and gene therapy are at a research stage.

Thalassaemia minor requires no treatment except genetic counselling, avoidance of inappropriate iron therapy and close monitoring during pregnancy.

Thalassaemia intermedia are most difficult form of thalassaemia to manage. Most of the patients need careful judgment regarding need of blood transfusion, iron chelation and splenectomy. Very often, the problems are complex and decisions controversial.

Prevention is possible through prenatal diagnosis. Using polymerase chain reactin (PCR) amplification of the globin gene, prenatal diagnosis can be carried out on chorionic villous sample or amniotic fluid. Sampling is done around 10th week of pregnancy and diagnosis is available within 3 to 7 days. Pre-implantation diagnosis has also been successful.

SICKLE CELL DISEASE

Sickle cell disease (SCD) is another group of hereditary haemoglobin disorder characterised by transformation of red cells into sickle shape on deoxygenation, it is produced due to single point mutation (**Figures 16 and 17**). The abnormal haemoglobin, Hb-S results from substitution of valine for glutamic acid at the 6th position of the β chain. The SCD includes sickle cell anaemia (homozygous Hb-S disease), sickle cell/β-thalassaemia, sickle cell /Hb-C disease and others. This disorder was first reported in USA in 1910 by James Herric. Typical manifestations of the disease were known to the Africans for Centuries.

Like thalassaemia, the world distribution of sickle cell gene parallels that of *Falciparum* malaria. Eight per cent of American blacks carry the gene for sickle cell trait. The SCD is inherited in an autosomal co-dominant manner.

The pathophysiology of SCD is related to the intra-cellular polymerisation of Hb-S and to the abnormal interaction that sickle erythrocytes have with the vascular endothelium. This process results in anaemia, vaso-occlusive episodes, organ damage and increased susceptibility to infection.

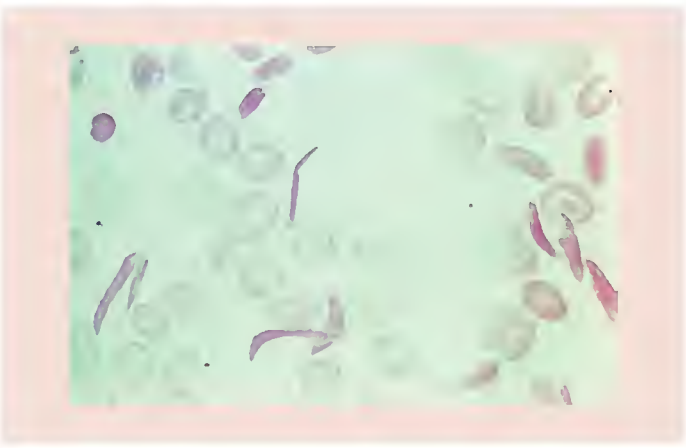

Figure 16: Sickle cells.

Figure 17: Sickle cells (Electron-microscope).

Clinical Manifestations

These include anaemia, pain, infection and damage to organ system. The whole picture is so variable that almost any symptom or sign could form a presenting feature of SCD. Ultimately, these are all related to haemolytic anaemia and vascular occlusion which in turn causes pain, organ dysfunction and organ failure. Growth failure and psycho-social problems are common. Splenic infarcts result in auto-splenectomy leading to frequent life-threatening episodes of septicaemia. Patients suffer from aplastic crisis, splenic sequestration crisis, vascular occlusion and infectious complications. Organ failure particularly related to heart and kidney are more often noted in adults while cerebral complications due to vaso-occlusion (strokes) are more often seen in children. Mortality of this disease is 10% to 20% in the first decade of life. Certain patients with SCD have very mild course or no problems at all. This is often due to the presence of high amount of Hb-F which interferes with polymerisation. The same situation can be seen if gene for a thalassaemia or hereditary persistence of Hb-F is co-inherited.

Painful crisis

Vaso-occlusion leading to pain is the commonest cause of debilitation in Hb-S disease. Acute onset of pain is referred to as a 'crisis'. Many children develop 'hand-foot' syndrome. It can also affect chest, abdomen and long bones especially in the juxta-articular position. This pain may last for 2 to 6 days.

Anaemia

Essentially a haemolytic process, anaemia of SCD can be correlated with intra-cellular polymer content. Infections especially parvovirus B19 can lead to profound drop in haemoglobin by producing red cell aplasia. This is called 'aplastic crisis' and is usually self-limited.

Another crisis known as 'megaloblastic crisis' is due to inadequate folate levels in the body. FA requirement is higher in haemolytic anaemia and this factor is responsible for severe anaemia in patients who are nutritionally weak. Haemolytic crises (rapidly accelerated haemolysis) can occur, especially, if patient has associated G6PD deficiency.

Splenic sequestration crisis is usually seen under the age of 2 years. The spleen rapidly enlarges (within hours) and most of the circulating red cell mass becomes sequestrated. This can recur and hence if severe, splenectomy is indicated. Milder cases can be managed with blood transfusions and careful observation.

Infections

Several abnormalities make these patients immune-compromised. Absent splenic function leads to infections with the encapsulated organisms, e.g. *Streptococcus pneumoniae* and *Haemophilus influenzae*. Pneumococcal infections can result in death within hours. Other immunological abnormalities are less well defined. Elderly patients are prone to get gram-negative infections due to *Escherichia coli* affecting urinary tract and this can even go into septicaemia. Osteomyelitis is common and besides *Staphylococcus aureus, Salmonella typhimurium* are the other common organisms. This is due to ability of these bacteria to flourish in partially necrosed bone.

Complications Affecting Organ Systems

Cardiovascular system

Anaemia leading to myocardial ischaemia, vaso-occlusive phenomenon causing myocardial infarction and repeated blood transfusions leading to restrictive cardiomyopathy secondary to iron overload can all occur in SCD.

Pulmonary system

Pulmonary manifestations are due to vaso-occlusion, infections or both. A typical clinical presentation called "acute chest syndrome" consists of sudden onset of chest pain and a local infiltrate on the chest radiograph which can be either due to infection or infarction. This affects 30% of patients and it can be life-threatening.

Central nervous system

Neurologic complications affect 25% of patients. These include transient ischaemic attacks, strokes and cerebral haemorrhage. Strokes are common in the first decade of life while haemorrhages occur in adults. Treatment includes red cell transfusion which may continue until the age of 5 years. This is to keep haemoglobin-S percentage below 30%. However, chronic transfusion therapy has its own hazards.

Hepato-biliary system

Gall-stones, recurrent abdominal pain due to vaso-occlusive crisis, hepatomegaly and hepatic dysfunction are all common. Like splenic sequestration crisis, patients may get hepatic sequestration crises as well.

Reproductive system

Placental infarcts can lead to intra-uterine growth retardation and low birth-weight babies. The frequency of spontaneous abortion is increased. Prophylactic transfusions do not help.

Urinary system

Kidney is a major target organ. Haematuria, hyposthenuria, abnormal acid load test, increased urinary tract infection,

hyperuricaemia and gout are all common. Renal failure is common in the elderly.

Ocular complications

Retina is an important vulnerable target for sickling. Proliferative retinopathy is commonly seen in SCD.

Orthopaedic

Besides hand-foot syndrome, patients can develop avascular necrosis of the hip. Osteomyelitis has been discussed earlier. Skin ulcers around the ankle may develop.

Treatment

This can be divided into 3 stages. General care, management of specific complications which include management of infections, blood transfusions, pain management and the newer therapeutic modalities.

General care

This includes treatment to relieve pain, prevention of dehydration, treatment of fever and psycho-social support. Dietary advice includes adequate calorie intake, adequate folic acid, vitamin-C, vitamin-E and zinc supplement.

Management of specific complications

Infections: These include prophylactic penicillin, immunisation to prevent infections and evaluation and treatment of the febrile episodes.

Pneumococcal vaccination at the age of 18 months followed by boosters every 5 years are recommended. Immunisation against *H. influenzae* is suggested by the age of 18 months. *Hepatitis-B* vaccination is also a must.

Transfusions: Transfusions are associated with 3 important problems, e.g. transmission of viral diseases, iron overload and allo-immunisation. Although, these can be used to treat each and every complications of SCD, their value has been demonstrated for only a few of them. Chronic transfusion therapy has been used with a reasoning that suppression of Hb-S would lead to decreased vaso-occlusive episodes. Even exchange-transfusions have been carried out.

Pain: This is the most frequent requirement of a patient with SCD. The guidelines include aggressive use of appropriate analgesics, ensuring fluid supplement and looking for the aetiology, especially the cause of infection.

Newer therapeutic modalities

Many chemical agents have been developed which may act as anti-sickling agents. None of them have been of any great therapeutic benefit. The most promising agent is hydroxyurea which has the ability to induce foetal haemoglobin synthesis. This has become the standard-of-care today. It decreases the number of vaso-occlusive episodes. The usual dose is 20 mg/kg per day. Extensive research, both in adults and children, has shown very satisfactory results with respect to marked freedom from painful crises, preservation of organ function and projected increase in the life-span. The drug is contraindicated during pregnancy. Co-administration of other haematopoietic agents, such as erythropoietin or butyric acid may also be useful.

Bone marrow transplantation has been carried out in patients with a total cure rate of 70% to 80%. However, only 35% of patients would have immunologically compatible donors and one must also consider the risk-benefit issue. Gene therapy may become applicable to SCD.

Prenatal diagnosis by chorionic villous biopsy is possible. Unfortunately, DNA analysis does not predict the clinical severity and many do not consider SCD as a serious enough problem for pregnancy to be terminated.

HAEMOGLOBIN-E DISORDERS

A mutation producing an amino-acid substitution β26Gu → Lys in haemoglobin molecule produces Hb-E. This mutation can be present in heterozygous, homozygous and Hb-E-β thalassaemia compound form. It is the commonest hereditary haemoglobin disorder in the eastern parts of India (Bengal and Assam). The Hb-E is characterised by mild anaemia even in homozygous individuals. However, HbE-β thalassaemia (double heterozygous state) produces severe manifestations like severe anaemia, splenomegaly and jaundice.

15.7 Acquired Haemolytic Anaemia

Farah F Jijina

INTRODUCTION

Haemolytic anaemias may be congenital or acquired. Acquired haemolytic anaemias are generally due to extra-corpuscular (extrinsic) defects, the only exception being paroxysmal nocturnal haemoglobinuria, where the defect is intrinsic. Common clinical features of acquired haemolytic anaemia are a rapid fall of haemoglobin and increased reticulocyte counts in the absence of bleeding, repeated attacks of jaundice with unconjugated hyperbilirubinaemia, dark urine due to oxidation of urobilinogen or haemoglobinuria and splenomegaly. Features of chronic haemolysis, such as gall-stones, skeletal changes, leg ulcers, or moderate or massive splenomegaly are mainly seen in inherited haemolytic anaemia, but may be seen in acquired haemolytic anaemia if it is long standing. **Table 1** gives a simple classification of the common acquired haemolytic anaemias. For immune haemolytic anaemia, any precipitating cause should be removed and steroids or other immunosuppressives may be required. For the non-immune haemolytic anaemias, an urgent correction for treatable causes like malaria or toxic chemicals may be life-saving.

AUTOIMMUNE HAEMOLYTIC ANAEMIA (AIHA)

AIHA occurs when a patient produces pathologic antibodies that attach to, and destroy red blood cells (RBCs), causing anaemia. These are classified into two types, according to the temperature at which the antibodies are active as: (a) warm active antibodies, and (b) cold active antibodies. Occasional patients may have both types of antibodies (**Table 2**).

Warm Active Antibodies

Auto-antibodies with the greatest activity at 37°C are responsible for 70% patients of AIHA. It may be idiopathic or secondary to an underlying disorder. A small subgroup of patients with idiopathic AIHA may also develop immune thrombocytopaenia. This condition is known as Evan's syndrome and is usually associated with a higher incidence of an underlying illness, such as systemic lupus erythematosus (SLE). Many disorders may be associated with warm AIHA (**Table 3**).

Table 2: Autoimmune Haemolytic Anaemias

- Multiple myeloma
- Thymoma
- Waldenström macroglobulinaemia
- Teratoma
- Acquired immunodeficiency syndrome
- Drugs: Methyldopa

Pathophysiology

The antibody is usually an immunoglobulin (Ig) antibody which may or may not fix complement. It is a pan-agglutinin and reacts with the red cell Rh antigen complex. The red cells coated with the Ig are then removed from the circulation by the spleen or portions of the cell membrane may be snagged by the macrophages, the remainder of the cell escaping and resealing to produce a spherocyte.

Clinical features

The clinical presentation may vary from mild to fulminant haemolysis. Idiopathic AIHA, can occur at any age, has no racial predilection and is more common in females.

Laboratory investigations

The classical feature on peripheral smear is the presence of microspherocytes. Other non-specific features of haemolytic anaemia, such as polychromasia, macrocytosis and nucleated red cells are also present. Occasionally erythrophagocytosis and agglutination may be seen. A persistently raised reticulocyte count is a typical finding in warm AIHA, but reticulocytopaenia may be rarely seen. Possible mechanisms for reticulocytopaenia include marrow shutdown from intervening infection, malignancy, parvovirus B19 infection, depleted vitamin B12/folic acid (FA) stores, or the autoantibody being directed at antigens on the reticulocytes.

Direct anti-globulin test (also called Coombs' test)

The direct antiglobulin test (DAT) is used to determine if red cells have been coated *in vivo* with Ig, complement, or both (**Figure 1**). A positive test demonstrates *in vivo* attachment of antibodies to red cells. It is positive in 95% of warm AIHA.

Indirect anti-globulin test (or indirect Coombs' test)

In indirect Coombs' test, patient's serum suspected of containing an antibody is incubated with normal red cells, which are then washed to remove unbound globulins. Agglutination that occurs when anti-human gammaglobulin is added indicates that autoantibody was present in the patient's serum. The indirect anti-globulin test is positive in 80% of patients of warm AIHA.

Coombs' negative AIHA

In 2% to 6% of patients, who present with clinical and haematological features of AIHA, may have a negative test for

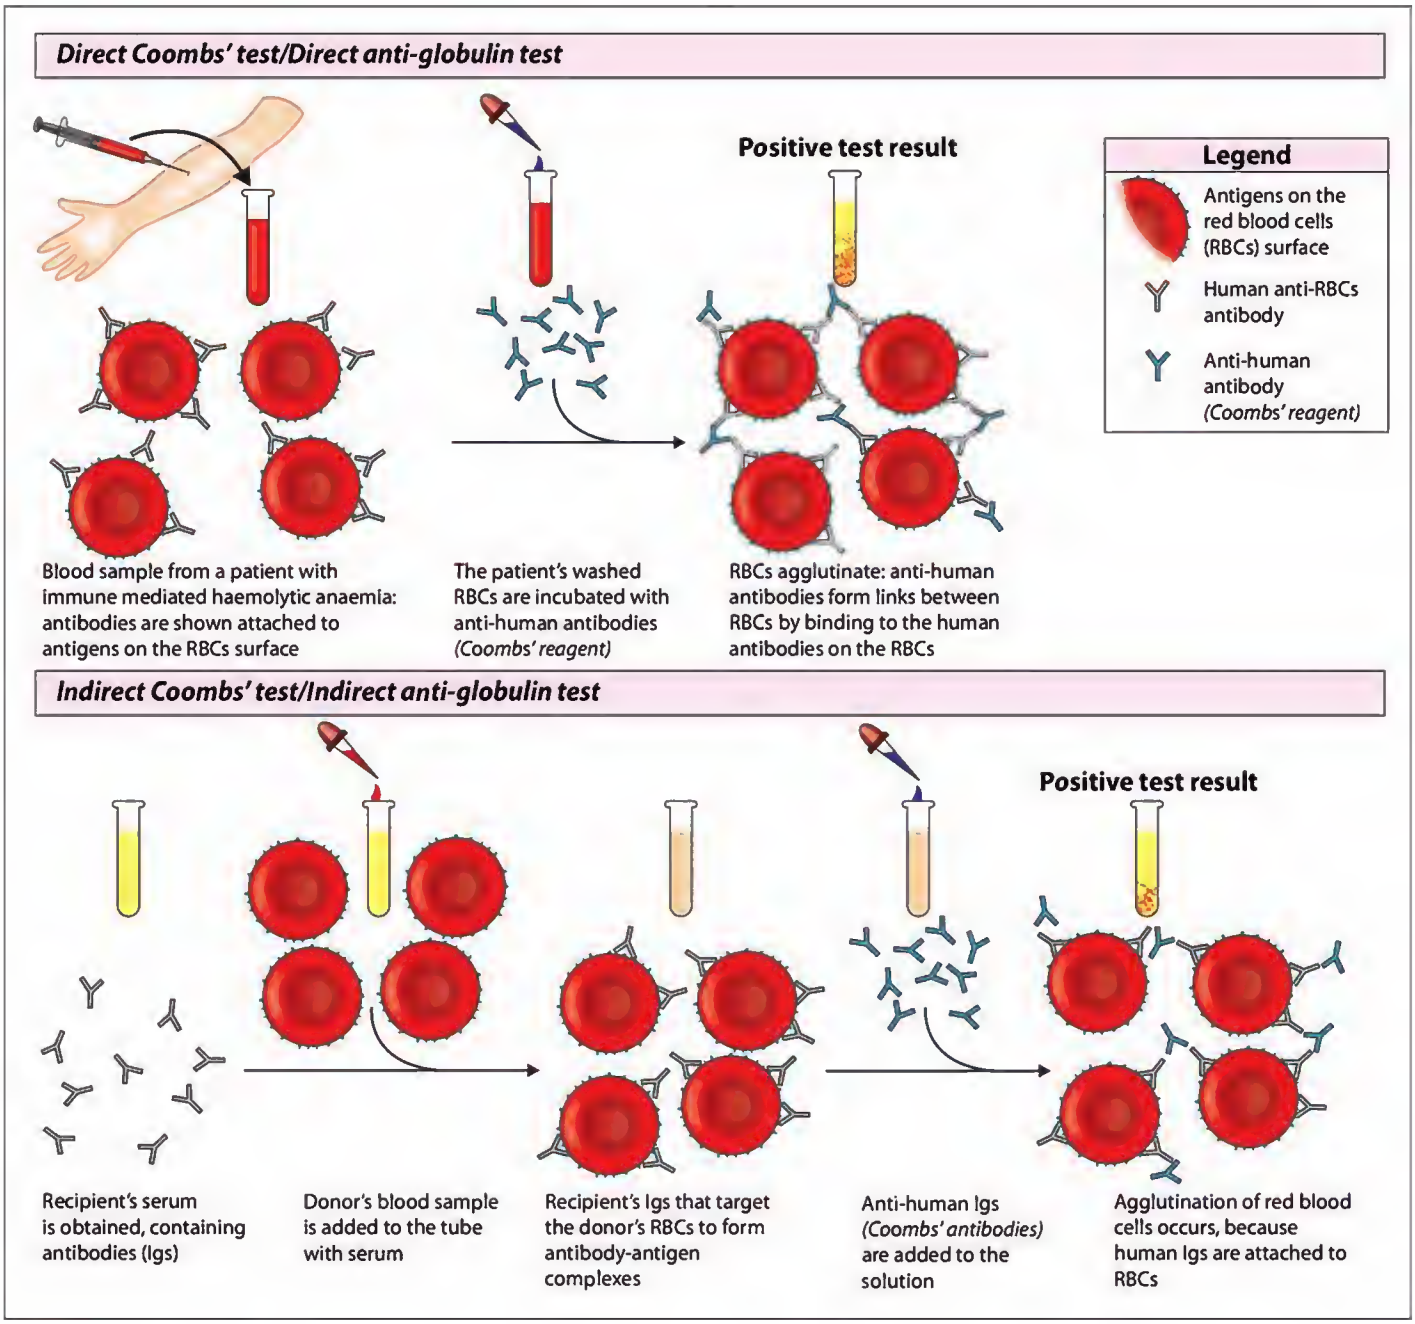

Figure 1: Direct and indirect Coombs' test.

technical reasons, presence of IgA autoantibodies or low affinity IgG autoantibodies.

Treatment

All patients of haemolytic anaemia need to be on FA supplements. In idiopathic warm AIHA, the initial treatment of choice is steroids, usually prednisolone, 1-1.5 mg/kg per day for a period of 4 to 6 weeks, followed by a gradual reduction. A response is seen within 7 days in 80% of patients, though patients often relapse on reducing the dose. Thus, only about 20% to 30% of treated patients achieve sustained complete remission. If there has been no response after 3 weeks of therapy, patient may be considered a steroid treatment failure.

Spleen is the major site of RBC sequestration and destruction and is also believed to be a major producer of IgG antibodies. Indications for splenectomy in AIHA include failure to respond to steroids or steroid dependency. About 50% to 60% of patients will respond to splenectomy; late relapses may occur.

Rituximab is a genetically engineered chimeric murine/human monoclonal anti-CD-20 antibody which targets B-cell precursors and mature B-cells. It is often used as second line therapy after steroid failure, especially when splenectomy is not possible. Rituximab has induced complete remissions in 30% to 50% patients with refractory warm AIHA. Other therapies include immunosuppressive drugs, such as azathioprine, cyclophosphamide and cyclosporine. Danazol may be useful.

Cold Active Antibodies

There are two clinical syndromes.

1. ***Cold agglutinin disease***

   This is caused by a pathologic IgM antibody directed against the red cell I antigen, is usually seen in adults and can be primary or secondary. Cold agglutinins usually attach to the red cell in the cooler peripheral circulation. As the blood proceeds back to the warmer central circulation, the antibody dissociates from the cell only to attack another unsuspecting red cell and begin the process again.

   The primary cold agglutinin disease occurs in older patients around 70 years of age. It is caused by a monoclonal IgM kappa antibody. Secondary cold agglutinin disease occurs in patients with Waldenström's macroglobulinaemia or other B-cell neoplasms and may also be seen in young patients after *Mycoplasma pneumoniae* or infectious mononucleosis. Most patients will present with features of a mild chronic haemolytic anaemia, with exacerbations in winter. Acrocyanosis can occur due to agglutinin of cells in the cooler vessels of the hands, nose, ears and feet. Few patients may have a mild hepatosplenomegaly. The peripheral smear shows agglutinin of red cells and rarely spherocytes.

   Treatment: Most patients with primary cold agglutinin disease do not require any specific treatment apart from avoiding cold temperatures. In severe cases, immunosuppressive therapy with cyclophosphamide or chlorambucil may be tried. Steroids are usually ineffective.

   Secondary cold agglutinin disease associated with infections, the course is transient and requires only supportive therapy (**Table 4**). For cold agglutinin disease associated with malignancy, effective treatment with chemotherapy is required.

2. ***Paroxysmal cold haemoglobinuria***

   In paroxysmal cold haemoglobinuria an antibody binds to the red cell at low temperature and fixes complement. When the cells are warmed, the complement cascade binds and disrupts the red cell membrane producing lysis. Patients may have a dramatic presentation with sudden onset of fever, back leg pain and haemoglobinuria after any exposure to cold. The episodes are generally self-limited. Attacks may be associated with measles, vaccinations, mumps, *M. pneumoniae*, influenza, cytomegalovirus (CMV) infections.

Table 4: Common Causes of Secondary Cold Agglutinin Disease

Neoplasms	Infections
Lymphomas	*Mycoplasma pneumoniae*
Waldenström macroglobulinaemia	Epstein-Barr virus
Chronic lymphocytic leukaemia	Cytomegalovirus
Kaposi's sarcoma	Adenovirus
Myeloma	Encephalitis
Non-haematological malignancies	Influenza viruses
	Rubella
	Varicella
	Human immunodeficiency virus (HIV)
	Mumps
Others	*Escherichia coli*
	Bacterial endocarditis
Autoimmune diseases	Syphilis
	Malaria

Drug and Chemical Induced Haemolytic Anaemia

Haemolytic anaemia may develop as a result of exposure to a variety of chemicals and drugs. There are two general mechanisms by which drugs and chemicals bring about haemolysis. The drug or chemical may directly interfere with the metabolic process of the red cell, e.g. G6PD deficiency. These aspects are covered in inherited haemolytic anaemia. Other agents can bring about oxidative denaturation of haemoglobin, leading to sequential formation of methaemoglobin, sulphaemoglobin and Heinz bodies. Certain chemicals and drugs like copper can produce haemolytic anaemia by non-oxidant mechanisms.

Drugs can also cause an immune reaction. Antibodies are formed against the drug and the red cells become damaged as a result of the drug antibody interaction or the presence of the drug may facilitate the development of red cell auto-antibodies. The most common drugs implicated now are cefotetan, ceftriaxone, and piperacillin (**Table 5**).

Haemolytic Anaemia Caused by Animal Venoms

Haemolysis may be caused by the venom of snakes, bees, wasps and spiders; however, most of these are rare. Snake venom, especially of the viper and cobra haemolyse red cells *in vitro*.

Haemolytic Anaemia Caused by Infections

Red cells may appear to be injured directly by various infections. Of these the commonest in our country is malaria. Most of the haemolytic manifestations of malaria are related to the invasion

of the erythrocyte by the organism, leading to destruction of the red cells. However, some cases of *Plasmodium falciparum* infections, may develop an acute intravascular haemolysis due to an autoimmune reaction.

Other infections that lead to haemolytic anaemia are infections by protozoa *Babesia*, trypanosomiasis, and visceral leishmaniasis. Profound fatal haemolytic anaemia can occur in clostridial sepsis with severe intravascular erythrocyte destruction.

Table 5: Drugs and Chemicals Causing Haemolytic Anaemia

Drugs and chemicals causing haemolytic anaemia by direct toxicity

- Acetylphenylhydrazine
- Arsine
- Chloramines
- Copper
- Formaldehyde
- Naphthalene
- Para-aminosalicylic acid
- Phenacetin
- Phenazopyridine
- Phenylhydrazine
- Potassium chlorate
- Resorcinol
- Sodium chlorate
- Sulphanilamide
- Sulphapyridine
- Sulphasalazine
- Sulphones

Drugs and chemicals causing haemolytic anaemia in G6PD deficiency

Analgesics
- Acetanilide

Antimalarials
- Pamaquin
- Pentaquine
- Primaquine

Nitrofurans
- Nitrofurantoin

Sulphonamides

Dapsone

Miscellaneous
- Acetylphenylhydrazine
- Methylene blue
- Nalidixic acid
- Naphthalene balls
- Phenylhydrazine
- Toluidine blue
- Trinitrotoluene

Drugs and chemicals causing haemolytic anaemia by immune mechanism

- Amidopyrine
- Cephalosporins
- Chlorpromazine
- Chlorpropamide
- Cisplatin
- Dipyrone teniposide
- Methyldopa
- Penicillin
- Piperacillin
- Quinine
- Rifampicin
- Sulphasalazine
- Stibophen
- Sulphonamides
- Teniposide
- Tetracycline

PAROXYSMAL NOCTURNAL HAEMOGLOBINURIA

Paroxysmal nocturnal haemoglobinuria (PNH) is an acquired disorder brought about by a somatic mutation of the PIG – A gene situated on the X chromosome. Normal red cells are protected against complement-mediated lysis by a protein called the membrane inhibitor of reactive lysis or CD59. PNH cells are deficient in this protein.

Clinical Manifestations

The disease, usually begins insidiously, has a prolonged course and can vary from the mild to very severe. The classical presentation is characterised by attacks of intra-vascular haemolysis and nocturnal haemoglobinuria along with other symptoms of chronic haemolysis, leucopaenia and thrombocytopaenia. Haemoglobinuria is seen in 80% of PNH patients at sometime during the course of their illness and is classically nocturnal but the cause of the nocturnal occurrence is not well understood. It is hypothesised that retention of carbon dioxide in sleep causes a slight fall in plasma pH sufficient to activate the alternate pathway of complement. Exacerbations of haemolysis may be precipitated by infections or inflammations. Other features are aplastic anaemia, and intra-vascular thrombosis, especially at unusual sites in the venous circulation. The diagnosis of PNH was made in the past, by a positive Ham's acidified serum lysis test and a sucrose lysis test. However, now with the availability of monoclonal antibodies and flow cytometry, red cells and granulocytes are analysed, using monoclonal antibodies to the GPI-anchored proteins CD55 (DAF) and CD59 and these are absent in PNH cells. The latest test, not routinely available, is the fluorescein-labelled proaerolysin variant, 5-fluorescent *aer*olysin (FLAER) test.

Treatment

Most patients of classical haemolytic PNH are treated with prednisolone 1 mg/kg per day for a period of 2 to 4 weeks, to control the haemolysis. Steroids are gradually tapered depending on the response of the patient. Danazol can also be effective in some patients and is often used along with steroids. Supportive therapy is important, including the replacement of iron and FA, and the administration of red blood cell transfusions if clinically required. The latest treatment consists of eculizumab (a monoclonal antibody against complement component C5) which is very effective in controlling haemolytic episodes of classical PNH. It has been shown to decrease the need for transfusions, decrease paroxysms, decrease thrombotic complications and improve quality of life in patients with classical PNH. The disease has a median survival of 10 to 15 years. Major cause of morbidity and mortality is due to thrombosis, bleeding and infections. Haematopoietic stem cell transplantation is the only definitive treatment for PNH. Due to the inherent morbidity and mortality of transplantation, it is only indicated in severe cases of PNH, such as those with thrombotic episodes, severe haemolysis and aplastic PNH. The overall cure rates are about 50%.

RED CELL FRAGMENTATION SYNDROMES

In certain disorders, red cells may undergo premature fragmentation and lysis leading to significant intra-vascular haemolysis. These may be divided into two major groups:

1. Macroangiopathic haemolytic anaemia associated with abnormalities of the heart and great vessels. In this condition, turbulence over narrow vessels or prosthesis valves causes intra-vascular haemolysis.
2. Microangiopathic haemolytic anaemia (MAHA) develops either as a result of diffuse deposition of fibrin in the micro-vasculature or when the vessels become narrow, rough and rigid. The classical example is thrombotic thrombocytopaenic purpura (TTP). In TTP there is MAHA, thrombocytopaenia, neurologic abnormalities, renal abnormalities and fever. The haemolytic uraemic syndrome is a disorder closely related to TTP but is localised mainly to the vascular endothelium of the kidneys. The mainstay of the treatment of this symptom complex is plasma exchange and response is variable. Other modalities of treatment such as steroids, aspirin, immunosuppressive agents, and vincristine have been tried, but their efficacy is unclear (**Tables 6 and 7**).

Table 6: Causes of Macro-Angiopathic Haemolytic Anaemias

Valvular prosthesis: Synthetic, homografts, xenografts
Valvoplasties
Valvular disease
Intra-cardiac patch repairs
Coarctation of aorta

Table 7: Causes of Micro-Angiopathic Haemolytic Anaemias

Disseminated intra-vascular coagulation
Disseminated malignancies
Chemotherapy
Malignant hypertension
Vasculitis: systemic lupus erythematosus, polyarteritis nodosa
Thrombotic thrombocytopaenic purpura
Haemolytic uraemic syndrome
Giant haemangioma
Drugs like cyclosporin
HELLP syndrome

Haemolytic anaemias are a group of diverse disorders which may be hereditary or acquired. Another differentiating features to be decided is whether there is intra-vascular/extra-vascular haemolysis. History and examination of peripheral smear are very important supplemented by a battery of other tests to establish the diagnosis.

Once the diagnosis is established the treatment of precipitating factors, supportive treatment and therapy with steroids and immunosuppressive may be instituted.

15.8 Aplastic Anaemia

Dharma R Choudhary, Tuphan Kanti Dolai

INTRODUCTION

Aplastic anaemia (AA) is defined as the presence of pancytopaenia with hypocellular marrow in which normal haemopoietic marrow is replaced by fat cells. AA is a life-threatening bone marrow failure disorder, if untreated, is associated with very high mortality.

EPIDEMIOLOGY

In Europe and USA, the incidence is about 2 to 3 per million of the population per year. It is 2- to 3-fold more common in Asia than in Europe. AA has been identified as a disease of the young and shows a biphasic age distribution between 15 and 25 years or after the age of 60 years, with a trough in middle life. It is commoner in males.

DEFINITION

Aplastic anaemia is defined as pancytopaenia with a hypocellular bone marrow without infiltration or fibrosis. To diagnose AA at least two of the following must be present: (i) haemoglobin less than 10 g/dL, (ii) platelet count less than 50,000/μL, and (iii) neutrophil count less than 1,500/μL (International Agranulocytosis and Aplastic Anaemia Study Group, 1987).

AETIOLOGY

Aetiologic classification of AA is shown in **Table 1**.

Table 1: Aetiologic Classification of Aplastic Anaemia

Hereditary
- Fanconi's anaemia
- Dyskeratosis congenita
- Shwachman-Diamond syndrome
- Other rare syndromes: reticular dysgenesis, etc.

Acquired
- Idiopathic
- Drugs
  - Cytotoxic drugs used in cancer chemotherapy, chloramphenicol phenylbutazone, indomethacin, diclofenac, chloroquine, ticlopidine, gold, hydantoins, etc.
- Paroxysmal nocturnal haemoglobinuria (PNH)
- Toxins: benzene, chlorinated hydrocarbons, organophosphates
- Viruses: Epstein-Barr virus (EBv), non-A, non-B, non-C, non-E hepatitis virus, human immunodeficiency virus
- Connective tissue disorders: eosinophilic fasciitis, immune thyroid disease, rheumatoid arthritis, systemic lupus erythematosus.
- Pregnancy
- Iatrogenic: radiation, cytotoxic drug therapy.

PATHOGENESIS

The pathogenesis of AA remains unclear, but an immune-mediated mechanism appears to be important. There is debate about whether the primary defect is in the haemopoietic stem cell itself or is the result of environmental factors, particularly immunological attack, on the cell. There is evidence of both quantitative and qualitative stem cell defects in AA and increased apoptosis of remaining early haemopoietic progenitor cells (HPC). Not only do cytotoxic suppressor T-lymphocytes release cytokines, such as interferon-gamma (IFN-γ) and tumour necrosis factor-alpha (TNF-α), those are inhibitory to HPC, but TNF-α also upregulates Fas antigen expression on CD34+ cells, which may be one of the possible mechanisms for the reduced survival of AA marrow progenitor cells. However, the most persuasive evidence for the autoimmune pathogenesis for AA remains the clinical response to anti-lymphocyte globulin (ALG) in about two-thirds of patients.

Telomere shortening is also seen in some patients with acquired AA. These patients show increased terminal restriction fragments (TRF) loss in leucocytes compared with age-matched controls, and the extent of the loss correlates with the duration of the disease. Mutations in the genes for telomerase, telomerase ribonucleic acid (RNA) gene and telomerase reverse transcriptase (TERT) have also been described in patients of AA.

CLINICAL PRESENTATION

AA patients seek medical attention for symptoms that occur as a result of low blood counts. Symptomatic anaemia results from the decrease in red cells, bleeding symptoms secondary to thrombocytopaenia and infections result from neutropaenia.

Physical examination is generally unremarkable, except for evidence of anaemia, cutaneous or mucosal bleeds. Lymphadenopathy and splenomegaly are not the features of AA; such findings suggest an alternative diagnosis, such as leukaemia or lymphoma.

DIAGNOSIS

Investigations for the diagnosis of AA are presented in **Table 2**. Patients with AA have varying degrees of pancytopaenia. The reticulocyte count is usually less than 1.0% despite high levels of erythropoietin. Marrow aspiration and biopsy are essential to confirm the diagnosis of AA. Marrow aspirate typically contains numerous spicules with empty, fat-filled spaces and relatively few haematopoietic cells with prominence of lymphocytes, plasma cells, macrophages, and mast cells with paucity of myeloid precursor and megakaryocytes. Marrow biopsy is essential to confirm the overall hypocellularity. The assessment of disease severity is important in treatment decisions and has prognostic significance. The severity of the disease is graded according to the blood counts and bone marrow findings as summarised in **Table 3**.

DIFFERENTIAL DIAGNOSIS OF PANCYTOPAENIA

Any disease that can present with pancytopaenia may mimic AA, if only the blood counts are considered. Differential diagnosis of pancytopaenia with hypocellular bone marrow is shown in **Table 4**.

Table 2: Investigations Required for the Diagnosis of Aplastic Anaemia

Full blood count, reticulocyte count
Blood film examination
Hb-F% in children
Bone marrow aspirates and trephine biopsy, including cytogenetics
Stress cytogenetics to exclude Fanconi's anaemia, if the age is <35 years
Ham test and/or flow cytometry for phosphatidylinositol glycan (PIG)-anchored proteins (CD55 and CD59) from red blood cells or granulocyte
Urine haemosiderin if Ham test positive or PIG-anchored protein deficiency
Vitamin B12 and folate level
Liver function tests
Viral studies: hepatitis A, B, C; Epstein-Barr virus; cytomegalovirus; human immunodeficiency virus
Anti-nuclear antibody and anti-dsDNA
Chest radiograph
Abdominal ultrasound
Direct and indirect Coomb's test to rule out immune cytopaenia

Table 3: Definition of Severity of Aplastic Anaemia (AA)

Severe AA (Camitta *et al*, 1976)
Bone marrow cellularity <25%, or 25% to 50% with <30% residual haemopoietic cells
Two out of three of the following
Neutrophils <500/μL
Platelets <20,000/μL
Reticulocytes <20,000/μL
Very severe AA (Bacigalupo *et al*, 1988)
As for severe AA but neutrophils <200/μL

Table 4: Differential Diagnosis of Pancytopaenia with Hypocellular Bone Marrow

Inherited and acquired aplastic anaemia
Hypocellular myelodysplasia syndromes
Rare aleukaemic leukaemia (acute myelogenous leukaemia)
Some acute lymphoblastic leukaemias
Some lymphomas of bone marrow
PNH
Myelofibrosis
Systemic lupus erythematosus
Hairy cell leukaemia
T-cell large granular lymphocyte disease
Tuberculosis, histoplasmosis, HIV, EBV
Drugs or toxin

TREATMENT

Supportive Care

AA should be considered a medical emergency. Many patients die due to grave consequences of severe pancytopaenia. AA can be cured by immunosuppressive therapy and by bone marrow transplantation. Androgens and haematopoietic growth factors have secondary roles, other modalities are discussed as under:

1. ***Transfusion support***

   Support with red cell and platelet transfusions is essential for patients with AA to maintain a safe blood count. Blood products from close relatives (who share histocompatability antigens) should be avoided. In the presence of bleeding manifestations, platelets to be transfused irrespective of platelet count. It is recommended to give prophylactic platelet transfusions when the platelet count is less than 10,000/μL (or <20,000/μL in the presence of fever).

2. ***Haemopoietic growth factors***

   There are currently no effective and safe haemopoietic growth factors to support red cells and platelets in patients with AA. A short course of subcutaneous granulocyte colony stimulating factor (G-CSF) at a dose of 5 μg/kg per day may be considered for severe systemic infections not responding to intravenous antimicrobials. G-CSF should be stopped, if there is no response by one week.

3. ***Prevention of infection***

   The risk of infection is determined by the severity of AA. Patients with AA are at risk of bacterial and fungal infections. *Aspergillus* infections have a very high mortality in patients with severe aplastic anaemia (SAA) because of the frequent prolonged periods of severe neutropaenia.

   Most important are measures directed toward increasing general hygiene. Oro-dental hygiene is important, and sources of infection should be treated appropriately. Routine rectal examinations should be avoided. Patients with a high-risk of infection should be managed in isolation. Prophylactic antimicrobials especially in very SAA are given to help in preventing infections.

4. ***Treatment of infection***

   As for all neutropaenic patients, fever may require immediate hospitalisation and treatment before the results of bacterial investigations are available. The duration of neutropaenia, the patient's infection history and recent antibiotics influence the antibiotic choice including the early introduction of antifungal therapy. Persistent fever should be investigated aggressively with high resolution computed tomography of the chest for fungal infections.

Immunosuppressive Therapy

Anti-thymocyte globulin (ATG) and cyclosporine (CSA)

Combining ATG and CSA has considerably improved upon ATG alone. The combination of horse-ATG and CSA is current standard therapy in SAA who do not have human leucocyte antigen (HLA) matched donor.

1. *Indications:* Immunosuppressive therapy is indicated for patients who are not eligible for sibling donor bone marrow transplantation. This includes: (i) patients with transfusion dependent non-SAA, (ii) patients with SAA or very SAA who are more than 30 to 45 years of age, and (iii) patients with severe or very severe disease who lack an HLA-compatible sibling donor.
2. *Criteria for response to immunosuppressive therapy:* Response to immunosuppressive therapy is categorised as complete, partial or no response. The response criteria are summarised in **Table 5**.

   Responses should be confirmed by two or more blood counts at least 4 weeks apart. The median time to response in most of studies is about 12 weeks. The overall response rate at 3 months in patients receiving ATG and CSA is between 60% and 80%.

Table 5: Criteria for Response to Immunosuppressive Therapy in Aplastic Anaemia

	Response Criteria for SAA	Response Criteria for Non-SAA
None	Still severe	Worse or not meeting criteria below
Partial	Transfusion independent No longer meeting criteria for severe disease	Transfusion independence (if previously dependent) or doubling or normalisation of at least one cell line or increase in baseline haemoglobin of >3 g/dL (if initially <6 g/dL) neutrophils of >500/μL (if initially <500/μL platelets of >20,000/μL (if initially <20,000/μL)
Complete	Haemoglobin normal Neutrophils >1,500/μL Platelets >1.5 lacs/μL	Same criteria as for severe disease

SAA = Severe aplastic anaemia.

3. *Administration:* The ATG is a pan-antilymphocyte immunoglobulin composed of purified animal polyclonal antibodies directed against human lymphocytes. Infections, haemorrhages, and fever are not an absolute contraindication for treatment with ATG. ATG is given as a daily intravenous infusion over 6 to 8 hours. The dose is 40 mg/kg per day for 4 days for horse-ATG. The dose is 3.75 mg/kg per day for 5 days for rabbit-ATG. A test dose must be given before hand to look for severe systemic reaction or anaphylaxis. Each daily dose should be preceded by methylprednisolone. Platelet transfusions should be given to maintain a safe platelet count (ideally >30,000/μL), but should not be given concurrently with ATG administration because of the antiplatelet activity of ATG. The patient should be nursed in isolation with reverse barrier nursing. On the 5th day of ATG, prednisolone at 1 mg/kg per day is commenced to help prevent serum sickness and continued for 9 days then withdrawn over the next 5 days. Serum sickness typically occurs between day 7 and 14 from the start of ATG treatment. Oral CSA should be commenced on the last day of prednisolone (day +14) at 5 mg/kg per day, aiming to keep the trough CSA blood level between 150 and 250 μg/L for adults and between 100 and 150 μg/L for children.

4. *Results of treatment:* The combination of ATG and CSA remains the currently recommended immunosuppressive regimen for both SAA and transfusion-dependent non-severe AA (NSAA). Immunosuppressive therapy using the combination of ATG and CSA is associated with response rate of between 60% and 80% with current 5-year survival rate of around 75%. Response to ATG and CSA is delayed and response usually does not start much before 3 months. Relapse (30%) may occur after immunosuppressive therapy. For the one-third of patients who are refractory to h-ATG/CSA, repeated courses of immunosuppression have yielded response rate varying from 30% to 70%. Re-treatment with ATG/CSA in relapsed AA has resulted in response rate of 50% to 60%.

5. *CSA dependence and relapse:* CSA dependency is observed in 26% to 62% of patients, necessitating long-term maintenance of the drug. Current immunosuppressive therapy regimens including CSA dose of 5 mg/kg per day and that should be taper very slow for at least 1 year, to minimise the risk of relapse.

   After long-term follow-up some patients with AA may proceed to frank paroxysmal nocturnal haemoglobinuria (PNH), acute leukaemia and myelodysplasia (MDS). The overall risk of developing a clonal cytogenetic abnormality/MDS at 10 years is between 5% and 20%. The risk of relapse is around 30%. Relapse can be successfully rescued by an additional course of ATG.

Other immunosuppressive drugs

1. *Androgens:* Useful androgens include nandrolone decanoate, oxymetholone, danazol and stanazolol. Nandrolone decanoate administered at 400 mg intramuscularly per week is one approach. Oxymetholone (2 mg/kg per day) has been used extensively in the treatment of AA for many decades before the availability of ATG and CSA. A study from Chandigarh reported that stanazolol (1 mg/kg per day) is ineffective for SAA and very SAA in children and it induced remission in 38% of NSAA patients. In a prospective clinical trial 16 patients of AA (12 males and 4 females; 6 severe cases and 10 moderate cases) were treated with 300 mg of danazol daily for 12 weeks. All patients completed the treatment period without occurrence of severe toxicity. Three female patients achieved partial remission, whereas only 2 of the 12 male patients did so. None of the responders had shown a response to previous immunosuppressive therapy. These findings indicate that danazol is effective for a subset of AA patients, and particularly for female patients with AA refractory to immunosuppressive therapy.

   The mechanism of action by which male hormones improve haematopoietic failure states remains unclear. The haemoglobin response frequently is more impressive than improvements in granulocyte or platelet levels. Androgens, if used, should be continued for at least 3 to 6 months because responses may require prolonged treatment. Hepatotoxicity is common side-effect with androgen.

2. *Other immunosuppressive agents:* Corticosteroids have no role in the treatment of AA. The use of high dose cyclophosphamide (45 mg/kg per day for 4 days) without stem cell support is also not recommended. Other immunosuppressive agents currently under investigation include an anti-IL-2 receptor monoclonal antibody (daclizumab), mycophenolate mofetil (MMF; CellCept), FK506, and rapamycin, etc.

Bone Marrow Transplantation

HLA-identical sibling donor transplantation

Patients with severe AA, if they are less than 40 years old and have an HLA compatible sibling, should be transplanted up front. The conditioning regimen used for patients aged less than 30 years is a non-myeloablative, highly immunosuppressive regimen to help prevent graft rejection, and graft-*versus*-host disease (GvHD). Transplantation for SAA from an HLA-identical sibling donor is now very successful

with a 75% to 90% chance of long-term cure. The incidence of graft rejection has fallen from more than 30% to around 5% to 10%. GvHD remains a problem: the probability of acute GvHD grade II-IV is 18 ± 3% and chronic GvHD of any grade is 26 ± 5%. Bone marrow is preferred source of stem cells as compared to mobilised peripheral blood stem cells (PBSCs) with less incidence of chronic GvHD.

There is a significant risk of late graft failure in AA following allogeneic bone marrow transplant, which is most commonly associated with discontinuing CSA too early or low CSA blood levels. Therapeutic CSA should be continued for at least 9 months before gradually reducing the dose to zero over the following 3 months.

Matched unrelated donor (MUD)

Bone marrow transplantation may be considered when patients fulfill all the following criteria. They should have a fully matched (at DNA level for both class I and II antigens) donor, less than 40 years old, failed at least two courses of ATG and CSA and for children, at least one course, SAA, and no evidence of active infection and or acute bleeding at time of bone marrow transplant.

The long-term survival of MUD bone marrow transplant around 30% with a high incidence of graft rejection, GvHD and severe infections.

Umbilical cord blood transplantation from matched sibling donors and unrelated donor will be one of the treatment options in future.

Summary of treatment for patients with AA is shown in **Table 6**.

Table 6: Summary of Treatment in Patients with Aplastic Anaemia

Age Less than 20 years		Age 20 to 40 years		Age More than 40 years	
Sibling Donor	**No Sibling Donor**	**Sibling Donor**	**No Sibling Donor**	**Sibling Donor**	**No Sibling Donor**
First line treatment					
BMT	ATG + CSA	BMT	ATG + CSA	ATG + CSA	ATG + CSA
Second line treatment					
ATG + CSA	2nd ATG + CSA MUD transplant CB transplant	ATG + CSA	2nd ATG + CSA, MUD transplant	BMT	2nd ATG + CSA, MUD transplant

BMT = Bone marrow transplant; ATG = Anti-thymocyte globulin; CSA = Cyclosporine; MUD = Matched unrelated donor; CB = Cord blood.

MANAGEMENT OF APLASTIC ANAEMIA IN PREGNANCY

Aplastic anaemia can present in pregnancy by chance, but other possible causes need exclusion. The disease may remit spontaneously after termination or after delivery. The disease may progress or relapse during pregnancy. Around 40% cases might relapse during pregnancy. Supportive care is the mainstay of treatment in pregnancy and the platelet count should be maintained more than 20,000/μL. CSA can be used safely during pregnancy.

PROGNOSIS

Course of AA is extremely variable. The one-year mortality for patients with SAA treated with transfusion only was more than 80%. In SAA patients treated only with androgens, mortality was 58% at 2 years, 60% at 5 years and 65% at 12 years. Some patients with drug-induced AA might spontaneously recover cytopaenies within 2 weeks. Without treatment most of the SAA and very SAA patients will die in the first 6 months of the diagnosis. Main causes of morbidity and mortality are bleeding and infections before and during treatment. Bone marrow transplantation is curative for approximately 80% of patients younger than 20 years, approximately 70% of patients aged 20 to 40 years. Combined immunosuppressive therapy with ATG and CSA leads to marked improvement in at least 70% of the patients. The disease may progress over 10 years to PNH, a MDS, or AML in as many as 40% of patients who initially responded to immunosuppressive therapy.

INDIAN PERSPECTIVE

In resource poor countries due to high cost of treatment for AA algorithm for the treatment of AA is not universal. Many patients can afford best supportive treatment only (blood product supports and anti-infective therapy). The options of androgen therapy [stanazolol (menabol) and oxymethalone (anapolom)] should be given to the patients who cannot afford transplant/ immunosuppressive therapy. The response rate for androgen therapy is approximately 5% to 10%. Those who respond require life-long androgen therapy and require monitoring particularly for hepatotoxicity of the drug. Cyclosporine as a single agent can be used as immunosuppressive therapy and response in the tune of 10% to 30% can be achieved, especially in moderately SAA.

ATG is available in different preparations (ATGAM, thymoglobulin and thymogam) in India and results of 50% to 70% can be achieved when it is used with cyclosporine.

The options of allogenic bone marrow transplantation should be offered to all eligible patients since it is the only curative treatment. The cost of allogenic bone marrow transplantation is approximately Rs 8 to 10 lakhs at most of the centres.

15.9 Acute Leukaemia

SH Advani

INTRODUCTION

Leukaemias are abnormal proliferation of lymphoid or myeloid, immature cells of haematopoietic system, which are characterised by aberrant or arrested differentiation leukaemic cells rapidly accumulate in the bone marrow cavity, ultimately replacing most of the normal haematopoietic cells with blast cells. The signs and symptoms are commonly as a result of bone marrow failure manifesting as anaemia, haemorrhage and infection.

DEFINITION

Acute leukaemias (ALs) are defined as a malignant clonal proliferation of lymphoid or myeloid precursor cell of unknown aetiology, leading to replacement of normal haematopoiesis by blast cells comprising 20% or more of bone marrow cells and infiltration of lymph nodes, spleen, liver or other organs. For therapeutic purposes, ALs are broadly classified as acute lymphoid leukaemia (ALL) or acute myeloid leukaemia (AML).

INCIDENCE

The incidence in the West varies from 1.3 to 2.5 per 100,000 persons per year. Roughly 75% of acute leukaemia (AL) cases occur in adults. The male to female ratio is 1.3:1. The ratio in children to adults is 4:1 for ALL and 1:6 for AML. ALL has its peak incidence at less than 10 years age while AML usually occurs at a mean age of 65 years.

AETIOLOGY

The exact aetiology of AL is not known. The risk of AL is increased as a result of atomic bomb exposure. However, in majority of the cases, no single cause can be pinpointed. Genetic disorders predisposing to leukaemia include ataxia telangiectasia, Bloom's, syndrome, Down's syndrome, Klinefelter syndrome, Fanconi's anaemia and Wiskott-Aldrich syndrome, Turner's syndrome, neurofibromatosis, severe combined immuno-deficiency and Li-Fraumeni syndrome (P53 deletion). Exposure to drugs like alkylating agents, nitrosoureas and epipodophyllotoxins have also been incriminated in the pathogenesis of ALs. Environmental factors include benzene, aromatic hydrocarbons (AMLs) and ionising radiations (AML, ALL). Retroviruses have been implicated in adult T-cell lymphoma (HTLV-I) in Japan and Africa. Epstein-Barr virus (EBV) has been associated with AL. The role of high-tension voltage and microwaves is only recently being evaluated; they probably are responsible for the clustering of cases seen in closed communities. Pre-leukaemia precedes AML in as many as 25% of cases. Five per cent of Hodgkin's disease patients treated with chemotherapy and radiotherapy develop secondary AL with a peak incidence at 6 years after the treatment.

CLINICAL PRESENTATION

AL presents with a short history of a few days to months (**Table 1**). They reflect expansion of the leukaemic cells at the cost of normal cells. Pallor, easy fatiguability and dyspnoea are due to anaemia. Thrombocytopaenia causes bleeding, especially purpura and easy bruising on dependent and traumatised areas. Granulocytopaenia results in increased incidence of infection, especially of the skin, gums, perianal region, lungs and urinary tract. The symptoms occur not only because of replacement of marrow by the malignant cells but also due to feedback inhibition of normal cells, altered micro-environment and saturation of stromal niche sites. However, non-leukaemic cells remain intact as is evident from the normal repopulation of marrow space following cytotoxic chemotherapy. Infiltration of leukaemic cells into other organs leads to hepatosplenomegaly, lymphadenopathy, mediastinal masses, chloromas or granulocytic sarcomas (soft tissue masses). Central nervous system (CNS) involvement may present with headache, vomiting, papilloedema and convulsions. Testicular involvement presents with a mass lesion or pain. The expanded cell mass is directly responsible for bone pains and sternal tenderness. Overt bleeding due to disseminated intravascular coagulation (DIC) is a common feature of acute promyelocytic leukaemia (AML-M3). It may be aggravated or precipitated by the initiation of therapy. Gum hypertrophy and leukaemia cutis are characteristic of acute monocytic leukaemia (AML-M4/M5).

Table 1: Diagnosis and Evaluation of Acute Leukaemia

Symptoms
- Fatigue, malaise, dyspnoea
- Fever, weight loss, petechiae, purpura
- Bone pains or abdominal pain
- Easy bruisability, gum bleeding, epistaxis, melaena

Signs
- Anaemia and pallor
- Thrombocytopaenia, ecchymosis, purpura, mucosal bleeding
- Fever, infections: (respiratory tract infection, perirectal abscess)
- Gum hypertrophy, lymphadenopathy, hepatosplenomegaly

Investigations
- Complete blood count including peripheral blood smear examination
- Liver function tests, renal function test, serum electrolytes, calcium, phosphorus, uric acid, lactate dehydrogenase
- Chest radiography for mediastinal adenopathy, chest infection
- Bone marrow aspiration (morphology, cytochemistry, immuno-phenotyping and cytogenetic studies, molecular studies)
- Cerebrospinal fluid examination for central nervous system involvement

INVESTIGATIONS

Total white blood cell (WBC) counts can be as high as 100,000/mm^3 or more. However, it is normal or low in nearly one-half of the cases. Haemoglobin level and platelet count are usually decreased at presentation. Bone marrow examination is essential for the diagnosis, and also to confirm complete remission and relapse following treatment. In addition to morphological evaluation, the cells are also subject to

cytochemistry, electron microscopy, immunophenotyping, cytogenetics and molecular studies. Rapid turnover of cells causes elevated serum lactate dehydrogenase, uric acid and alkaline phosphatase. Coagulation tests may show evidence of DIC, especially in AML-M3. Cerebrospinal fluid (CSF) examination is mandatory in all patients of ALL to evaluate CNS involvement at presentation and follow-up. If therapy is commenced without adequate precautions like hydration, allopurinol and diuresis then tumour lysis syndrome may be precipitated; this is characterised by hyperkalaemia, lactic acidosis, and hyperphosphataemia. Radiograph of the chest may show a mediastinal mass in T-cell ALL.

DIFFERENTIAL DIAGNOSIS

Differential diagnosis of AL includes other neoplastic haematopoietic diseases like lymphomas, myelodysplastic syndrome (MDS) and multiple myeloma. Other haematological disorders, like aplastic anaemia, severe megaloblastic anaemia (due to folate or B12 deficiency), viral infections (like EBV), disseminated tuberculosis, or myelophthisic anaemia (infiltration of bone marrow by other carcinoma) can present with similar picture. Careful morphologic examination and immunophenotype of the cells will exclude all other haematopoietic malignant disorders.

CLASSIFICATION

Morphology

The French-American-British (FAB) classification for AL is shown in **Tables 2 and 3**. For AML, the FAB classification was widely used. However, the new World Health Organization (WHO) classification is now gaining acceptance (**Table 4**).

Table 4: WHO Classification of Acute Myeloid Leukaemia (AML)

I. AML with recurrent cytogenetic translocations
- AML with t(8;21) (q22;q22) AML1/CBF alpha/ETO
- Acute promyelocytic leukaemia
- AML with t(15;17) (q22;q12) and variants PML/RAR alpha
- AML with abnormal bone marrow eosinophils inv (16) (p13;q22) t (16;16) (p13;q22) CBF beta/MYH1
- AML with 11q23 MLL abnormalities

II. AML with multilineage dysplasia
- With prior MDS
- Without prior MDS

III. AML with myelodysplastic syndrome, therapy related
- Alkylating agent-related
- Epipodophyllotoxin-related

IV. AML not otherwise categorised
- AML minimally differentiated
- AML without maturation
- AML with maturation
- Acute myelomonocytic leukaemia
- Acute monocytic leukaemia
- Acute erythroid leukaemia
- Acute megakaryocytic leukaemia
- Acute basophilic leukaemia
- Acute panmyelosis with myelofibrosis

Table 2: French-American-British (FAB) Classification of Acute Lymphoid Leukaemia (ALL)

Cytologic features	ALL-L1	ALL-L2	ALL-L3
Cell size	Small	Large heterogeneous	Medium to large and homogeneous
Cytoplasmic amount	Scanty	Variable, often moderate	Moderately abundant
Nucleoli	Not visible or inconspicuous	One or more, often large	One or more, often prominent
Nuclear shape	Regular, occasional clefting or indentation	Irregular clefting and indentation common	Irregular, oval to round
Nuclear chromatin	Homogeneous	Variable, heterogeneous	Finely stippled and homogeneous

Table 3: French-American-British (FAB) Classification of Acute Myeloid Leukaemia (AML)

Subtype	FAB Type	Frequency (%)	Morphology	MPO	SB	NSE
Minimally differentiated leukaemia	M0	5	No azurophil granules	–	–	–
Acute myeloblastic leukaemia (AML) without maturation	M1	15	Few azurophilic granules or Auer rods	±	±	–
AML with differentiation with maturation	M2	25	Some maturation beyond promyelocytes; Auer rods	++	++	–
Acute promyelocytic leukaemia (APL)	M3	5	Hypergranular promyelocytes; Auer rods	+++	+++	–
Acute myelomonocytic leukaemia (AMML)	M4	25	≥ 20% monocytes; monocytoid cells in blood	++	++	++
Acute monocytic leukaemia (AMOL)	M5	5	Monoblastic (M5A) promonocytic (M5B)	±	–	+++
Acute erythroleukaemia	M6	5	Predominance of erythroblasts; dyserythropoiesis	–	–	–
Acute megakaryocytic leukaemia	M7	10	'Dry' aspirate; biopsy with blasts and dysplastic	–	–	–

MPO = Myeloperoxidase; SB = Sudan black; NSE = Non-specific esterase.

According to this new classification, presence of more than 20% blasts in the bone marrow is diagnostic of AL. The changes are easily summarised, the leukaemias with consistent cytogenetic abnormalities and these that are MDS related were taken into separate groups, the rest of the old FAB classification was put under the 'AML not otherwise categorised' entry. In general, ALL blasts are smaller (10 to 15 mm), have a thin rim of cytoplasm and are Tdt-positive (**Figure 1**). AML blasts are larger (12 to 20 mm), and have discrete nuclear chromatin, multiple nucleoli and Auer rods (**Figures 2 and 3**). They are Sudan black and myeloperoxidase positive. Morphology and cytochemistry are sufficient to allow an accurate subtyping in most cases.

Immunophenotyping

The recent development of highly specific monoclonal antibodies to differentiate antigens as well as advances in flow cytometry has made immunophenotyping readily available. Immuophenotyping is useful in defining lineage (B-cell *versus* T-cell) and stages of differentiation of ALL, identifying characteristic

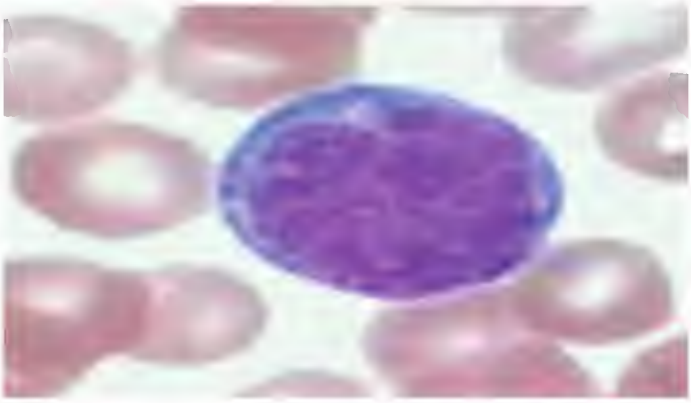

Figure 1: Lymphoblasts—bone marrow.

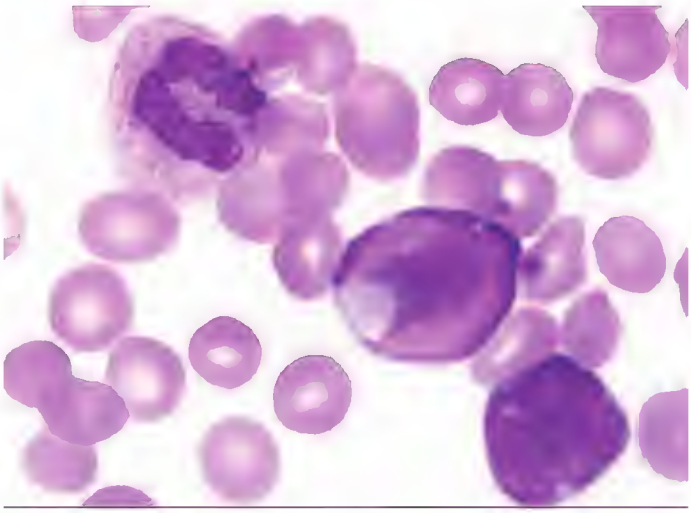

Figure 2: Myeloblast—bone marrow.

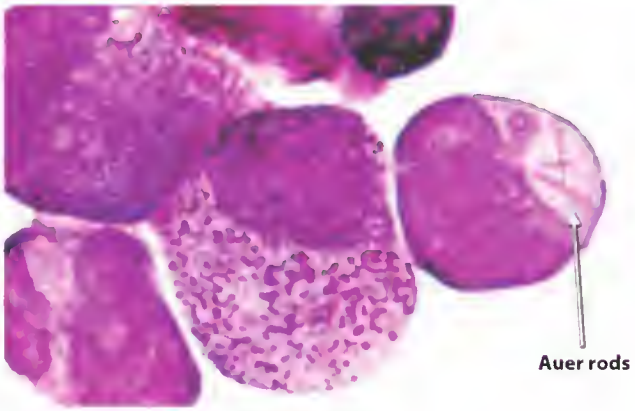

Figure 3: AML-M2 Auer rods.

features of AML, aiding in lineage determination in AL that are morphologically undifferentiated, diagnosing rare entities, such as AML-M6, AML-M7 or minimally differentiated AML M0, recognising mixed lineage or biphenotypic AL (ALL with myeloid markers or AML with lymphoid markers), and distinguishing AL from other haematopoietic and non-haematopoietic disorders. Groups of monoclonal antibodies that recognise the same antigens have been identified and are designated as cluster group of differentiation. The most useful and commonly used antibodies for the study of AL are listed in **Tables 5 and 6**. Reactivity with one antigen is not sufficient, but when used in combination these antibodies can help determine the cell lineage.

Table 5: Immunophenotyping in Acute Leukaemia

Subtype	Cluster designation of monoclonal antibodies
Acute lymphoblastic leukaemia	
T-cell	CD1, CD2, CD3, CDS, CD4, CD8, CD7
B-cell	CD10±, CDI9, CD20, CD22, S Ig+
Pre B	CD9, CD10, CDI9, clg M, HLA-DR
CALLA	CD10
Acute myeloid leukaemia	
M1, M2, M3	CD11, CDI3, CD33
M4, M5	CD11, CDI3, CDI4, CDI5, CD33
M6	Glycoprotein, spectrin
M7	CD41 (glycoprotein IIb/IIIa)/CD43 (glycoprotein Ib) S

Ig = Immunoglobulin; HLA = Human leucocyte antigen; CALLA = Common acute lymphoid leukaemia antigen.

Table 6: Co-relation of ALL Subtypes with Surface Markers

Pre B-cell	CD10+, CD19+, CD20+, CD21+, HLA DR+	Presence of CD10 (common ALL antigen) connotes a favourable prognosis
Mature B-cell	CD19+, CD20+, CD21+, slg +	Correlates with L3 leukaemia - Burkitt's leukaemia, needs intensified therapy
T-cell	CD3+, CD5+, CD7+	Associated with older age, high initial WBC count, mediastinal mass and higher risk of CNS disease

ALL = Acute lymphoid leukaemia; CALLA = Common acute lymphoid leukaemia antigen; WBC = White blood cell; CNS = Central nervous system.

Molecular Studies

Three major techniques of molecular analysis are currently used to diagnose and monitor AL, namely, Southern blot analysis, the polymerase chain reaction (PCR) and fluorescent *in situ* hybridisation (FISH). These methods enable the demonstration and characterisation of genetic abnormalities inherent in leukaemic cells. Southern blot analysis is currently the most sensitive method for the detection of minimal residual disease after treatment. The chromosomal abnormalities and oncogenes associated with various acute leukaemias are shown in **Table 7**.

THERAPY

The goal of therapy in AL is eradication of the leukaemia along with the restoration of normal haematopoiesis. At presentation the tumour load is 10^{11} to 10^{12} cells; chemotherapy can reduce it by 3 to 5 logs. Hence, the patient still has 10^{8} leukaemic cells when the marrow examination shows complete remission (**Figure 4**). Therefore, to achieve a long-term cure, the patient needs further treatment. The initial high-dose chemotherapy given to reduce the leukaemic cells below the levels of morphologic detection is called induction. This is followed by another course of chemotherapy meant to further attenuate the leukaemic burden consolidation or early intensification. Low-dose oral therapy given for 18 months to 2 years is called maintenance therapy. High-dose therapy given more than 6 months after induction is termed late intensification. The state-of-the-art treatment of AL is summarised in **Table 8**. Each mode of therapy has a specific aim and the drugs are selected accordingly.

Table 7: Non-Random Chromosomal Abnormalities and Oncogenes Associated with Acute Leukaemia

Disease	Chromosomal rearrangement	Involved gene	Comments
Acute lymphoblastic leukaemia (ALL)			
Early-B precursor	t(4;1l)	MLL	High-risk associated with infantile leukaemia
Common ALL	t(9;22)	BCR-ABL	High-risk
Pre-B	t(1;19)	IGH-IL3	High-risk
B ALL	t(8;14)	IGH-MYC	Needs short duration intensive therapy
Acute myeloid leukaemia (AML)			
AML M1	t(12;21)	TEL-AML1	Good prognosis
AML M2	t(8;21)		
AML M3	t(15;17)	PML-RARα	
AML M4	inv 16		
AML M5	t(9;11), 11q23		
AML M6	del(7q) and del (5q)		Poor chemotherapy response
AML M7	t(12; 21), trisomy 21		Poor chemotherapy response

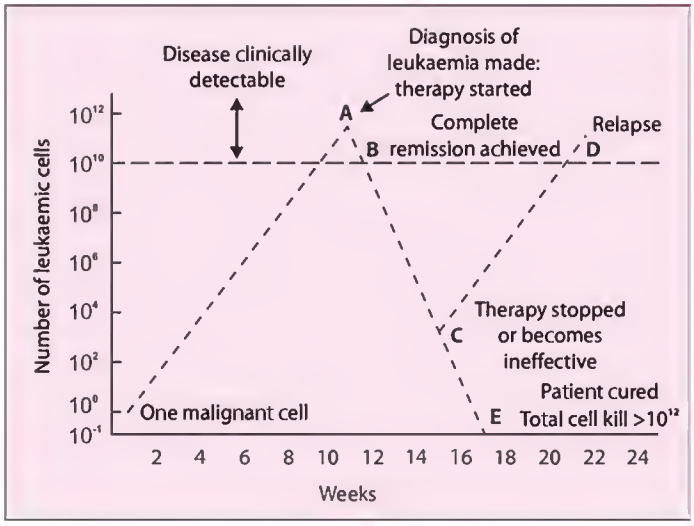

Figure 4: Cell turnover in acute leukaemia diagnosis and treatment.

Table 8: State-of-the-Art Treatment Protocol for Adult Acute Leukaemia

Acute myelogenous leukaemia

Anthracycline and cytarabine-based induction regimens
Intensive post-remission therapy: either bone marrow transplant or high-dose cytarabine is required for prolonged remission
Maintenance therapy is not generally indicated with the exception of acute promyelocytic leukaemia

Acute promyelocytic leukaemia

Retinoic acid and anthracycline and cytarabine-based treatment
Management of disseminated intravascular coagulation
Administration of cryoprecipitate or fresh frozen plasma to maintain fibrinogen >100 mg/dL;
Platelet transfusions to maintain platelet count >50,000/μL
Bone marrow transplant, high-dose cytarabine therapy are reserved for relapsed disease

Acute lymphoblastic leukaemias

Four or five drug induction regimens using anthracyclines, cyclophosphamide, and/or asparaginase in addition to vincristine and prednisone
Intensive consolidation therapy based on cytarabine combined with anthracyclines, epidophyllotoxins, or antimetabolites
Protracted maintenance therapy (approximately 2 years) based on oral methotrexate combined with mercaptopurine
Prophylactic intrathecal chemotherapy (with or without cranial radiotherapy) for central nervous system prophylaxis

Supportive care is extremely important in the treatment of AL. The major portion of therapy-related morbidity and mortality can be averted by meticulous attention to these aspects. Adequate hydration, allopurinol and low-dose steroid therapy for the first 48 hours are important to prevent tumour lysis, especially when the cell count is high. All chemotherapies are myelotoxic. Hence, supportive care includes blood and platelet transfusions and antibiotics whenever indicated. Platelet transfusion should be given whenever there is overt bleeding or the platelet count falls below 10,000/mm^3. It needs to be replaced every 24 to 48 hours. Keeping the haemoglobin as near normal as possible clearly reduces morbidity and improves the ability of the patient to combat septicaemia. Infections and haemorrhage are the primary cause of death in patients with leukaemia. Untreated infection in the neutropaenic host can be fatal. All febrile episodes in a neutropaenic patient are considered to be due to infection unless proved otherwise, even in negative blood, urine and cultures. Common regimen for the treatment of febrile neutropaenia includes antipseudomonal penicillin or cephalosporin coupled with an aminoglycoside. Patients with central venous catheter may require early institution of vancomycin. The use of granulocyte transfusions is still controversial. All patients should be given prophylaxis for *Pneumocystis carinii* and fungal infections.

ACUTE LYMPHOBLASTIC LEUKAEMIA

Combination chemotherapy remains the primary therapeutic modality with evolving indications for limited radiation therapy. Current treatment for ALL is divided into four phases as described below.

Remission Induction

Although prednisolone and vincristine are capable of producing remission in approximately 80% of patients, it is now clear that it is inadequate. The addition of a third agent, either L-asparaginase, daunorubicin raises the induction remission rate to 90% and significantly prolongs remission. However, addition of a fourth induction agent, usually an anthracycline, improves remission duration even in patients with poor-risk factors.

Central Nervous System Prophylaxis

The concept of CNS prevention therapy is based on the assumption that undetectable CNS leukaemia is present at the

time of diagnosis. In high-risk patients cranial irradiation and intrathecal methotrexate prevent CNS relapse. However, long-term ALL survivors have adverse effects of CNS irradiation on neurological and intellectual functions. The combination of intrathecal and moderate-dose intravenous methotrexate, maintenance triple intrathecal therapy (methotrexate, cytarabine and hydrocortisone) and high-dose intravenous methotrexate alone appear to provide equivalent protection to that offered by cranial irradiation.

Consolidation

The cranial prophylaxis is followed by another dose of chemotherapy meant to decrease the leukaemic burden to the minimum. The drugs used for consolidation are a combination of drugs used for induction and maintenance therapy.

Maintenance

Methotrexate and 6-mercaptopurine are the two drugs most frequently administered. This therapy is continued for 2 years in order to eradicate the dormant leukaemic cells. The dosage of these drugs should be adjusted to maintain the total leucocyte count between 1,000/mm^3 and 3,000/mm^3. The most commonly used intensive therapy protocol for children with ALL in India is shown in **Table 9**.

This protocol is being used in major centres across the country. This protocol has been designed along with National Cancer Institute (NCI), USA. Analysis of the results over the last decade revealed 70% to 75% patients have hepatosplenomegaly or lymphadenopathy or both. Two-third of patients have C-ALL, while 18% to 20% have T-ALL.

Complete response was achieved in 92% patients at the end of induction.

Table 9: MCP-841 Protocol Used for Childhood Acute Lymphoblastic Leukaemia

Induction-I (Month 1 and Month 3)		
L-asparaginase	6000 units/m^2	Days 2,4,6,8,10,12,14,16,18,20
Vincristine	1.4 mg/m^2	Days 1, 8, 15, 22, 28
Daunomycin	30 mg/m^2	Days 8, 15, 28
Prednisolone	40 mg/m^2	Days 1 to 28
IT methotrexate	12 mg	Days 1, 8, 15, 22, 28
Induction-2 (Month 2)		
Cyclophosphamide	750 mg/m^2	Day 1, 15
6-mercaptopurine	75 mg/m^2	Days 1 to 7, 15 to 22
IT methotrexate	12 mg	Days 1, 8, 15, 22
Cranial radiotherapy	1200 cGy	Days 5 to 15
Consolidation (Month 4)		
Vincristine	1.4 mg/m^2	Days 1, 15
Cyclophosphamide	750 mg/m^2	Day 1
Daunomycin	30 mg/m^2	Day 15
Cytosar	100 mg/m^2	Days 1, 2, 3 and 15, 16, 17
6-mercaptopurine	75 mg/m^2	Days 1 to 8, and 15 to 22
Maintenance (3 Monthly Cycle x 6 Cycles)		
L-asparaginase	6000 units/m^2	Days 1, 3, 5, 7
Vincristine	1.4 mg/m^2	Day 1
Daunomycin	30 mg/m^2	Day 1
Prednisolone	40 mg/m^2	Days 1 to 7
6-mercaptopurine	75 mg/m^2	Days 15 to 90 (5 days per week)
Methotrexate	15 mg/m^2	Days 15, 22, 29...90 (once per week)

IT = Intrathecal.

Relapse was seen in 25% to 30% of patients. Most relapses were seen during maintenance and within first few months of completion of therapy. For the entire series, overall survival, disease-free survival and event-free survival are 55.7%, 55.5% and 51.9%, respectively.

ACUTE MYELOID LEUKAEMIA

Advances in the treatment of adult AML have resulted in substantially improved complete remission rates.

While the chemotherapy has remained the same over last two decades, progress in the treatment is attributed to the following: application of high-dose therapy (cytarabine) in first remission with rescue bone marrow transplant, identification of the major histocompatibility complex leading to successful application of bone marrow transplant and recognition of the importance of infection and the development of prophylaxis for prevention of Gram-negative infection, fungal infection and *cytomegalovirus* infection. Treatment should be sufficiently aggressive to achieve complete remission because partial remission offers no substantial survival benefit. Approximately 60% to 70% of adults with AML can be expected to attain remission status following appropriate induction therapy. More than 15% of adults with AML (about 25% of those who attain complete remission) can be expected to survive 3 or more years and may be cured. Remission rates in adult AML are inversely related to age, with an expected remission rate of greater than 65% for those younger than 60 years of age. Other adverse prognostic factors include CNS involvement with leukaemia, systemic infection at diagnosis, elevated WBC count (>100,000/mm^3), secondary AML, and history of myelodysplastic syndrome. Cytogenetic abnormalities which indicate a good prognosis include t(8;21), inv(16), and t(15;17). Normal cytogenetics portends average-risk AML. Patients with AML that is characterised by deletions of the long arms or monosomies of chromosomes 5 or 7; by translocations or inversions of chromosome 3, t(6;9), t(9;22); or by abnormalities of chromosome 11q23 have particularly poor prognosis with chemotherapy. For practical purposes, antileukaemic therapy is similar for all subtypes. Factors that predict for shorter response durations with chemotherapy (high initial WBC count, monocytic morphology and age) may also result in shorter remission duration following transplantation.

Induction Therapy

Induction therapy is the mainstay of treatment. It consists of a combination of cytarabine (100-200 mg/m^2 per day for 7 days) and an anthracycline (daunorubicin 40-50 mg/m^2 per day for 3 days); the addition of a third agent (thioguanine or etoposide) may improve the results. The overall complete remission rate is 65% after a single course of therapy. About 5% patients are currently refractory to therapy and 5% succumb to infection and haemorrhage during remission induction. AML arising from myelodysplasia or secondary to previous cytotoxic chemotherapy has a lower rate of remission than *de novo* AML. Supportive care during remission induction treatment should routinely include red blood cell and platelet transfusions when appropriate. Empiric broad-spectrum antimicrobial therapy is an absolute necessity for febrile patients who are profoundly neutropaenic (absolute neutrophil count <500/mm^3). Careful

construction in personal hygiene, dental care, and recognition of early signs of infection are appropriate in all patients. White blood cell transfusions can be beneficial in selected patients with aplastic marrow and serious infections that do not respond to antibiotics.

Achievement of remission is defined as a normal peripheral blood cell count, normocellular marrow with less than 5% blasts in the marrow and no signs or symptoms of the disease. In addition, there are no signs or symptoms of CNS leukaemia or other extra-medullary infiltration.

Post-Remission Therapy

Post-remission therapy is designed to eliminate clonogenic cells which remain in bone marrow and are detectable as minimal residual disease. Further therapy options to eradicate minimal residual therapy are intensive treatment with high-dose cytarabine-containing combinations and myeloablative therapy, followed by allogenic or autologous bone marrow transplant. The duration of consolidation therapy ranges from one cycle to four or more cycles. High dose cytarabine-based chemotherapy can be complicated by severe gastro-intestinal, neurologic or pulmonary toxic effects. Patients in the good-risk group have a reasonable chance of cure with intensive consolidation, and it may be reasonable to defer transplantation in that group until early first relapse. Poor-risk factors include deletion of 5q and 7q, trisomy 8, t(6;9), t(9;22), and a history of myelodysplasia or antecedent haematologic disorder. The poor-risk group is unlikely to be cured with consolidation chemotherapy and allogeneic bone marrow transplant in first complete remission is a reasonable option for patients with an human leucocyte antigen (HLA)-identical sibling donor. Allogeneic bone marrow transplant offers the best anti-leukaemic therapy as cure.

The 5-year survival with chemotherapy alone is 30% to 40%. Chemotherapy alone is able to prolong survival without achieving cure in a majority of the patients with AML. Allogeneic bone marrow transplant provides cure for up to 50% of AML patients. The application of modern immunotherapy in the course of treatment may be beneficial in the near future.

Therapy for Recurrent AML

Treatment with new agents under clinical evaluation are particularly appropriate in patients with recurrent AML and should be considered whenever possible. There are a number of newer agents with activity in recurrent AML, including amsacrine, mitoxantrone, diaziquone, high-dose cytarabine, homoharringtonine, idarubicin, and etoposide; some of these agents are being tested in combination regimens. A study with mitoxantrone and cytarabine was successful in 50% to 60% of patients who experienced relapse after initially obtaining a complete remission. Gemtuzumab ozogamicin anti-CD33 antibody has shown some response in relapsed patients. However, it leads to prolonged myelosuppression. Allogeneic stem-cell transplantation in early first relapse or in second complete remission provides a disease-free survival rate of approximately 30%.

Allogeneic stem-cell transplantation can salvage some patients whose disease fails to go into remission with intensive chemotherapy. Autologous bone marrow transplant has no survival benefit.

ACUTE PROMYELOCYTIC LEUKAEMIA

The large lysosomal granules seen in APL have high probability of severe haemorrhagic complications and DIC during early induction therapy. Aggressive transfusion support with fresh frozen plasma, cryoprecipitate and platelets is often necessary. Remission induction of APML with all-transretinoic acid (ATRA) alone or in combination with cytotoxic agents, is used. ATRA induction appears to normalise the coagulopathy more quickly than does conventional induction therapy, but it can be associated with the development of hyperleucocytosis and acute respiratory distress syndrome, 'ATRA syndrome'. Prompt recognition of the syndrome and aggressive administration of steroids can prevent severe respiratory distress. It is now well recognised that oral administration of ATRA (45/m^2/day) can induce remission in 70% to 90% of patients with APL. Coagulopathy is occasionally a problem in patients undergoing induction with ATRA plus chemotherapy. This coagulopathy can lead to catastrophic intracranial bleeding, but can be well-controlled by replacement of clotting factors. The use of heparin for control of DIC remains controversial.

Arsenic trioxide has become standard treatment for relapse of APL. As O_3 is also used as induction therapy in India.

BONE MARROW TRANSPLANT

Allogeneic Bone Marrow Transplantation

Allogeneic bone marrow transplant results in the lowest incidence of leukaemic relapse. The use of bone marrow transplant as primary post-remission therapy is limited by the need for a HLA matched sibling donor and the increased mortality from bone marrow transplant of patients who are older than 50 years of age. Good-risk factors include young age, t(8;21), inv(16) and t(15;17) associated with APL.

For patients planned for transplant, transfusion of blood products from potential donors should be avoided. Histocompatibility testing should be done at the earliest possible time. Most studies demonstrate that the rate of leukaemic relapse is decreased following bone marrow transplant in first remission compared with chemotherapy alone. Factors that predict for shorter response durations with chemotherapy may also result in shorter remission duration following transplantation. Bone marrow transplant has yielded a high rate of complete response in patients for whom initial induction therapy failed and autologous bone marrow transplantation may produce long-term leukaemia-free survival in approximately one-third of patients in either first relapse or second complete remission. The use of bone marrow or stem-cell transplantation as post-remission therapy has a curative role in ALs. High doses of chemotherapy with or without total body radiation are used in an effort to maximise leukaemia cell kill. Haematopoiesis is restored by the infusion of HLA-matched stem cells harvested from an HLA-compatible donor (sibling, parents) thereby rescuing the patient from the consequences of bone marrow failure. Because of differences in HLA composition, the graft may reject the host cells resulting in graft-*versus*-host disease (GvHD).

This complication may increase the risk of infection and represents a major source of morbidity and mortality in transplant patients. Allogeneic bone marrow transplant in first

complete response using HLA-compatible related donors resulted in a 5-year, disease-free survival in approximately 45% to 50%, with relapse rates ranging only from 10% to 20%. However, a significant number of patients succumb to such complications as GvHD, infection, or interstitial pneumonitis affecting the overall survival of the group as a whole. The transplant-related complications increases with age, and it is not advisable to offer allogeneic bone marrow transplant of patients older than the age of 50 to 55 years. As the median age of patients with AML is approximately 65 years, it is clear that most patients with this disease are not eligible for this form of therapy. In addition, only approximately 30% of eligible patients have an HLA-compatible donor. Despite meeting the minimum requirements of age and availability of a donor, a significant number of patients still fail to undergo transplantation.

Autologous Bone Marrow Transplantation

Majority of patients do not have an acceptable HLA-matched donor and cannot undergo allogeneic bone marrow transplant. In an attempt to allow such patients to undergo high-dose therapy with curative intent, the use of the patient's own bone marrow obtained while in CR as a source of haematopoietic reconstitution. Such an approach was thought to provide the anti-leukaemic benefits associated with high-dose conditioning regimens yet avoid the toxic complications. However, one major disadvantage is the potential contamination of the autologous graft by residual leukaemia cells. The inability of currently available laboratory techniques to reliably detect minimal residual disease and predict outcome based on its presence represents a major problem in leukaemia therapy. Hence, there is a concern that despite the high-dose conditioning designed to eradicate residual leukaemia cells in the body, patients will ultimately relapse because undetectable leukaemia cells will be reinfused with the graft. Results from these trials have generally reported a disease-free survival of approximately 40% to 50%. Relapse rates (50% to 60%) are higher than allogeneic bone marrow transplant, but as expected the toxicities are less. In studies that have used either immunologic or pharmacologic methods to purge bone marrow there has been a profound suppression of normal bone marrow progenitors resulting in delayed engraftment and generally shown a decrease in the duration of neutropaenia and a prolonged period of haematologic recovery. Therefore, studies using newer more sensitive techniques, such as PCR or multiparameter flow cytometry, will continue to address the issue of graft contamination by minimal residual disease.

PROGNOSIS

Survival in ALL has improved from 1% in 1965 to 50% in the mid 70s and up to 70% in the mid 80s and currently up to 90%. A variety of prognostic factors have been identified in AL (**Table 10**). Improvement in supportive care, mainly in preventing and treatment of infections has helped to decrease the leukaemic fatality-rate.

Less than one-third of the patients with AML who are treated with the current intensive chemotherapy are permanently cured. Of those who have an HLA-matched sibling donor and have a bone marrow transplant in the first remission more than 50% will be cured. In early relapse or second chemotherapy-induced remission, only a small fraction of patients can be salvaged by bone marrow transplant. The results of bone marrow transplant are equivocal.

Table 10: Prognostic Features in Acute Adult Leukaemia

Acute Lymphoblastic Leukaemia

- White blood cell count: High count associated with poor prognosis
- Leukaemic cell immunophenotype: T-cell has a favourable prognosis, pre-B cell has an intermediate prognosis, whereas mature B-cell has a poor prognosis with standard regimens
- Age: Older age associated with worse prognosis
- Philadelphia chromosome: Positive disease has a worse prognosis
- Time to complete response: Patients requiring > 4 to 5 weeks to achieve a complete response have a lower likelihood of being cured

Acute Myeloid Leukaemia

- Age: Older age is associated with a reduced incidence of complete response
- Antecedent haematologic disorder or secondary acute myelogenous leukaemia
- These subgroups have a lower incidence of complete response and a reduced overall survival
- Cytogenetics: The t(15;17), t(8;21), and inv(16) denote good prognostic subgroups; abnormalities of chromosome 5 or 7, trisomy 8, and t(9;11) denote poor prognostic subgroups

RELAPSED ACUTE LEUKAEMIA

Relapse is defined as the recurrence of evident leukaemia. The bone marrow is the most common site of relapse. It is either due to residual disease or the emergence of drug resistance. The multidrug resistant gene may have a significant role to play in refractory and relapsed leukaemias. Early bone marrow relapse occurring during treatment or within six months after cessation of therapy has a poor prognosis unless salvaged by allogeneic bone marrow transplant. Where there is no compatible donor, aggressive chemotherapy is employed using infusions of high-dose methotrexate and cytarabine. CNS relapse is an extra-medullary relapse occurring in 3% to 8% of patients within 18 to 24 months after the start of front-line treatment. Local therapy to the meninges by intrathecal chemotherapy combined with systemic chemotherapy together with CNS irradiation in previously non-irradiated patients will cure 40%. Testicular relapse usually manifests itself 4 to 6 months after cessation of maintenance thereby. A single involved testis should be removed and in bilateral involvement local radiation with 20 cGy should be applied. Systemic chemotherapy should include maintenance therapy for at least one year. Combined relapse most frequently involves the bone marrow and CNS. The prognosis is extremely unfavourable and transplantation is the only chance of cure.

15.10 Chronic Myeloid Leukaemia and Other Myeloproliferative Disorders

Tapan Kumar Saikia

INTRODUCTION

In recent years, our understanding of myeloproliferative conditions has improved significantly. Therefore, in the 4th edition (2008) of World Health Organization (WHO) classification of myeloid neoplastic pathologies, the nomenclature of myeloproliferative disorders (MPDs) has been changed to myeloproliferative neoplasms (MPNs) to accurately reflect the neoplastic nature of these diseases. William Dameshek in 1951 brought the concept of 4 pathological conditions of chronic myelogenous leukaemia (CML), essential thrombocythaemia (ET), polycythaemia vera (PV) and primary myelofibrosis (PMF) as related ones. Since then, significant advances have occurred in understanding the biology and the management of these. Additionally, new entities have been included. The diagnosis of these disorders has serious implications for our country. This is due to paucity of diagnostic and therapeutic facilities.

Definition

MPNs are clonal myeloproliferation (i.e. peripheral blood granulocytosis, thrombocytosis or erythrocytosis) that is devoid of dyserythropoiesis, granulocytic dysplasia or monocytosis.

CLASSIFICATION

Currently, the WHO classification is accepted internationally. This is a dynamic classification based on amalgamation of newer biological information to already known parameters. The WHO 2008 classification is comprehensive and includes histology and genetic information (**Table 1**). The classification also provides scope for further investigation of relatively ill-understood categories.

Some important changes in the current classification and diagnosis of MPNs include: (a) the nomenclature (MPDs to MPNs), (b) diagnostic algorithms for PV, ET, and PMF need information regarding JAK2V617F and similar activating mechanism along with additional clinical, laboratory, and histologic parameters even in absence of JAK2V617F or simliar mutations, (c) reduction of threshold of platelet counts to more than or equal to 450 x 10^9/L for ET, (d) some cases previously diagnosed as chronic eosinophilic leukaemia (CEL) could now be categorised as myeloid and lymphoid neoplasms with eosinophilia and abnormalities of PDGFRA, PDFGRB, or FGFR1, and (e) systemic mastocytosis as an MPN.

EPIDEMIOLOGY

All MPNs are uncommon disorders, with an incidence of 0.2-3 (average 0.5) per 100,000 persons per year. Nevertheless, it appears that the exact incidence is under-reported in registries as diagnosis has remained a challenge, especially of PV, ET and PMF. The average age is 60 years, but may occur at any age, CML being not uncommon in children and young adults. There is slight male preponderance for MPNs except for ET.

AETIOLOGY

Exact aetiologies of MPNs remain unknown. Radiation may play a role in some cases. Congenital or familial cases have been reported. Much molecular work needs to be done in this field. Aetiopathogenesis and maintenance of MPNs appear to be dependent on the molecular abnormalities like bcr-abl chimeric oncogene in CML and JAK2 and possibly TET2 mutations in other types.

Table 1: The 2008 World Health Organization Classification for Myeloid Neoplasms

Acute myeloid leukaemia (AML)
Myelodysplastic syndrome (MDS)
Myeloproliferative neoplasms (MPNs)
Chronic myelogenous (myeloid) leukaemia (CML)
Polycythaemia vera (PV)
Essential thrombocythaemia (ET)
Primary myelofibrosis (PMF)
Chronic neutrophilic leukaemia (CNL)
Chronic eosinophilic leukaemia (CEL), not otherwise classified
Hypereosinophilic syndrome (HES)
Mast cell disease (MCD)
MPNs, unclassifiable
MDS/MPNs
Chronic myelomonocytic leukaemia (CMML)
Juvenile myelomonocytic leukaemia (JMML)
Atypical chronic myeloid leukaemia (ACML)
MDS/MPN, unclassifiable
Myeloid neoplasms associated with eosinophilia and abnormalities of PDGFRA, PDGFRB, or FGFR1
Myeloid neoplasms associated with PDGFRA rearrangement
Myeloid neoplasms associated with PDGFRB rearrangement
Myeloid neoplasms associated with FGR1 rearrangement (8p11 myeloproliferative syndrome)

CHRONIC MYELOGENOUS (MYELOID) LEUKAEMIA

CML is characterised by the presence of an abnormal chromosome known as Philadelphia chromosome (Ph) resulting from reciprocal translocation of a part of the long arms of chromosomes 9 and 22. At the molecular level, the abl gene from chromosome 9 is translocated to bcr in chromosome 22; likewise, part of bcr gets translocated to chromosome 9, resulting in bcr-abl chimeric oncogene and finally translated to bcr-abl chimeric protein. This brings about increased proliferation, reduced apoptosis and loss of adhesion of immature cells in marrow stroma. White blood counts rise to a high level with appearance of immature cells; platelet counts may also rise in many cases.

Clinical features include: asymptomatic cases detected on routine blood examination, weight loss, low-grade fever, malaise, and left hypochondrial pain caused by splenomegaly. Median age is 55 to 60 years in Western countries and about 40 years in many Asian countries. There is slight male preponderance. Clinically and haematologically 3 distinct phases of the disease are defined—chronic, accelerated and blastic. **Table 2** shows

the investigations required for the diagnosis of CML. It cannot be over emphasised that a cytogenetic and/or molecular diagnosis is of prime importance in diagnosing CML accurately as morphological features of other MPNs can overlap those of CML.

Table 2: Diagnosis of Chronic Myelogenous Leukaemia

Chronic Phase or Any Phase at Presentation
Blood: Leucocytosis with immature cells at various stages of maturation, thrombocytosis in some.
Absent or reduced leucocyte alkaline phosphatase (LAP) score
Marrow aspirate and trephine biopsy: Morphology suggestive of myeloid hyperplasia with a shift to the left
Cytogenetics: Conventional karyotyping for presence of t (9;22) and/or FISH for bcr-abl
Molecular: RQ-PCR for bcr-abl level
Accelerated phase: Blasts 10% to 19% in blood or marrow, basophils ≥ 20%, platelets <100 x 10^9/L
Blastic phase: Blasts ≥ 20% in blood or marrow

FISH = Fluorescent in situ hybridisation; RQ-PCR = Quantitative.

Treatment

Chronic phase (CML-CP)

Before the advent of biological agents (also known as targeted therapy) and tyrosine kinase inhibitors (TKIs), patients were treated with oral busulfan, hydroxyurea, interferon-alpha and allogeneic haematopoietic stem cell transplantation (HSCT). While oral cytotoxic drugs like busulfan or hydroxyurea had no significant impact on the natural history of the disease, interferon-alpha could produce meaningful cytogenetic responses in 15% to 20% of patients and many became long-term survivors. However, interferon had significant constitutional side-effects.

HSCT remains the only proven curative modality for CML. It brings about leukaemia cell eradication with cytotoxic therapy and graft *versus* leukaemia (GVL) effect. A long-term survival of more than 15 years has been reported in more than 50% patients. Others have died due to treatment-related mortality (TRM) or relapse. Some (10%) survivors live with significant chronic GVHD. In young patients it can be the treatment of choice as first-line therapy (<20 years) or in those resistant to TKIs. The cost is usually one time (unless prolonged chronic GVHD occurs) and less expensive than imatinib which needs to be taken for an indefinite period. This is regardless of the less expensive imatinib available in India. The timing for a best outcome following transplant is within the first year of the diagnosis.

Discovery of imatinib mesylate (2-phenylaminopyrimidine derivative) and its clinical use since 1998 has completely changed our approach for the management of CML-CP. Imatinib is a small molecule with activity on p210 bcr-abl protein by competitively inhibiting phosphorylation on the ATP binding site of the protein. It is an oral preparation with 98% bioavailability and a long half-life (14 to 18 hours), taken as single daily dose of 400 mg. Higher doses of 600 mg or 800 mg are not to be used routinely but can be used for inadequate responders. Imatinib is the first generation TKI. The results of the IRIS trial at 5-year follow-up have shown complete cytogenetic response of 69% at 12 months and 87% cumulative at 5-year, event free survival of 83%, and estimated overall survival of 89% with 7% progressing to accelerated or blastic phases. About 60% patients are continuing to receive the drug at 8-year follow-up. Currently, imatinib is standard of care for all newly diagnosed patients with CML.

It has a favourable toxicity profile. Grades 3-4 side-effects of cytopaenia (neutropaenia 17%, anaemia 4%, thrombocytopaenia 9%), elevated liver enzymes 5%, skin rash, muscle cramps, upper gastrointestinal symptoms, oedema, fatigue, occurring in only 1% to 2% cases. Hepatotoxicity if develops early and is severe, the drug is usually discontinued. However, grades 1-2 toxicities occur in 40% to 60% of the patients.

Second generation TKIs like dasatinib (~300 times more potent than imatinib), a dual kinase inhibitor (abl and src), nilotinib (~30 times more potent than imatinib), bosutinib and INNO4 have been developed and are undergoing clinical trials at various phases. Dasatinib at 100 mg daily and nilotinib at 400 mg twice daily were initially approved for use in imatinib intolerant and resistant cases. They have recently been approved for first-line therapy. Efforts are on to develop many other TKIs which could be better than currently available ones. **Table 3** shows the details of currently available TKIs.

Table 3: Tyrosine Kinase Inhibitors for Treatment of CML

Names (potency)	Mechanisms	Current Use
Imatinib (x 1)	Inhibits bcr-abl, PDGFR, others	CP, AP, BP
Dasatinib (x 300)	Inhibits bcr-abl, src	IM-resistant/ intolerant, AP, BP, CP
Nilotinib (x 30)	Inhibits bcr-abl	IM-resistant/ intolerant, AP, CP.

CP = Chronic phase; AP = Accelerated phase; BP = Blastic phase; IM = Imatinib.

Accelerated phase

As disease progression is associated with accumulation of additional genetic and molecular abnormalities, management becomes increasingly difficult. Imatinib in a 600 mg daily dose can produce haematological response in ~60% of patients with major cytogenetic responses in a fraction; overall survival at 3 years is reported as 60%. Second generation TKIs also produce significant responses. If feasible, younger patients should receive allogeneic HSCT.

Blastic phase

It is extremely difficult to achieve durable responses in blastic phase patients. Any form of therapy that includes any TKIs produces 30% to 50% remissions with median survival of 3 to 10 months. Only an allogeneic HSCT may achieve long-term survival in 10% to 20% of patients.

POLYCYTHAEMIA VERA (PV)

It is defined by an elevated red cell mass in the absence of conditions that induce secondary erythrocytosis, such as hypoxia or inappropriate erythropoietin production. As it is a clonal stem cell disorder, it is often accompanied by increased platelets and granulocytes. PV is associated with acquired point mutations of the JAK2 tyrosine kinase in more than 90% of cases. JAK2 is an intracellular signalling molecule and its constitutive expression leads to excess production of various blood cells in

the marrow. The diagnostic criteria for PV are given in **Table 4**. In the absence of availability of facilities to study JAK2, one can reasonably diagnose PV with splenomegaly, raised PCV (red cell mass), subnormal erythropoietin level and marrow biopsies.

Table 4: Diagnostic Criteria for Polycythaemia Vera

Major Criteria
Hb >18.5 g/dL (men), >16.5 g/dL (women) or Hb/Hct >99th percentile of reference range for age, sex or altitude of residence or Hb >17 g/dL (men), >15 g/dL (women) if associated with a sustained increase of ≥2 g/dL from baseline that cannot be attributed to correction of iron deficiency or elevated red cell mass more than 25% above mean normal predicted values
Presence of JAK2V617F or similar mutation
Minor Criteria
Bone marrow trilineage myeloproliferation
Subnormal serum erythropoietin level
Endogenous erythroid colony growth

Hb = Hoemoglobin; Hct = Hoemotocrit.

Clinical features include splenomegaly, facial or conjunctival a plethora, hypertension, hepatomegaly, cutaneous ulcers and gouty features. It is a chronic disease with a median survival of 10 years or more. Disease progression leads to massive hepatosplenomegaly, marrow fibrosis in the majority and transformation into acute leukaemia in 20% to 25% cases.

Management includes cases: (i) phlebotomies for all to maintain a haematocrit levels at less than 45% in men and more than 42% in women, (ii) use of low-dose aspirin 100 mg daily in all reduces the incidence of thrombosis and risk of cardiovascular deaths, (iii) cytotoxic drugs like hydroxyurea are usually reserved for high-risk patients with risk of vascular events, older than 60 years of age and lowering platelet count and reducing the spleen size.

ESSENTIAL THROMBOCYTHAEMIA (ET)

Diagnostic criteria for ET are given in **Table 5**. Reactive thrombocytosis, which is a very common phenomenon, should be carefully ruled out by looking for a primary focus of other illnesses. JAK2 mutations occur in 30% to 50% of cases and are of mixed clonality. Clinically, many patients are asymptomatic or may develop vasomotor, thrombotic, or haemorrhagic manifestations. Splenomegaly occurs in ~25% cases. It is about 2.5 times more common in males. Most patients live more than 10 years after the diagnosis.

Table 5: Diagnostic Criteria for Essential Thrombocythaemia

Platelet count ≥450 x 10^9/L
Megakaryocyte proliferation with large and mature morphology. No or little granulocyte or erythroid proliferation
Not meeting WHO criteria for CML, PV, PMF, MDS or other myeloid neoplasm
Demonstration of JAK2V617F or other clonal marker or no evidence of reactive thrombocytosis

Management modalities include, close observation and starting treatment when platelets rise more than 1,000 x 10^9/L with hydroxyurea, anagrelide and interferon-alpha with an aim to lower platelet counts. Some may require early intervention. Aspirin is also used commonly to prevent thrombosis. Heparin, warfarin or thrombolytic agents are used in the presence of thrombosis.

PRIMARY MYELOFIBROSIS (PMF)

It is the least common type of the major MPNs and carries a poor prognosis with a median survival of 3.5 to 5.5 years. JAK2 mutations are detected in ~50% of cases. Diagnostic criteria are given in **Table 6**. Reactive myelofibrosis may occur in some chronic infections including tuberculosis. Splenomegaly is the most common presenting feature. Anaemia develops with disease progression. Constitutional symptoms are caused by cytokine release. Extramedullary haematopoiesis causes massive splenomegaly leading to hypersplenism and typical morphological features of red cells in peripheral blood. Marrow aspirates are often a dry tap and trephine biopsies are mandatory for the diagnosis.

Table 6: Diagnostic Criteria for Primary Myelofibrosis

Major Criteria
Megakaryocyte proliferation and atypia accompanied by either reticulin and/or collagen fibrosis, or in its absence increased marrow cellularity, granulocytic proliferation and often decreased erythropoiesis
Not meeting WHO criteria for CML, PV, MDS, or other myeloid neoplasm
Demonstration of JAK2V617F or other clonal marker or no evidence of reactive marrow fibrosis
Minor Criteria
Leucoerythroblastosis
Increased serum LDH
Anaemia
Palpable splenomegaly

Management includes, close observation in earlier stages with reservation of hydroxyurea for later stages. Interferon-alpha may ameliorate some features for a certain period. Blood transfusions become the most important supportive care once significant anaemia sets in. Attempts are onto develop new molecules like pomalidomide, a thalidomide analogue that may offer meaningful palliation. Allogeneic stem cell transplantation remains a curative therapy in selected patients.

Management of Rare MPNs

No standard of care has emerged for these uncommon conditions. Most patients remain under observation and managed symptomatically. Nevertheless, certain conditions like hypereosinophilic leukaemia with PDGFRA and PDGFRB rearrangements and certain types of systemic mastocytosis can be treated effectively with low-dose imatinib.

15.11 Myelodysplastic Syndromes

Rajat Kumar, Seema Tyagi

DEFINITION

The myelodysplastic syndromes (MDS) are a heterogeneous group of clonal disorders characterised by ineffective haematopoiesis, leading to one or more cytopaenias, marrow dysplasia, and a tendency for leukaemic progression. The overall disease incidence is about 4 per 100,000 population but this rises to more than 30 per 100,000 in those over 70 years of age. As the longevity increases in India, MDS is being diagnosed more frequently.

CLINICAL FEATURES

The clinical features of MDS relate to the presence and severity of cytopaenias and are non-specific. MDS is common in the elderly. A detailed history and examination should be done to consider the differential diagnosis and exclude other causes of cytopaenias with reversible causes (**Table 1**).

Table 1: Clinical Evaluation and Investigations

History	Comments
Prior exposure to chemotherapy/radiation Family history of MDS/AML Recurrent infections or bleeding/bruising	Prior chemotherapy/radiation may predispose to MDS
	Ongoing cytotoxic therapy may be a cause of reversible cytopaenia with dysplasia in BM and is not MDS
Examination	
Pallor/infection/bruising Splenomegaly	
Baseline Investigations	
Full blood count Macrocytosis, cytopaenia(s) Occasionally,neutrophilia, monocytosis, thrombocytosis if additional myeloproliferative component	Dysplasia is better detected on aspirate and cellularity on bone marrow biopsy
Blood film examination	
Assay of serum ferritin, vitamin B12 and folate levels	
Bone marrow aspirate	
Bone marrow trephine biopsy	
Bone marrow cytogenetic analysis	Bone marrow cytogenetics are normal in about 50% of MDS patients.
Exclude reactive or other causes of dysplasia or secondary cytopaenias by relevant investigations: Megaloblastic anaemia HIV infection, Hepatitis B and C Cirrhosis with hypersplenism Alcoholism	Clinical assessment will determine the extent of investigations
Undiagnosed haemoglobinopathies or low grade haemolytic anaemias with erythroid dysplasia	
Severe intercurrent illness tuberculosis, kala-azar	Facilities for BM cytogenetics are lacking in many Indian centres

DIAGNOSIS

The diagnosis of MDS is usually suspected because of persistent unexplained peripheral blood cytopaenias. The bone marrow aspirate examination may show a single or multi-lineage dysplasia (**Figures 1 to 3**). The laboratory work-up is shown in **Table 1**. The "minimal" morphologic criteria in bone marrow for the diagnosis of MDS are: in the appropriate clinical setting, at least 10% of the cells of at least one myeloid BM lineage (erythroid, granulocytic, megakaryocytic) must show unequivocal dysplasia for the lineage to be considered as dysplastic in a cellular marrow. If a patient with clinical and other laboratory features consistent with MDS has inconclusive morphologic features, a presumptive diagnosis of MDS can be made if a specific clonal chromosomal abnormality is present. However, cytogenetic studies are normal in approximately 40% to 50% cases at diagnosis.

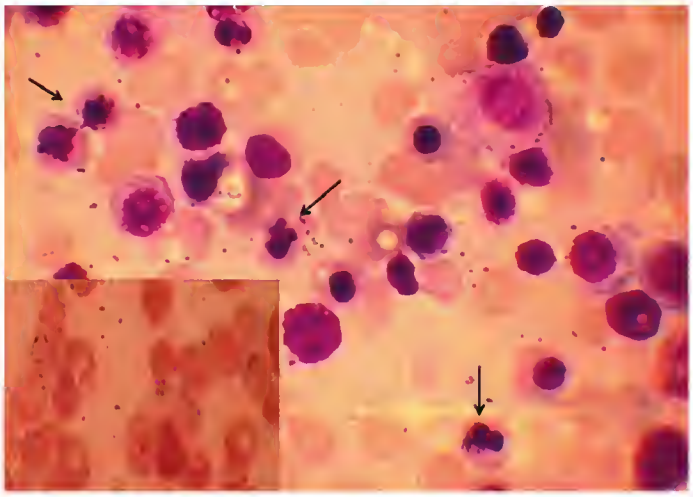

Figure 1: Bone marrow smear shows erythroid hyperplasia with dyserythropoiesis (Giemsa x 1000). Inset picture shows ring sideroblasts (Perl's stain x 1000).

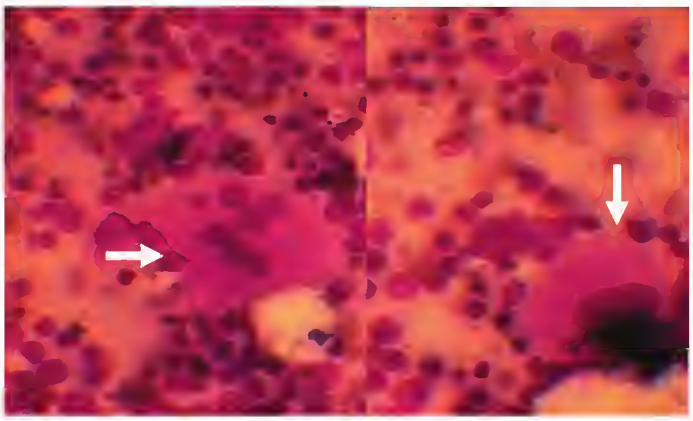

Figure 2: Bone marrow aspirate smear shows a cellular marrow with dysmegakaryopoiesis (Giemsa x 400).

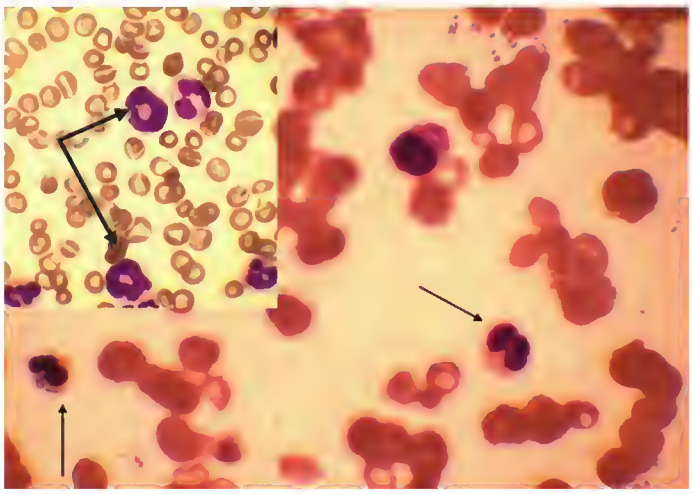

Figure 3: Peripheral smear shows dysplastic neutrophil and erythroid cell (thin arrows). Inset picture shows two ring neutrophils (thick arrows) (Giemsa x1000).

CLASSIFICATION

The MDS were initially classified as per the French-American-British (FAB) classification. This was revised by the WHO in 2001. The latest revision by the WHO was made in 2008 by lowering the threshold of bone marrow blasts from 30% to 20% for the diagnosis of acute myeloid leukaemia (AML) (**Table 2**). Paediatric MDS has been considered a different entity.

AETIOPATHOGENESIS AND BIOLOGY

Prior chemotherapy/radiotherapy predisposes to MDS, but most patients have no such history. The pathological processes responsible are: (a) augmented apoptosis, leading to ineffective haematopoiesis and peripheral cytopaenias, (b) accumulated genetic lesions causing tendency for transformation to AML, (c) chromosomal abnormalities, mostly deletions and monosomy, leading to loss of tumour suppressor genes, and (d) immune dysregulation of bone marrow micro-environment causing disruption of signal transduction pathways. There is an overlap and evolution between MDS, aplastic anaemia, paroxysmal nocturnal haemoglobinuria (PNH) and AML.

TREATMENT

Till recently, MDS had a dismal prognosis, but recent advances in therapy are improving the outcomes. The only curative treatment for MDS is bone marrow transplantation, but the majority of patients are not eligible on account of age and co-morbid conditions. Their prognostication is based on the International Prognostic Scoring System (IPSS) (**Table 3**). A more recent WHO based Prognostic Scoring System (WPSS) is more dynamic and includes transfusion requirement as a prognostic factor. The National Comprehensive Cancer Network (NCCN) guidelines are very useful in considering the appropriate therapy for patients with MDS, subdividing treatment based on IPSS risk (**Table 4**).

Table 2: World Health Organization's Revised 2008 Classification of Myelodysplastic Syndrome

Disease	Blood Findings	Bone Marrow Findings
Refractory cytopaenia with unilineage dysplasia (RCUD): (refractory anaemia [RA]; refractory neutropaenia [RN]; refractory thrombocytopaenia [RT])	Unicytopaenia or bicytopaenia (occasional) No or rare blasts (<1%)	(a) Unilineage dysplasia: ≥10% of the cells in one myeloid lineage (b) <5% blasts (c) <15% of erythroid precursors are ring sideroblasts
Refractory anaemia with ring sideroblasts (RARS)	Anaemia, No blasts	(a) ≥15% of erythroid precursors are ring sideroblasts (b) Erythroid dysplasia only <5% blasts
Refractory cytopaenia with multilineage dysplasia (RCMD)	Cytopaenia(s) No or rare blasts (<1%) No Auer rods <1 × 10^9/L monocytes	(a) Dysplasia in 10% of the cells in 2 myeloid lineages (neutrophil and/or erythroid precursors and/or megakaryocytes) (b) <5% blasts in marrow (c) No Auer rods (d) ±15% ring sideroblasts
Refractory anaemia with excess blasts-1 (RAEB-1)	Cytopaenia(s) <5% blasts No Auer rods <1 × 10^9/L monocytes	(a) Unilineage or multilineage dysplasia (b) 5% to 9% blasts (c) No Auer rods
Refractory anaemia with excess blasts-2 (RAEB-2)	Cytopaenia(s) 5 to 19% blasts Auer rods ± <1 × 10^9/L monocytes	(a) Unilineage or multilineage dysplasia (b) 10% to 19% blasts (c) Auer rods ±
Myelodysplastic syndrome—unclassified (MDS-U)	Cytopaenias <1% blasts	(a) Unequivocal dysplasia in less than 10% of cells in one or more myeloid lineages when accompanied by a cytogenetic abnormality considered as presumptive evidence for a diagnosis of MDS (b) <5% blasts
MDS associated with isolated del (5q)	Anaemia, usually normal or increased platelet count No or rare blasts (<1%)	(a) Normal to increased megakaryocytes with hypolobated nuclei (b) <5% blasts (c) Isolated del (5q) cytogenetic abnormality (d) No Auer rods

Table 3: International Prognostic Scoring System (IPSS) for *De Novo* Myelodysplastic Syndromes

Scoring and survival in *De novo* MDS

	Score value				
Prognostic variable	0	0.5	1.0	1.5	2.0
Marrow blast %	<5	5 to 10	—	11 to 20	20 to 30
Karyotype	Good	Intermediate	Poor	—	—
Cytopaenia	0/1	2/3	—	—	—

Karyotype: *Good = Normal, –Y, del (5q), del (20q); Intermediate = Other abnormolities; Poor = Complex (> 3 abnormolities) or chromosome 7 anomolies. [This excludes karyotype t(8;21), inv 16 and t(15;17) which are considered AML and not MDS].*
Cytopaenias: *Haemoglobin concentrotion <10g/dL, neutrophils < 1800/μL and plotelets <100,000/μL.*

Risk Categories	Overall Score	Median Survival (Years) in Absence of Therapy
Low	0	5.7
Intermediate - 1 (Int-1)	0.5 to 1.0	3.5
Intermediate - 2 (Int-2)	1.5 to 2.0	1.1
High	>2.5	0.4

Table 4: Summary of Medical Management of Myelodysplastic Syndromes

All Patients		Best Supportive Therapy	
Patient Characteristics		**First-line Treatment**	**Second-line Treatment**
IPSS: Low, Int-1	Anaemia	Lenalidomide	Other treatment/BMT
	Del 5q	EPO/DBO ± G-CSF	AZA/DEC or Other/BMT
	S EPO < 500 mU/mL	ATG/CSA	
	S EPO >500 mU/mL	AZA/DEC	ATG/Other
	Thrombocytopaenia/Neutropaenia		
IPSS: High, Int-2	Transplant candidate	BMT	
	No Donor	AZA/DEC/Chemotherapy	
	Comorbid	Supportive care	
Selected Patients	High serum ferritin + (a) BMT candidate or (b) expected long survival	Iron chelation	

Int = Intermediate; BMT = Bone marrow transplantation; EPO = Erythropoietin; DBO = Darbepoietin; G-CSF = Granulocyte-colony stimuloting foctor; AZA = Azocytidine; DEC = Decitobine; ATG = Anti-thymocyte globulin; CSA = Cyclosporine A.

Supportive Care Alone

For most patients with MDS, observation and supportive care is appropriate. Blood transfusions for symptomatic anaemia should be given.

Erythropoiesis Stimulating Agents: Erythropoietin and Darbepoietin

Relief of anaemia with erythropoiesis stimulating agents (ESAs) + granulocyte-colony stimulating factor (G-CSF) is effective in about 25% of mainly low-risk MDS patients. If there is no response in 8 weeks, this should be stopped. Predictors of response are low or nil requirement of blood transfusions and relatively low levels of serum erythropoietin for the degree of anaemia.

Iron Chelation

Recently, a number of guidelines have recommended iron chelation in patients with transfusional iron overload, but this is not universally accepted. Effective iron chelation is known to improve survival in patients with thalassaemia, but the survival benefit is usually associated with 10 years of iron chelation. Since most newly diagnosed patients with MDS are older than 70 years, it is unclear whether they will survive long enough to achieve any benefit from expensive iron chelation. It seems reasonable to use iron chelation in chronically transfused patients who are expected to live for many years.

Lenalidomide

Lenalidomide, an oral immunomodulatory agent, has been approved for the management of MDS classified as low risk or intermediate-1 risk and with a deletion 5q cytogenetic abnormality. The recommended dose is 10 mg per day continuously. Cytopaenias are common and are particularly pronounced in MDS with deletion 5q, but the majority of cytopaenias occur in the first 8 weeks of the treatment. The major benefit is independence from transfusion.

Immunosuppression in Myelodysplastic Syndrome

The present guidelines for the treatment of MDS recommend use of immunosuppressive therapy for a subset of patients likely to respond. Most studies have shown responses between 30% and 50% in selected patients with anti-thymocyte globulin (ATG). Cyclosporine used alone leads to responses in 30% selected patients.

The predictors of response and survival reported are: (a) younger age, (b) low IPSS score, (c) presence of HLA-DR15, (d) shorter duration of red cell transfusion dependence, (e) marrow hypocellularity, and (f) presence of PNH clone.

DNA-Hypomethylating Agents

The United States-Federal Drug Authority (US-FDA) approved the use of DNA-hypomethylating agents, 5-azacytidine (AZA)

in 2004 and decitabine in 2006 for use in all subtypes of MDS. These drugs are not curative. In Phase III multicentre trial, patients with higher-risk of MDS were randomly assigned to receive AZA at 75 mg/m^2 per day for 7 days every 28 days or conventional care (best supportive care, low-dose cytarabine, or intensive chemotherapy). After a median follow-up of 21.1 months, median overall survival was 24.5 months for the AZA group *versus* 15.0 months for the conventional care group. The drug should be given for 4–6 cycles before determining whether benefit has occurred. The response rates to decitabine are similar to those observed with AZA.

Bone Marrow Transplantation

The only curative treatment for MDS is allogeneic haematopoietic stem cell transplantation (HSCT). All patients who are considered as eligible for HSCT should be referred to a transplant centre as soon as a diagnosis is made. Younger patients would get myeloablative conditioning, while older ones are given reduced intensity conditioning.

15.12 Chronic Lymphocytic Leukaemia

M Mahapatra, Renu Saxena

Chronic lymphocytic leukaemia (CLL) is a clonal, proliferative disorder of monoclonal B-lymphocytes which is characterised by accumulation of mature looking lymphocytes in the blood, lymph nodes, spleen, bone marrow and other organs. It is not rare in Asians and in India, it forms about 17% of new cases of haematological malignancy. The disease is rare in young people, but the incidence rises in the fourth decade of life and continues to rise exponentially with median age at diagnosis being 70 years.

PATHOPHYSIOLOGY

CLL is a disease of slow accumulation of tumour cells due to disrupted or defective apoptosis. CLL cells overexpress several anti-apoptotic proteins including bcl-2, mcl-1, bak and XIAP and have diminished expression of pro-apoptotic proteins like bax. This leads to monoclonal accumulation of neoplastic B-cells. Recently, it has been shown that micro-RNAs (miRs) may be involved in the pathogenesis and progression of CLL, e.g. miR15 and miR16 at 13q14; miR16 normally regulates expression of bcl-2. Also, silencing of genes by methylation occurs in CLL in a gene-specific manner that is greater than that observed in normal B-cells, providing support for the importance of epigenetic silencing of genes in CLL.

There are two subsets of CLL: (i) leukaemias whose cell of origin has successfully traversed the germinal centre, resulting in the mutated immunoglobulin heavy chain variable region genes (IgVH) phenotype, and (ii) leukaemias that are derived from naïve B-cells with the unmutated (germline) IgVH sequence. Approximately 60% of patients with CLL have cells with mutated IgVH genes (less than 98% identity to germline), whereas the remaining patients have cells exhibiting unmutated IgVH (98% or greater sequence identity with germline) resulting in inferior survival in the latter group.

CLINICAL FEATURES

Although most patients with CLL are elderly, around 25% to 30% patients in India are less than 55 years. Twenty-five per cent of patients may be asymptomatic and diagnosed only on routine blood testing. Common manifestations include: fatigue, malaise and reduced exercise tolerance. Generalised lymphadenopathy and splenomegaly may be noted on physical examination. Less common manifestations are enlargement of tonsils, abdominal masses due to mesenteric or retroperitoneal lymphadenopathy, and skin infiltration. Patients can also present with features of anaemia, which may be related to marrow replacement or more rarely, to autoimmune haemolysis or aplasia. Patients with CLL are prone to repeated infections, such as pneumonia and herpes zoster.

LABORATORY DIAGNOSIS

Diagnostic Criteria

The diagnosis of CLL, as defined by the International Workshop on Chronic Lymphocytic Leukaemia (IWCLL) 2008, requires the presence of at least 5000/μL B-lymphocytes in the peripheral blood. The clonality of the circulating B-lymphocytes needs to be confirmed by flow cytometry. In the absence of lymphadenopathy or organomegaly (as defined by physical examination or computed tomographs), cytopaenias, or disease-related symptoms, the presence of less than 5000/μL B-lymphocytes is defined as 'monoclonal B-lymphocytosis' (MBL). MBL may progress to frank CLL at a rate of 1% to 2% per year. The definition of small lymphocytic lymphoma (SLL) requires the presence of lymphadenopathy and/or splenomegaly with less than 5000/μL B-lymphocytes in blood.

Peripheral Blood and Bone Marrow

A complete blood count, review of the peripheral smear, and immunophenotyping are required for diagnosis and prognosis in CLL. On peripheral smear examination, the lymphocytes appear mature with a 'soccer ball' chromatin pattern. There are increased 'smudge cells' or 'basket cells' as a result of the fragility of the CLL cells (**Figure 1**). Those patients with ≥30% smudge cells are more likely to have mutated IgVH and have a better prognosis than with more than 30% smudge cells. Some cases have increased large cells, atypical cells or prolymphocytes (<55%), with more open chromatin and prominent 'punched-out' nucleoli. If ≥55% of the cells are prolymphocytes, it is diagnosed as prolymphocytic leukaemia.

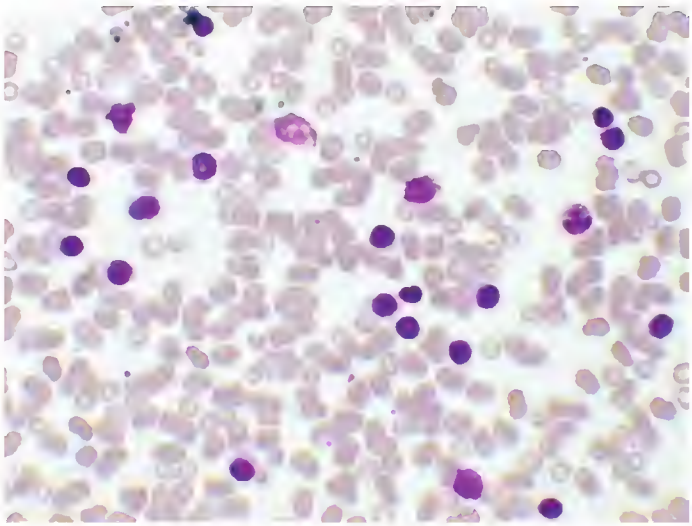

Figure 1: Chronic lymphocytic leukaemia. Peripheral smear showing leucocytosis with mature lymphocytes and degenerated basket cells.

In addition to lymphocytosis, anaemia, (with spherocytic RBC as shown in **Figure 2**) neutropaenia and thrombocytopaenia can develop as a consequence of bone marrow infiltration or chemotherapy. Hypogammaglobulinaemia is common in CLL and becomes more frequent and marked as the disease progresses.

The bone marrow aspirate in patients with CLL characteristically shows greater than 30% lymphoid cells. The bone marrow biopsy shows nodular, interstitial, mixed or diffuse infiltrate of CLL

cells. Although bone marrow examination provides important information about marrow reserve, pattern of infiltration, etc. it is not mandatory for the diagnosis if peripheral blood lymphocytes are consistent with CLL on morphology and immunophenotyping. It may be useful under the following circumstances:

1. To assess normal marrow reserve and to establish the cause of anaemia and thrombocytopaenia.
2. To rule out paratrabecular localisation or cyclin D1 staining in atypical cases.
3. To assess the pattern of marrow infiltration, which is of prognostic value.
4. To assess response following chemotherapy—minimal residual disease (MRD)—negative marrow following chemotherapy predicts a prolonged remission.

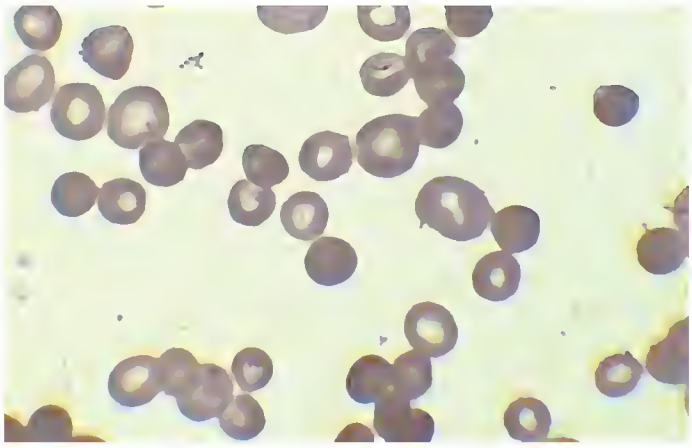

Figure 2: Peripheral smear showing spherocytic red blood cells in patients with CLL.

Immunophenotype

It is of vital importance to differentiate correctly CLL from other condition which mimic like CLL. This is to properly & effectively use new and effective treatment for CLL (**Table 1**). Flow cytometry, or immunophenotyping is now the standard approach to establish the diagnosis of CLL. CLL cells have a relatively consistent immunophenotype, which differentiates CLL from mantle cell lymphoma, hairy cell leukaemia, follicular centre cell lymphoma, splenic lymphoma with villous lymphocytes, and other indolent B-cell malignancies.

Table 1: Diseases that can Mimic Chronic Lymphocytic Leukaemia

Malignant Causes	
B-Cell	
	Monoclonal B-cell lymphocytosis
	Prolymphocytic leukaemia
	Mantle cell lymphoma
	Follicular lymphomas
	Splenic lymphoma with villous lymphocytes
	Hairy cell leukaemia
	Waldenström macroglobulinaemia
T-Cell	
	Polygranular lymphocytic leukaemia
Benign Causes	
Bacterial (e.g. tuberculosis)	
Viral (e.g. infectious mononucleosis)	

CLL cells express B-cell markers, including dim sIg, CD19, dim CD20 and CD23, as well as the pan T-cell marker CD5. Kappa or lambda restriction is always present, establishing the presence of a clonal B-cell population. In contrast, presence of CD10, FMC7, or CD79b (all typically absent on CLL cells) or bright expression of CD11c, CD20, or CD25 (all typically dim on CLL cells) suggests an alternative low-grade B-cell lymphoproliferative malignancy. Expression of CD5 without CD23 suggests mantle cell lymphoma. CLL is always a B-cell neoplasm and the World Health Organization nomenclature reclassified the entity formerly known as T-CLL as T-prolymphocytic leukaemia. Repeating immunophenotyping after the initial diagnosis is not required unless there is a suspicion of transformation to a more aggressive histology or for presence of minimal residual disease following treatment.

Surrogate Markers for IgVH Mutational Status

Both CD38 and ZAP-70 have been evaluated as surrogate markers for IgVH mutational status, as these can be measured readily by flow cytometry. CLL patients with more than 30% CD38+ cells had unmutated IgVH and a worse prognosis than those with less than 30% CD38+ cells. However, there is disagreement about the number of cells that are required to define positivity, with values ranging from 5% to 30%. ZAP-70 is a member of the Syk-ZAP-70 protein kinase family and is expressed in T-cells and natural killer cells. B-cells may also express ZAP-70, particularly when activated. Gene expression studies in CLL have shown that cells with unmutated IgVH have increased expression of ZAP-70 (>20% cells positive), whereas those with mutations have low levels. ZAP-70 positivity also correlates moderately with CD38 positivity and the presence of poor-risk cytogenetics, i.e. del 11q22–q23, del 17p13, and trisomy 12. Moreover, unlike CD38, the ZAP-70 status appears stable over time. The major obstacle in the routine use of ZAP-70 is the variability in the assay as a result of the sensitivity of different antibodies and differences in protocols for sample preparation and analysis.

Cytogenetics

Conventional metaphase cytogenetics can identify chromosomal aberrations in only 20% to 50% of cases, because of the low *in vitro* mitotic activity of CLL cells. Abnormalities noted in descending frequency of occurrence include trisomy 12, deletions at 13q14, structural aberrations of 14q32, and deletions of 11q, 17p, and 6q. Interphase cytogenetics by fluorescence *in situ* hybridisation (FISH) improves the sensitivity of detecting abnormal cytogenetics (80% cases) with 13q14 deletion being the most common. The two microRNA genes, associated with the good prognostic group 13q14 deletion, are miR-15 and miR-16.

STAGING

On the basis of clinical features and bone marrow involvement, CLL can be staged according to Rai and Binet staging system (**Table 2**). Both staging system have important role in predicting the median survival and for treatment planning.

PROGNOSTIC FACTORS

Patients in low and intermediate groups may have an indolent course spanning over decades or may progress rapidly with shortened survival. Recently, few other prognostic factors have been identified in patients with CLL (**Table 3**).

Table 2: Rai and Binet Staging of Chronic Lymphocytic Leukaemia

Rai Staging

Stage	Modified Stage	Description
0	Low risk	Lymphocytosis
I	Intermediate risk	Lymphocytosis + Lymphadenopathy
II	Intermediate risk	Lymphocytosis + Splenomegaly ± Lymphadenopathy
III	High risk	Lymphocytosis + Anaemia ± Splenomegaly or Lymphadenopathy
IV	High risk	Lymphocytosis + Thrombocytopaenia ± Anaemia ± Splenomegaly ± Lymphadenopathy

Binet Staging

Stage	Blood Counts	Involved Areas
A	Haemoglobin: >10.0 g/dL and platelets: >100 x 10^9/L	<3
B	Haemoglobin: >10.0 g/dL and platelets: >100 x 10^9/L	>3
C	Haemoglobin: <10.0 g/dL and platelets: <100 x 10^9/L or Both	Any number

Note: For Roi staging: Anoemio = hoemoglobin <11 g/dL; thrombocytopoenio = plotelets <100 x 10^9/L; lymphocytosis = >15 x 10^9/L.

For Binet staging following constitute one oreo each: Cervicol lymph nodes (LN), oxillory LN, inguinol LN, spleen, liver.

Table 3: Prognostic Factors in Chronic Lymphocytic Leukaemia that Predict an Unfavourable Outcome

Routine Markers

- Advanced Rai and Binet clinical stage
- Lymphocytic doubling time less than 12 months
- Elevated lactic dehydrogenase
- Elevated β2 microglobulin level
- Elevated thymidine kinase
- Elevated soluble CD23
- Atypical morphology or CLL/PLL
- Diffuse pattern of bone marrow infiltration
- Fludarabine resistance

Newer Markers

- Del(11q) and del(17p) using interphase FISH
- Unmutated immunoglobulin heavy chain variable region genes (IgVH genes)
- VH3.21 gene usage independent of IgVH
- ZAP-70 (≥20% positive)
- CD38 (≥30% positive)

TREATMENT

It is estimated that one-third of patients with CLL never require therapy; one-third need treatment at diagnosis; and one-third have disease progression over years and require treatment at some point. The indications for treatment and the type of treatment will vary according to patient's age and condition. The International workshop on CLL guidelines provides objective criteria for starting treatment in patients with CLL (**Table 4**).

Table 4: International Workshop Guidelines on Chronic Lymphocytic Leukaemia for Initiation of Treatment

- Evidence of progressive marrow failure as manifest by worsening anaemia and/or thrombocytopaenia
- Massive (>6 cm below left costal margin) or progressive or symptomatic splenomegaly
- Massive nodes (>10 cm in the largest diameter) or progressive or symptomatic lymphadenopathy
- Progressive lymphocytosis with an increase of more than 50% over a period of 2 months or lymphocyte doubling time of <6 months
- Autoimmune anaemia and/or thrombocytopaenia poorly responsive to corticosteroids or other standard therapy
- Presence of a minimum of any one of the following disease-related symptoms: unintended weight loss of ≥10% body weight within 6 months, significant fatigue (ECOG performance status ≥2), fever of >100.5°F or 38.0°C for 2 or more weeks without infection, night sweats >1 month without infection

Common initial treatments in India include chlorambucil, cyclophosphamide, chlorambucil/prednisolone, fludarabine, fludarabine/cyclophosphamide (FC) or fludarabine/cyclophosphamide/rituximab (FCR). The choice of treatment depends on the aggressiveness of the disease, patient's age and cost of therapy. Although more aggressive chemotherapies may improve the depth and duration of remission, no randomised trials could show that this translates into improved survival. Recently, a large randomised trial has demonstrated that FCR improves overall survival, compared to FC, in previously untreated patients with advanced CLL.

Chemotherapeutic Agents

Chlorambucil

Oral chlorambucil in a dose of 0.1 to 0.4 mg/kg per day has served as initial, front-line therapy for CLL for several decades and is still considered appropriate by many specialists, particularly in a frail or medically unfit patient. The advantages of single agent chlorambucil or cyclophosphamide are related to their toxicity profiles, low cost and convenience in use, however, they are associated with very low complete response rate. Combination of chlorambucil and prednisolone (20 to 80 mg per day) given for 15 days and repeated every month for a maximum of 6 months, leads to a better response rate, but with no survival advantage.

Fludarabine

Fludarabine, a purine analogue inhibits the synthesis of DNA, RNA and proteins and also activates apoptosis. Fludarabine as a single agent therapy has been shown to achieve higher response rate and progression-free survival when compared to chlorambucil. It is administered in the dose of 25 mg/m^2 for 5 consecutive days and repeated every 4 to 6 weeks for 4 to 6 cycles. Myelosuppression, immunosuppression, autoimmune haemolytic anaemia, hearing loss, renal failure and skin rash can be observed as the adverse effects. Phase 2 trials showed that FC produces increase response rates and progression free survival in patients with CLL.

Bendamustine

Single agent bendamustine has shown improved responses when compared with chlorambucil. Complete responses are reported in 31% of bendamustine recipients *versus* 2% with chlorambucil.

Monoclonal antibodies

Rituximab (monoclonal anti-CD20 antibody) as a single agent in high-doses or in combination with fludarabine and cyclophosphamide can achieve high response rates in patients with CLL. Alemtuzumab is a recombinant DNA-derived humanised monoclonal antibody (Campath-1H) that is directed against the CD52, protein present on the surface of mature B- and T-lymphocytes. It is used as second-line therapy for CLL patients who have failed fludarabine therapy. Immunosuppression and infusional reactions are common adverse effects.

Haematopoietic Stem Cell Transplantation (HSCT)

Autologous stem cell transplantation (Auto-SCT) may prolong progression-free survival in patients with CLL and low-risk features. However, it does not appear to be curative in CLL and its use is rapidly declining with advent of modern immunochemotherapy. Allogeneic stem cell transplantation (Allo-SCT) remains a unique modality because of its graft-*versus*-CLL effect and can be effective in otherwise refractory disease. However, its role in CLL is less defined, except for young patients with high-risk features, because of the high treatment related mortality. Recently, with the development of reduced intensity conditioning regimens, a good number of patients of CLL are managed with Allo-SCT.

COMPLICATIONS IN CHRONIC LYMPHOCYTIC LEUKAEMIA

Infections

Infection remains a potentially lethal complication of CLL. Though its pathogenesis is multifactorial, hypogammaglobulinaemia is the major defect. Patients treated with purine analogues develop infections with opportunistic pathogens like *Pneumocystis jirovecii, Aspergillus* and *Candida.* Antifungal and co-trimoxazole prophylaxis should be given to all patients on treatment. Use of prophylactic gammaglobulin reduces infection-related morbidity (not mortality), but is very expensive.

Autoimmune Phenomenon

Autoimmune haemolytic anaemia (AIHA)

CLL patients can have dysregulated immunity leading to formation of immunogloublin (Ig)G antibodies against surface red blood cell antigen. This results in haemolytic anaemia. AIHA occurs in 10% patients of CLL. Prednisolone at the dose of 1 mg/kg per day is the treatment of choice.

Pure red cell aplasia (PRCA)

PRCA in CLL is characterised by severe anaemia, reticulocytopaenia and depleted red cell precursors in the bone marrow. Control of CLL is necessary for the resolution of PRCA. Additional treatment with corticosteroids may be required.

Autoimmune thrombocytopaenia

Autoimmune thrombocytopaenia or secondary ITP may be observed in patients of CLL.

Richter Transformation

A Richter transformation occurs when CLL transforms into another lymphoid malignancy, such as prolymphocytic leukaemia, diffuse large cell lymphoma, Hodgkin's disease, multiple myeloma or acute leukaemia. *Richter syndrome* refers to the development of a diffuse large B-cell lymphoma or its immunoblastic variant in a patient with CLL.

15.13 Lymphoid Neoplasms

Bharath Rangarajan, Purvish M Parikh

Lymphoid neoplasms consist of cancers grouped together because they arise from the cells of the immune system. However, they are clinically heterogeneous and distinction between different entities and accurate diagnosis is essential for prognostication and treatment. The previous classifications have mainly relied on the morphological features of the lymphomas and some have also taken clinical behaviour into consideration. The identification of Reed-Sternberg (RS) cell separated Hodgkin's lymphoma from non-Hodgkin's lymphoma (NHL). The presence of lymphoid blasts in the peripheral blood distinguishes acute lymphoblastic leukaemia (ALL) from chronic lymphocytic leukaemia (CLL) and other chronic lympho-proliferative disorders which show mature lymphoid cells in the peripheral blood. The current WHO classification relies on morphological, immunophenotypic, genetic and clinical features to subtype lymphomas (**Table 1**).

HODGKIN'S LYMPHOMA

Hodgkin's disease or lymphoma is characterised by pleomorphic lymphocyte infiltrate interspersed by malignant multinuclear giant cells (RS cells). After a long controversy regarding the cell of origin of the pathological RS cells, now it has been accepted that Hodgkin's-RS cells are clonal lymphoma cells derived from B-cells, hence the term Hodgkin's lymphoma is preferred over the Hodgkin's disease. The majority of patients in developing countries are associated with Epstein-Barr virus (EBV) in the RS cells (as compared to 33% positivity in USA). Chronic stimulation due to EBV infection is postulated to result in pleomorphic infiltration; some of the cells undergo a clonal malignant transformation subsequently. Hodgkin's lymphoma is different from other cancers. The malignant RS cells form only a fraction of the enlarged lymphoid tissue. Rarely Hodgkin's lymphoma can be familial.

History and Physical Examination

There is a bimodal age distribution with one peak in mid to late twenties and the other one in late adulthood. The usual presentation is with painless lymphadenopathy, commonly in cervical region (76%). These have a characteristic rubbery feel. Other areas of involvement include lymphoid tissue in the mediastinum (60%), abdomen and groin, axilla, and spleen (20% to 25% each). Less common sites include liver, bone marrow, extra-nodal soft tissue, lungs, bone, pleura, pericardium and Waldeyer's ring; bony involvement is characterised by sclerosis. Constitutional symptoms (commonly termed as B symptoms) indicate systemic disease.

These include unexplained weight loss (>10% of body weight over 6 months), unexplained fever (>38°C for >3 days) and drenching night sweats. Symptoms like pruritus, pain in enlarged lymph nodes after consuming alcohol and Pel-Ebstein fever (alternating febrile and afebrile periods lasting for several days) are uncommon. As many as 47% of cases are wrongly treated with anti-tubercular drugs before the correct diagnosis is achieved stressing the importance of biopsy and confirmation of diagnosis.

Table 1: WHO Staging of Non-Hodgkin's Lymphoid Neoplasms

Precursor B- and T-Cell Neoplasms
Precursor B-lymphoblastic leukaemia/lymphoma
Precursor T-lymphoblastic leukaemia/lymphoma

Mature B-Cell Neoplasms
Chronic lymphocytic leukaemia/small lymphocytic lymphoma
B-cell prolymphocytic leukaemia
Lymphoplasmacytic lymphoma/Waldenstrom macroglobulinaemia
Splenic marginal zone B-cell lymphoma
Hairy cell leukaemia
Plasma cell neoplasms
- Plasma cell myeloma
- Plasmacytoma
- Monoclonal immunoglobulin deposition diseases
- Heavy chain diseases

Extra-nodal marginal zone B-cell lymphoma (MALT lymphoma)
Nodal marginal zone B-cell lymphoma
Follicular lymphoma
Mantle cell lymphoma
Diffuse large B-cell lymphoma
Mediastinal (thymic) large B-cell lymphoma
Intravascular large B-cell lymphoma
Primary effusion lymphoma
Burkitt lymphoma/leukaemia
Lymphomatoid granulomatosis

Mature T- and NK-Cell Neoplasms
T-cell prolymphocytic leukaemia
T-cell large granular lymphocytic leukaemia
Aggressive NK-cell leukaemia
Adult T-cell leukaemia/lymphoma
Extra-nodal NK-T-cell lymphoma, nasal type
Enteropathy type T-cell lymphoma
Hepatosplenic T-cell lymphoma
Sub-cutaneous panniculitis like T-cell lymphoma
Blastic NK-cell lymphoma
Mycosis fungoides/Sezary syndrome
Primary cutaneous CD30 positive T-cell lymphoproliferative disorders
- Primary cutaneous anaplastic large cell lymphoma
- Lymphomatoid papulosis
- Borderline lesions

Angioimmunoblastic T-cell lymphoma
Peripheral T-cell lymphoma, unspecified
Anaplastic large cell lymphoma

Immunodeficiency Associated Lymphoproliferative Disorders
Lymphoproliferative diseases associated with primary immune disorders
Human immunodeficiency virus-related lymphomas
Post-transplant lymphoproliferative disorders
Methotrexate-associated lymphoproliferative disorders

WHO classification of Hodgkin's lymphoma identifies 2 classes

1. Classical Hodgkin's lymphoma (CHL): CHL is further subdivided into 4 subtypes:
   (a) Nodular sclerosis (NS)
   (b) Mixed cellularity (MC)
   (c) Lymphocyte-rich
   (d) Lymphocyte-depleted
2. Nodular lymphocyte-predominant Hodgkin's lymphoma (NLPHL)

Diagnosis of Hodgkin's lymphoma requires demonstration of typical RS cells in the biopsy. Fine needle aspiration cytology (FNAC) can be misleading in patients with suspected lymphoma. RS cells are large multi-nucleated giant cells with a clear halo around prominent nucleoli (caterpillar or owl-eye appearance), which are scattered amidst a background rich in lymphocytes, histiocytes, eosinophils and plasma cells, effacing the normal lymphoid architecture. Based on the relative preponderance of these cells as well as the degree of sclerosis or fibrosis, various subtypes of Hodgkin's lymphoma are identified. Immuno-phenotyping suggests positivity for CD15 and CD30 in CHL and for CD45 in NLPHL, along with other B-cell markers.

Nodular sclerosis is the most common subtype in the Western population. Developing countries like India have mixed cellularity as the commonest histology (66% to 74%). Patients with lymphocyte predominant type tend to have localised disease and no symptoms. They also have increased risk of a second malignancy, and therefore, they are cured by less intensive therapy. As a general rule, however, histological type does not influence treatment decisions in classical Hodgkin's lymphoma with NLPHL being the exception where early stages may require only observation or radiotherapy alone.

Staging

The common perception is that Hodgkin' lymphoma spreads to contiguous areas through lymphatics. The Ann Arbor staging system is based on this concept (**Table 2**). The diagnostic and staging work-up is shown in **Table 3**. Originally a staging laparotomy and splenectomy was considered mandatory for staging. With the availability of better imaging modalities, staging laparotomy has hardly any role in the present era.

The advent of positron emission tomography in staging and prognostication of Hodgkin's lymphoma has now given birth to the philosophy of response based escalation or de-escalation of treatment. PET based staging and response evaluation tailored treatment also allows for identification of high-risk group patients, poor responders and non-responders to chemotherapy and subsequent appropriate escalation of treatment to improve cure rates. This prevents unnecessary over-treatment and long-term treatment related complications. In addition to staging, other prognostic factors like mediastinal involvement, 'X' disease, lactate dehydrogenase levels are important prognostic factors which determine the aggressiveness of the therapy. The adverse prognostic factors for early stage disease include higher age, elevated erythrocyte sedimentation rate, large mediastinal man, not Nodular lymphocyte-predominant Hodgkin's lymphoma or nodular sclerosis an histology and more than 4 involved nodal regions. Adverse prognostic factors for the advance disease are presented in **Table 4**.

Table 2: Ann Arbor Staging for Lymphoma

Stage	Description
I	Involvement of a single lymph node region or a single extralymphatic organ or site (IE)
II	Involvement of two or more lymph node regions on the same side of the diaphragm (II) or localised involvement of an extralymphatic organ or site (IIE)
III	Involvement of lymph node regions on both sides of the diaphragm (III) or localised involvement of an extralymphatic organ or site (IIIE) or spleen (IIIS) or both (IIISE)
IV	Diffuse or disseminated involvement of one or more extralymphatic organs with or without associated lymph node involvement. Bone marrow and liver involvement are always stage IV

Designation of Alphabetical Suffixes in Lymphoma Staging

A	No symptoms
B	Fever (temperature, >38°C), drenching night sweats, unexplained loss of >10% body weight within the preceding 6 months.
X	Bulky disease (a widening of the mediastinum by more than one-third or the presence of a nodal mass with a maximal dimension >10 cm).
E	Involvement of a single extra-nodal site that is contiguous or proximal to the known nodal site.

Table 3: Diagnostic and Staging Work-up in Lymphoma

Mandatory Procedures

History: Fever, weight loss and night sweats
Physical examination: Measurement of all palpable lymph node with biopsy of doubtful nodes
Tissue excision biopsy for immunohistochemistry and further cytogenetic/molecular studies if needed (not FNAC)
Complete blood count and biochemistry (including LDH)
Chest radiograph
Computed tomography (CT) of thorax, abdomen and pelvis
Bone marrow biopsy and aspiration

Optional Procedures

Post-nasal space/Neck CT if cervical nodes are involved
Liver biopsy
Radioisotope bone scan if stage IV
Pleural cytology if there is pleural effusion
PET scan (accepted staging procedure in Hodgkin's and for response evaluation in NHL)
Lymphangiography and Gallium scan (decreasing use after PET scan availability)
Staging laparotomy with splenectomy (not done at present time)
Bone scan and skeletal survey
MRI (if suspicion of CNS disease/parameningeal or intracranial extension of disease)
Lumbar puncture and CSF examination (if suspicion of CNS disease/testicular involvement/parameningeal or intracranial extension of disease)

FNAC = Fine needle aspiration cytology; LDH = Lactate dehydrogenase; PET = Positron emission tomography; NHL = Non-Hodgkin's lymphoma; CNS = Central nervous system; MRI = Magnetic resonance imaging; CSF = Cerebrospinal fluid.

Treatment

Chemotherapy

Various chemotherapeutic regimen are listed in **Table 5**. ABVD regimen is associated with less myelotoxicity, less incidence of secondary leukaemias and infertility; and has been established as the standard chemotherapeutic regimen in patients with Hodgkin's lymphoma. The stage of the disease and the

prognostic factors decide the number of cycles required and the necessity of radiotherapy.

Radiotherapy

Radiotherapy was the mainstay of treatment in Hodgkin's lymphoma. For supra-diaphragmatic disease, *Mantle field* radiation was used. The mantle field comprises of submandibular, cervical, supra-clavicular, infra-clavicular, axillary, mediastinal, subcarinal and hilar lymph nodes. Para-aortic (involving para-aortic lymph nodes up to L4-5 - *Inverted 'Y' field*, splenic and pelvic field radiation was used for infra-diaphragmatic disease. These extensive radiation fields were associated with higher incidence of radiation toxicities which has led to the development of smaller radiation portals. In involved field radiation (IFRT) that is commonly used in the present era of combined modality treatment, the field encompasses the involved lymph node regions (e.g. upper cervical and supraclavicular lymph nodes in one field).

Combined modality therapy

Combined modality therapy including radiotherapy and chemotherapy is now the standard treatment for almost all advanced stage Hodgkin's lymphoma and for selected patients with early stage disease. Advantages of such a strategy include early effective treatment of systemic disease, delay in induction of irreversible loss of bone marrow function and potential to use smaller radiotherapy field.

Treatment of relapses

The relapse rate of Hodgkin's lymphoma varies from approximately 20% for the early stage favourable, 30% for the early stage unfavourable, and over 50% for the advanced Hodgkin's lymphoma with multiple poor prognostic factors. A large number of these patients can be salvaged with second-line chemotherapy regimens (**Table 6**).

High-dose chemotherapy followed by autologous haematopoietic stem cell transplant (Bone marrow transplant) has been used extensively in patients with relapsed and refractory Hodgkin's lymphoma, the rationale being based on a steep dose-response relationship.

Table 6: Treatment Strategies in Patients with Hodgkin's Lymphoma Based on Stage of Disease

Stage	Treatment
Early stage favourable	Chemotherapy (2 ABVD) and involved field RT
Early stage unfavourable	Chemotherapy (6-8 cycles) + involved field RT
Advanced stage	Chemotherapy (8 cycles) with or without consolidating local RT (20-30 Gy)/RT to X disease

RT = Radiotherapy.

NON-HODGKIN'S LYMPHOMA

NHL is a group of lymphoid malignancies resulting from the clonal expansion of B- or T-lymphocytes (**Table 1**).

Aetiology and Pathogenesis

The cause in most cases of NHL is unknown. Various factors associated with the development of NHL are shown in **Table 7**.

Table 7: Aetiologic Factors Implicated in the Development of Non-Hodgkin's Lymphoma

Immunodeficiency: SCID, hypogammaglobulinaemia, ataxia telangiectasia, Wiskott-Aldrich syndrome
Infections: EBV, HTLV-I, HIV, HHV-8, HCV, *Helicobacter pylori*, *Chlamydia psittaci*
Herbicides: 2, 4-dichlorophenoxy acetic acid
Diet: Meat, fat
Previous treatment for Hodgkin's disease

SCID = Severe combined immunodeficiency; EBV = Epstein-Barr virus; HTLV = Human T-cell lymphotropic virus; HIV = Human immunodeficiency virus; HHV = Human herpes virus.

It is now accepted that the incidence of certain lymphomas increases in immunodeficient subjects, e.g. HIV associated or congenital immunodeficiency syndromes. The increased incidence of lymphomas in immunodeficient individuals is associated with infectious agents, e.g. Kaposi's sarcoma and primary effusion lymphoma with human herpes virus-8, primary central nervous system (CNS) lymphoma and post-transplant lymphomas with EBV. The association of certain subtypes of lymphomas with bacterial infections is also now established and includes mucosa-associated lymphoid tissue lymphoma with *Helicobacter pylori*, primary cutaneous lymphoma with *Borrelia burgdorferi*, and ocular adnexal lymphoma with *Chlamydia psittaci*.

Lymphoid neoplasms are also associated with specific cytogenetic abnormalities and oncogene rearrangements which place normally silent genes next to promoter regions of immunoglobulin (Ig) or T-cell receptor (TCR) which activates the gene and initiates oncogenesis. These are summarised in **Table 8**.

Classification

The 1995 classification of NHL, provided by the WHO is commonly followed (**Table 1**).

History and Physical Examination

Clinically, most patients present with lymph node enlargement with or without hepatosplenomegaly. Extra-lymphatic presentations are common in the regions of head and neck, gastrointestinal tract, skin, bone marrow and rarely in the bone, testis, liver and lungs. The presence of B symptoms is known to have an adverse prognosis in patients.

Table 8: Cytogenetic and Molecular Abnormalities Associated with Non-Hodgkin's Lymphoma

t(8;14) (q23;q32)	c-MYC/IgH	Burkitt lymphoma
t(2;8) (p12;q23)	c-MYC/Igκ	Burkitt lymphoma
t(8;22) (q23;q11)	c-MYC/Igλ	Burkitt lymphoma
t(11;14) (q13;q32)	BCL1(CCND1)/ IgH	Mantle cell lymphoma, plasma cell myeloma
t(14;18) (q32;q21)	BCL2/IgH	Follicular lymphoma, diffuse large B-cell lymphoma
t(3;14) (q27;q32) and t(V;3q27)	BCL6/IgH, variable/BCL6	Large B-cell lymphoma, follicular lymphoma
t(14;18) (q32;q21)	MALT1/IgH	MALT lymphoma (gastric, pulmonary)
t(3;14) (p14;q32)	FOXP1/IgH	MALT lymphoma (ocular adnexal, thyroid)
t(1;14) (p22;q32)	BCL10/IgH	MALT lymphoma (pulmonary)
t(9;14) (p13;q32)	PAX5(BSAP)/ IgH	Lymphoplasmacytic lymphoma, plasma cell myeloma
inv(14) (q11;q32) or t(14;14) (q11;q32)	TCRÎ±/TCL1	T-prolymphocytic leukaemia
t(X;14) (q28;q11)	TCRÎ±/MTCP1	T-prolymphocytic leukaemia
t(11;18) (q21;q21)	AP12/MLT	MALT lymphoma
t(2;5) (p23;q35)	NPM/ALK	ALCL (70% to 80%)
t(1;2) (q25;p23)	TPM3/ALK	ALCL (10% to 20%)

Laboratory Evaluation

Laboratory studies are shown in **Table 3**. Immunophenotyping and flowcytometry studies on biopsy sample are valuable for sub-classification of NHL, prognostication and treatment planning (use of monoclonal antibody, e.g. rituximab-anti-CD20 antibody). Cerebrospinal (CSF) studies are necessary to rule out CNS involvement in selected cases. Imaging studies include chest radiography, computed tomography of chest and abdomen. Positron emission tomography has emerged a valuable non-invasive, bio-imaging technique for accurate staging and re-staging of lymphomas.

Staging System

The anatomic staging system used is the Ann Arbor staging (**Table 2**).

Prognostic Factors

The prognostic factors also determine the risk of relapse in patients with lymphoma and the International prognostic index (IPI) predicts the response and survival rates with standard chemotherapy (**Table 9**).

Table 9: Non-Hodgkin's Lymphoma-International Prognostic Index (IPI) and Follicular Lymphoma-IPI and Treatment Outcomes

Score	Complete Response (%)	5-Year Survival (%)
International prognostic index		
0,1	35	73
2	27	51
3	22	43
4,5	16	26
Follicular lymphoma international prognostic index		
0,1	36	90
2	37	77
3,4,5	27	52

Treatment

Each individual patient has to be subtyped and treatment planned according to type of NHL, age, performance score, co-morbidities, etc. This is essential as the disease specific treatment can achieve high cure rates in some types of NHL, e.g. cure rates above 90% in paediatric patients with Burkitt's lymphoma with appropriate chemotherapy protocol.

Low-grade NHL

The indolent histological subtypes of NHL include follicular lymphoma, marginal zone lymphoma, lymphoplasmacytic lymphoma, and small lymphocytic lymphoma. More than 80% of patients present with advanced stage disease with bone marrow involvement. However, even in advanced stage, most patients are asymptomatic. Although chemotherapy produces responses in most patients, the disease-free survival and overall survival may not be altered by chemotherapy. The median survival is 7 to 8 years. Chemotherapy regimens may include cyclophosphamide, vincristine and prednisolone or anthracycline based regimen like cyclophosphamide, doxorubicin, vincristine and prednisolone (CHOP). The newer purine analogue fludarabine alone or in combination with cyclophosphamide or mitoxantrone is associated with higher response rates and longer disease-free survival and is one of the first-line chemotherapy regimens at present.

The current standard of care in CD 20 positive NHL is chemo-immunotherapy. Rituximab is a chimeric monoclonal antibody (MoAb) directed against the B-cell-specific antigen CD20 expressed on NHL. It induces apoptosis and use with chemotherapy has reported better outcomes. Maintenance

with rituximab has also shown to improve relapse-free interval and overall survival in follicular NHL. The drug is usually well tolerated except for infusional reactions in few patients. In elderly patients with localised disease it may be worthwhile to defer chemotherapy till the symptoms develop. The use of radio-immunotherapy with Yttrium 90 (^{90}Y) or Iodine 131 (^{131}I) conjugated anti CD20 antibodies, though effective in relapsed and refractory settings, is limited in India mainly due to lack of availability. High-dose chemotherapy with autologous bone marrow transplant may be considered in patients with relapsed diseases particularly in young patients.

High-grade NHL

Diffuse large B-cell lymphoma constitutes more than 50% of the adult high grade NHL. CHOP chemotherapy cyclophosphamide regimen is a commonly used and most extensively studied in patients with high grade NHL. The patients with early stages (IA, IB IIA) and low IPI scores have good long-term survival. This regimen produces complete response in 45% to 55% of patients and cure approximately in 30% to 35%.

Mantle cell lymphoma, anaplastic large cell lymphoma, Burkitt's lymphoma, peripheral T-cell lymphoma, etc. constitute the other group of high grade or aggressive NHL. These lymphomas have poorer cure rates with standard CHOP regime and require more aggressive therapy. Addition of rituximab may be helpful. Other more aggressive regimens are associated with toxicity but no additional survival benefit.

Radiotherapy

Radiotherapy has limited role in the treatment of low grade lymphoma and is used rarely for symptom control in chemo-refractory patients. A select group of patients with high grade lymphomas and 'X' disease, specified extra-lymphatic sites like bone, primary CNS lymphoma, etc. patients may be treated with involved field radiotherapy (whole brain radiotherapy in case of CNS lymphoma).

Treatment of relapsed NHL

As the cure rates and survival of NHL patients have improved steadily in the last 4 decades, relapsed disease is now treated aggressively with salvage regimens with an attempt to cure the disease. The chemotherapy regimens for relapsed disease include DHAP, ESHAP, MINE, ICE, etc. (**Table 5**).

Autologous haematopoietic stem cell transplantation is standard of care for all eligible patients below 65 years of age after achieving disease control with second-line salvage chemotherapy. The conditioning regimens are similar to those for Hodgkin's lymphoma.

ONCOLOGIC EMERGENCIES ASSOCIATED WITH LYMPHOMA

Superior venacaval obstruction syndrome and tumour lysis syndrome are the two common emergencies seen and are discussed in the Chapter "Oncological Emergencies".

CONCLUSIONS

The classification of lymphomas have improved as also the staging with non-invasive diagnostic modalities. Chemotherapy and chemotherapy with biologicals have become the mainstay of treatment and radiotherapy is less preferred mode of treatment in developing countries like India due to cost constraints.

15.14 Plasma Cell Dyscrasias

Pankaj Manubhai Shah

INTRODUCTION

Plasma cells and plasmacytoid lymphocytes are the most mature cells of B-lymphocyte origin and may secrete immunoglobulins (Igs). Plasma cell dyscrasias (PCD) are a group of disorders characterised by uncontrolled proliferation and accumulation of a single clone of immunoglobulin (Ig) secreting cells (plasma cell) and secretion of a structurally homogeneous Ig or its polypeptide chains. Multiple myeloma, Waldenstrom's macroglobulinaemia, primary amyloidosis, heavy chain diseases and monoclonal gammopathy of undetermined significance (MGUS) are traditionally included in this group. Amyloidosis has been discussed separately.

IMMUNOGLOBULIN SYNTHESIS AND STRUCTURE

Ig is synthesised and incorporated into the outer membrane of resting B-lymphocytes. Presentation of an antigen to B-cell results in cell proliferation and subsequently differentiation into a clone of plasma cells, synthesising large amount of antibody specific for the antigen and secretion of the antibody into the extra-cellular fluid. Different antigenic stimuli give rise to antigenically different types of Igs, producing diffuse gamma globulin band on electrophoresis. Basic structure of Ig consists of 2 heavy (H) polypeptide chains and 2 light (L) polypeptide chains of the same type.

IgG, IgA, IgM, IgE and IgD are 5 major types of Igs, each defined by type of heavy chain they possess. The light chain of molecule may be kappa or lambda. IgM is the first Ig produced during primary immune response. IgM is also known as macroglobulin due to its pentameric structure and large size. IgM efficiently binds complement and is restricted to intra-vascular space. IgG is the major Ig in the serum. It is normally produced during secondary immune response. It consists of 4 isotypic subclasses (IgG 1 to 4). It is the only Ig transported across the placenta providing passive immunity to the newborn. IgA is the main antibody in saliva, tears and secretions of gastrointestinal and respiratory tract and serves as the first-line of local defense against environmental agents. IgD is thought to act as a cell surface receptor that binds antigen and triggers B-cell proliferation and differentiation. IgE serum levels can be elevated during parasitic infections or in atopic individuals. IgG makes up the largest proportion of Ig in adult plasma, followed by IgA and IgM. The distribution of these proteins in normal serum is parallel to the observed distribution of monoclonal protein (M protein) types in PCD.

Abnormal Synthesis of Immunoglobulins

Ig production and secretion becomes abnormal when an abnormally large monoclonal population of plasmacytes or lymphocytes cells develops from a single precursor cell. This clone produces identical molecules or identical fragments of Ig. As the secreted Ig is homogeneous, the electrophoretic band is discrete and homogeneous. The M protein spike or band is formed which is commonly referred as a paraprotein. The presence of this paraprotein is the most characteristic feature of PCD. The production of normal Igs may be reduced and the normal antibody responses to antigens may be blunted. In normal Ig synthesis, there is a balance between the heavy and the light chains. There is an imbalance between the heavy and the light chains' synthesis in PCD. In myeloma, the most common abnormality is the excess production of light chains over heavy chains. These excess light chains pass into the extra-cellular fluid and are eliminated in urine as Bence-Jones protein. In 11% of myeloma only light chains are secreted. This type of myeloma is referred to as "Bence-Jones myeloma". In heavy chain disease, the neoplastic cells secrete only fragments of intact molecules of the heavy chains. Very rarely neoplastic plasma cells may not secrete paraprotein.

Detection of Monoclonal Proteins

Clinical presentation of PCD is highly variable and related to the sites of infiltration by neoplastic cells and biochemical properties of the protein being overproduced. Frequently, patients are asymptomatic and the diagnosis is suggested by detection of abnormal protein by laboratory profile. The most important means of detecting PCD is electrophoretic measurement of Ig in both serum and urine. The serum electrophoresis with cellulose acetate membrane is satisfactory for screening purpose. The M protein is usually seen as a dense and discrete band on the cellulose acetate membrane. High-resolution agarose gel electrophoresis is more sensitive for the detection of small M proteins. Immuno-electrophoresis or immunofixation with agarose gel or both should be used to confirm the presence of the M protein and to distinguish the Ig class and its light chain type. Radial immunodiffusion is useful for quantitative assessment of Ig. Bence-Jones proteins are made up of light chains, which cross the glomerular filter. Bence-Jones proteins precipitate at 40-60°C, dissolve at 100°C and reprecipitate on cooling. Routine urine examination does not detect presence of Bence-Jones protein. Immunoelectrophoresis or immunofixation of 24-hour urine specimen reliably detects Bence-Jones protein. The detection of a monoclonal urinary light chain peak in the presence of a large amount of protein including albumin raises the possibility of primary amyloidosis or amyloidosis secondary to myeloma.

AETIOLOGY

The aetiology of PCD is not completely understood. The predisposing factors include radiation exposure, chronic antigenic stimulation and environmental exposure to benzene at work place.

MULTIPLE MYELOMA (MYELOMATOSIS, PLASMA CELL MYELOMA OR KAHLER'S DISEASE)

Multiple myeloma is a malignancy arising from the plasma cell. Myeloma may arise unicentrically or multicentrically from the

bone marrow, or as a localised tumour in other sites. It constitutes 10% of haematological malignancy. Majority of cases are seen above the age of 50 years and male to female ratio is 3:2.

Clinical Features and Complications

Multiple myeloma can remain asymptomatic for many years and 20% of cases may be detected by routine laboratory work-up. In symptomatic patients, clinical consequences result from the abnormal accumulation of myeloma cells within the marrow, causing disruption of normal bone marrow function, reflected by anaemia, destruction and invasion of bone surrounding the bone marrow cavity (**Figures 1 and 2**), production and release of M protein from myeloma into the blood stream and/or into the urine, reduction of normal immune function reflected by reduced level of normal Igs and increased susceptibility to infection.

Skeletal System

Skeletal manifestations result from diffuse or focal areas of osteolysis in anatomic relation to an expanding mass of plasma cells. The patients may present with localised area of bone pain and/or swelling in conjunction with marked tenderness; back pain is common. Severe intractable discomfort may represent pathologic fracture. Compression fractures of vertebra are common and can cause the patient to lose height. In 15% of patients, firm plasma cell tumour arising from underlying bone destruction may be palpated on the skull, sternum, clavicle and ribs. Multiple 'punched-out lytic-lesions' are the most frequent radiographic abnormalities (Figure 1). There is a little osteoblastic activity or periosteal reaction unlike the situation in other metastatic lesions of bones. Occasionally only diffuse osteoporosis is seen, which on microradiography may reveal extensive bone destruction. Isotope bone scan may be normal, as there is minimal osteoblastic activity. Computed tomography (CT) and magnetic resonance imaging (MRI) may detect abnormality when routine radiograph is normal in symptomatic patients.

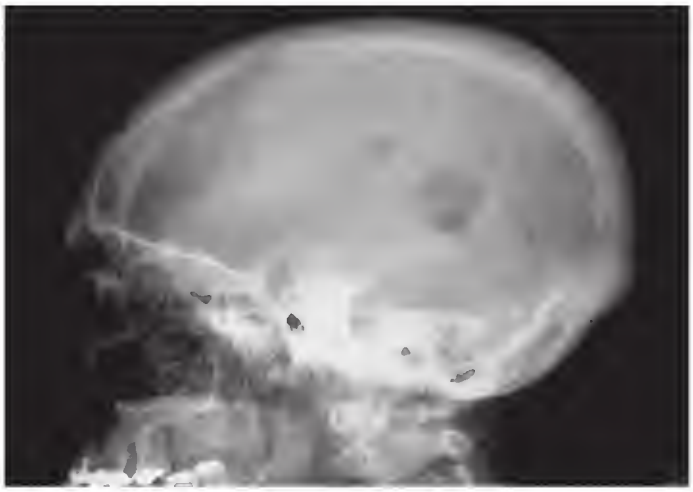

Figure 1: Radiograph of the skull showing multiple punched-out lytic lesions in multiple myeloma.

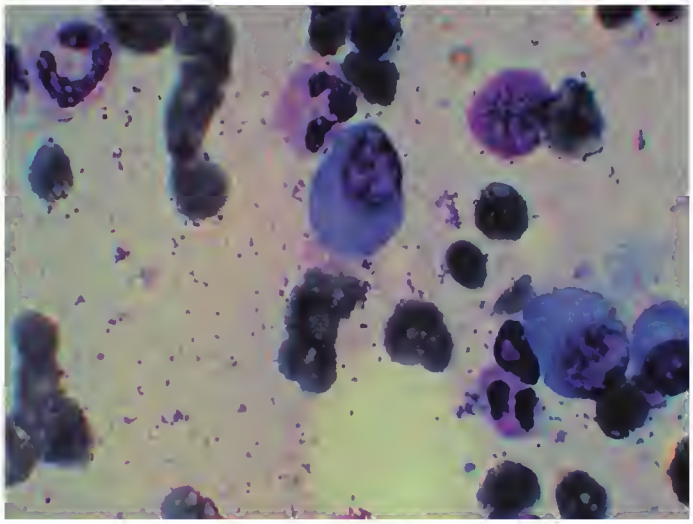

Figure 2: Bone marrow slide showing plasmacytosis. (Haematoxylin and eosin) in multiple myeloma.

Hypercalcaemia

Hypercalcaemia and hypercalciuria due to mobilisation of calcium from bone may accompany myelomatous bone disease. Serum calcium is elevated in one-fourth of patients on presentation. It causes nausea, polyuria, constipation and confusion. It is often precipitated by enforced bed rest and dehydration.

Haematological Manifestations

Normocytic normochromic anaemia is frequent. The peripheral blood smear shows marked rouleaux formation that reflects high globulins. Progressive anaemia, neutropaenia and thrombocytopaenia are suggestive of infiltration of marrow by plasma cells. The M protein may specifically interact with clotting factors leading to acquired clotting abnormalities; it can also coat platelets and interfere with function of platelets. Neutropaenia and inhibition of normal B-cell function leads to the development of bacterial infection. When large number of plasma cells appear in peripheral blood, it is known as plasma cell leukaemia. Bone marrow aspiration shows presence of increased number of plasma cells that may show morphologic abnormalities. Some plasma cells show multinucleation and cytoplasmic vacuoles. When bone marrow aspiration is normal, aspiration from radiological abnormal area should be attempted.

Renal Manifestations

Proteinuria, Bence-Jones proteinuria and elevated serum creatinine levels suggest renal involvement in myeloma. Major causes of renal damage are 'myeloma kidney' and hypercalcaemia. Myeloma kidney is characterised by the presence of large, waxy, laminated casts in the distal and collecting tubules. The casts are composed of mainly precipitated monoclonal light chains. The extent of cast formation correlates directly with the severity of renal insufficiency. Hypercalcaemia and hyperuricaemia are major and treatable causes of renal insufficiency. Amyloidosis and deposition of monoclonal light chains in the renal glomeruli may produce nephrotic syndrome and renal insufficiency. Acquired Fanconi's syndrome may develop due to deposition of light chains in proximal tubule.

Infections

Recurrent bacterial infections are major cause of illness in patients with myeloma due to marked depression of normal immunoglobulin production. *Streptococcus pneumoniae* and *Haemophilus influenzae* are the most common pathogens. Herpes zoster could be seen more commonly in patients with myeloma complicated by renal failure.

Neurological Manifestations

Vertebral lesions due to plasma cell proliferation lead to radiculopathy/cord compression. Serum protein abnormality may lead to amyloid infiltration of nerves and neuropathy. Intra-cranial plasmacytoma usually represents extension of myelomatous lesions of skull.

Hyperviscosity

High paraprotein levels, particularly IgM, occasionally cause hyperviscosity. Clinical features of hyperviscosity include bruising, epistaxis, hazy vision, headache, gastrointestinal bleeding, sleepiness and variety of ischaemic neurological symptoms.

Diagnostic Procedures and Tests

Tests should be performed to confirm diagnosis, detect complications, assist in the staging of disease and establish baseline value for monitoring the progress. Investigations include complete blood count, serum creatinine, serum electrolytes, serum calcium, serum albumin, serum and urine electrophoresis and immunofixation, bone marrow aspirate and biopsy, complete skeletal survey (plain radiographs of bony skeleton), beta-2 microglobulin and biopsy of solitary or extra-medullary lesion.

Differential Diagnosis

The differential diagnosis of multiple myeloma includes multiple bony secondaries from carcinoma of prostate, breast, thyroid and other organs. Eosinophilic granuloma may also produce multiple lytic lesions in the skull. Biopsy may be required to confirm the diagnosis.

Course and Prognosis

The disease runs a chronic course extending over few years. Most patients succumb to their disease within 36 to 48 months. Various measures to predict prognosis are described. The staging system of Durie and Salmon which is based on haemoglobin, serum calcium and M protein concentration, as well as characteristics of bone survey, classifies patients into three stages which correlates with myeloma cell mass (**Table 1**). Recently, a new staging system has been developed by International myeloma working group after analysing 10,750 untreated symptomatic patients from all over the world. Serum beta-2 microglobulin, serum albumin, platelet count, serum creatinine and age are important prognostic factors. Based on these observations, a combination of beta-2 microglobulin and serum albumin provided the simplest, most powerful and reproducible three stage international staging system.

It is increasingly being appreciated that genetic abnormalities that induce myeloma are the major drivers of disease course and prognosis. These abnormalities can be detected with tests like metaphase cytogenetics and fluorescent *in situ* hybridisation (FISH). Genetic abnormalities like deletion 17, t(14;16) confer a much worse prognosis than that by a hyperdiploid karyotype, t(6;14), t(11;14) and t(4;14). In future, we may see a staging system based predominantly on underlying genetic abnormalities.

Table 1: Staging System for Multiple Myeloma

Dories-Salmon Staging System

Stage	Criteria	Estimated Tumour Burden	Median Survival (in Months)
I	All of the following:		
	Haemoglobin: >10 g/dL	<0.6 x10^{12} cells/m^2 (low)	61 for IA
	Serum calcium: <12 mg/dL		
	Bone radiograph: Normal or solitary lesion		
	Low M-component production		
	IgG level <5 g/dL		
	IgA level <3 g/dL		
	Urine light chain <4 g/24 hour		
II	Fitting neither I nor III	0.6 to 1.20 x 10^{12} cells/m^2 (intermediate)	55
III	One or more of the following:		
	Haemoglobin: <8.5 g/dL	>1.20 x10^{12} cells/m^2 (high)	15 to 30
	Serum calcium: >12 mg/dL		
	Advanced lytic bone lesions		
	High M-component production		
	IgG level >7 g/dL		
	IgA level >5 g/dL		
	Urine light chains >12 g/24 hour		

Sub-classification based on serum creatinine levels: A <2 mg/dL, B >2 mg/dL

International Staging System	Stage (% of Patients)	Median Survival (in Months)
β_2M <3.5 mg/L, alb ≤3.5 g/dL	I (28%)	62
β_2M <3.5 mg/L, alb <3.5 g/dL, *or*	II (39%)	44
β_2M = 3.5 mg/L to 5.5 mg/L		
β_2M >5.5 mg/L	III (33%)	29

Management

The indications for treatment are symptomatic disease, usually due to the presence of hypercalcaemia, renal impairment, anaemia or bony disease. Asymptomatic patients do not require active treatment. However close clinical follow-up, physical examination and measurement of serum and urinary paraprotein every 3 months should be carried-out. Up to 10% of asymptomatic multiple myeloma cases can enter a symptomatic phase every year.

Symptomatic patients need treatment directed control of myeloma activity and to correct complications of myeloma. Supportive care extended to patients during work-up and treatment can lead to significant reduction in initial mortality and morbidity in these patients. Common complications and their treatments are summarised in **Table 2**.

Table 2: Treatment of Complications in Multiple Myeloma

Complication	Therapeutic Options
Bone disease	Bisphosphonates-pamidronic or zolendronic acid in all with bone disease including osteopaenia Monitor renal function Radiation to bony lesions refractory to analgesics or causing cord compression Surgical intervention to treat pathologic fracture Pain control with narcotic analgesics avoid non-steroidal anti-inflammatory drugs (NSAIDs)
Anaemia	Packed cell transfusion Erythropoietin is controversial
Hypocalcaemia	Intravenous fluids and corticosteroids Biphosphonate for severe hypercalcaemia
Infections	Vaccination against *Streptococcus pneumoniae*, *Haemophilus influenzae* and influenza Intravenous immunoglobulin therapy for recurrent life-threatening infection associated with hypogammaglobulinaemia *Pneumocystis jiroveci* prophylaxis with trimethoprim and sulphamethoxazole for patients on high-dose steroids
Renal failure	Correct dehydration, hyperuriasemia and hypercalcaemia. Avoid NSAIDs, and intravenous contrast
Hyperviscosity	Plasmapheresis for symptomatic patient Therapy with a regimen containing high-dose dexamethasone

The choice of initial chemotherapy depends upon need for stem cells harvest after high-dose chemotherapy. Currently practiced chemotherapy regimens are summarised in Table 3. All regimens can prolong survival but none are curative. Patients are initially divided into those who are eligible for high-dose chemotherapy with stem cell rescue and those who are not. Use of melphalan, cyclophosphamide and nitrosourea should be avoided as initial induction therapy in patients planned for high-dose chemotherapy with stem cell rescue, as these drugs damage stem cells, which would be difficult to collect later for transplantation. The options in these patients include 'non-stem cell toxic' drugs like thalidomide, lenalidomide, bortezomib alone or in combination with dexamethasone or VAD. Patients not eligible for high-dose chemotherapy are treated with combination of melphalan, prednisolone with or without thalidomide. Drugs, like lenalidomide and bortezomib, are characterised by high response rates even in patients with "high-risk cytogenetics".

High-dose chemotherapy with hematopoietic stem cell rescue helps in prolonging survival compared to conventional therapy by approximately one year by autologous approaches. There is no survival benefit for early *versus* late transplant. There is also a role for two back-to-back (tandem) transplants in select cases. For maintenance, low-dose thalidomide or alternate day prednisolone is used.

Therapy for relapse cases depends on the timing of relapse, age, prior therapy and clinical status. Options include repeat primary conventional therapy, high-dose therapy with stem cell support, high-dose cyclophosphamide, thalidomide, bortezomib, arsenic trioxide and high-dose steroids.

Treatment of Localised Myeloma

Local irradiation gives pain relief and helps to clear lesion. Isolated extra-medullary plasmacytoma occurring in the tonsils, nasopharynx and paranasal sinuses also disappear after adequate radiotherapy. Rarely surgery may be required followed by radiotherapy.

Variant Forms of Myeloma

Smouldering myeloma

Biologically these patients have very indolent course. The M protein level is more than or equal to 3 g/dL and marrow contains more than or equal to 10% plasma cells. They have no anaemia, renal insufficiency or bony lesions. These patients do not require treatment till the disease progresses.

Plasma cell leukaemia

These patients have more than 20% plasma cells in peripheral smear and have poor response to therapy. Haematopoietic stem cell transplantation may be tried, but relapses are common.

Non-secretory myeloma

In 1% cases of myeloma, plasma cells may produce abnormal protein but do not secrete in plasma. Immune peroxides staining may detect M protein in plasma cells.

POEMS syndrome/osteosclerotic myeloma

These patients have single or multiple osteosclerotic lesions on radiography and have polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy and skin changes. Local irradiation of sclerotic area is the treatment of choice.

Waldenstrom's macroglobulinaemia

In this condition there is proliferation of plasmacytoid lymphocytes secreting IgM protein. Patients often have lymphadenopathy and hepatosplenomegaly but no bony lesions. The most common symptoms are fatigue and manifestations of hyperviscosity (headache, epistaxis and visual disturbances); although characteristics are seen in 5% of patients. Treatment is same as for low grade lymphomas.

Heavy chain disease

These are rare group of lymphoplasmacytoid malignancies producing only various types of heavy chain molecules, which include gamma (γ), alpha (α) and mu (μ). Gamma heavy chain disease is characterised by lymphadenopathy, fever anaemia

Table 3: Chemotherapy Regimen Used in the Treatment of Myeloma

Regimen	Usual Dose	Response Rate	Comment
Pulse dexamethasone	Dexamethasone 40 mg orally day 1 to 4, 9 to 12 and 17 to 20 Repeat every 4 to 5 weeks	45% 25% to 35% in relapsed cases	Helpful in patient with initial aggressive disease, renal failure or impending spinal cord compression
Dexamethasone and thalidomide	Dexamethasone 40 mg orally day 1 to 4, 9 to 12 and 17 to 20 Thalidomide 200 mg orally day 1 to 28, Repeat every 4 weeks	65% to 70% 50% in relapsed cases	Currently used frontline therapy. Useful in relapsed cases. Neuropathy and DVT are potential side-effects
Thalidomide	200 to 400 mg/day orally	35% 25% to 45% response rate in relapse cases	Low-dose useful as maintenance therapy Lenalidomide causes fatigue, thrombosis, skin rash and leucopaenia
Lenalidomide and dexamethasone	Lenalidomide and high-dose dexamethasone	70% first-line therapy	
	Lenalidomide and low-dose dexamethasone	80% first-line therapy	Low-dose dexamethasone has lesser steroid induced toxicities
Melphalan and prednisolone	Melphalan 8 to 10 mg orally on day 1 to 7 Prednisolone 60 mg orally day 1 to 7 Repeat every 6 weeks	50% to 55%	Well tolerated; widely used; slow to act; not good in renal insufficiency
Melphalan prednisolone and thalidomide	Melphalan 4 mg/m^2 day 1 to 7 Prednisolone 40 mg/m^2 day 1 to 7 Thalidomide 100 mg orally day 1 to 28	80%	Recommended in elderly with myeloma
Bortezomib	1.3 mg/m^2 on day 1, 4, 8 and 11 every 28 days	70% 25% in relapsed cases	Produces neuropathy

and malaise. Some cases develop oedema of glottis and palate due to lymphatic obstruction. Disease runs progressive downhill course. Alpha heavy chain disease is the most common amongst heavy chain diseases and is characterised by infiltration of lamina propria of small intestine by lymphoplasmacytoid cells which secret incomplete alpha chains. Chronic diarrhoea, malabsorption and weight loss are major symptoms. Extensive lymphadenopathy in midline, such as paraaortic and mesenteric group, can be demonstrated. Usually alpha heavy chain disease is progressive and foatal. Mu heavy chain disease is characterised by the demonstration of mu chain fragment in the serum. The patient may present with chronic lymphatic leukaemia or lymphoma.

Monoclonal gammopathy of undetermined significance

Patients with MGUS have an M protein in the serum without findings of multiple myeloma, macroglobulinaemia, amyloidosis, or lymphoma and with fewer than 10% plasma cells in the bone marrow. These patients are asymptomatic and should not be treated. They must, however, be followed carefully with protein electrophoresis, bone marrow biopsy and skeletal survey since about 2% per year will progress to develop one of the symptomatic B-cell neoplasm and may then require therapy.

15.15 Bleeding Disorders

Kanjaksha Ghosh

INTRODUCTION

Approach to a bleeding patient must follow the classical approach in medicine, i.e. taking history, physical examination and finally deciding about the order and priority of laboratory investigations which will assist in the diagnosis, prognosis and management.

CAUSES OF BLEEDING

Bleeding takes place because of defective/deficient coagulation factors, defective or deficient platelet function or platelet count, diseases of the blood vessels, and combination of all these factors. These defects or deficiencies can arise either due to a genetic cause or due to acquired causes. Acquired causes could again be diverse in nature and may involve traumatic, inflammatory (infective), neoplastic, and drug-induced processes (**Table 1**).

Table 1: Causes of Bleeding in a Patient

Inherited Bleeding Disorders

Deficiency of coagulation factors, i.e. Haemophilia A, B, von Willebrand disease, etc.

Defective platelet number and/or function, i.e. Glanzmann's thromboasthenia, Bernard-Soulier syndrome, etc.

Defective blood vessel wall, i.e. Hereditary haemorrhagic telangiectasia, Marfan syndrome, Pseudoxanthoma elasticum, etc.

Acquired Disorders Causing Systemic Bleeding

Disseminated intravascular coagulation, i.e. snake-bite, septicaemia, malignancy, obstetric accidents, etc.

Deficiency of coagulation factors due to:

- Lack of production/secretion
  - Acquired von Willebrand disease due to hypothyroidism, chronic/acute liver disease.
- Development of antibody to coagulation factors
  - Autoimmune disorders
  - Lymphoreticular malignancies
  - Drugs: penicillin, factor VIII inhibitor, INH, factor XIII inhibitors, heparin-induced thrombocytopaenia and other drug-induced thrombocytopaenia
  - Miscellaneous: old age, post-partum
- Absorption/utilisation of coagulation factors, amyloidosis causing factor X deficiency.

Drugs and vitamin deficiency

- Aspirin, clopidogrel by knocking down platelet function
- Heparin, hirudin, argatroban, oral anticoagulants, etc.
- Vitamin K deficiency, vitamin C deficiency
- Drugs causing marrow aplasia, thrombocytopaenia

Vasculitic disorders of uncertain aetiology

Disorders involving high molecular weight or its clearing activity (ADAMTS-13)

Generally, in congenital disorders of blood coagulation, patient is usually healthy but his disease is a consequence of bleeding (anaemia, haemarthrosis, epistaxis, gum bleeding, genitourinary, gastrointestinal bleeding, etc.). Occasionally bleeding could be trivial in the form of purpura, petechiae, ecchymoses or may be life-threatening like intracerebral bleed, severe bleeding in the lungs, gastrointestinal and genitourinary tract, retroperitoneal or retro-pharyngeal bleed, which can quickly obstruct the major airway.

CLINICAL PATTERNS OF BLEEDING

Severe coagulation factor deficiency as in haemophilia tends to produce joint bleeding (haemarthrosis), intra-muscular bleeds and deeper tissue bleeds, whereas platelet defects/deficiencies tend to produce mucocutaneous bleeding. von Willebrand disease (vWD), where there is low levels of circulating factor VIII and platelet dysfunction due to absence of von Willebrand factor (vWF) produces a clinical picture that is a combination of platelet defect (mucocutaneous bleed) as well as severe factor VIII deficiency (haemarthrosis).

HISTORY

Taking a patient's past history of bleeding particularly with reference to spontaneous bleeding, minor traumatic bleeding, bleeding during falling of deciduous teeth, severe post-operative bleeding, and minor bleeding requiring transfusion; all point to a congenital bleeding tendency. Present history can be elicited taking the points from **Table 2**.

Table 2: History of Bleeding Disorders

Abnormal bruising
Abnormal bleeding from cuts and abrasions
Nasal bleeding
Menorrhagia
Haemarthroses
Bleeding after dental extraction
Bleeding during childbirth
Bleeding during surgery
Previous history of anaemia and transfusion
Drug history
Family history

Drawing a pedigree is an important exercise to find out whether the bleeding disorder is X-linked or autosomal, recessive or dominant in inheritance. Inheritance pattern gives a fair clue to the nature of the defects, which lead to bleeding.

As wound healing and blood coagulation are closely related, congenital defects like afibrinogenaemia/dysfibrinogenaemia and factor XIII deficiency may be associated with delayed wound healing, umbilical cord bleeding or central nervous system (CNS) bleeding following delivery. About 25% to 30% of haemophilia are due to new mutations, hence may not have a family history. Bleeding tendency in other members of a family points to an inherited defect. Sometimes this history may not be straightforward, but exploring the nature of early and unusual deaths in the family may reveal that the cause was excessive bleeding.

Physical examination in the patients may show haemarthrosis, chronic synovitis, muscle haematoma or Volkman's ischaemic contracture due to compartment syndrome following a bleed, compressive neuropathy, petechiae, purpura, ecchymoses, nasal bleeding, gum bleed, bleeding from urogenital, gastrointestinal tract, etc. Sometimes hereditary disorders of connective tissues can give rise to bleeding diathesis and physical examination in these patients may reveal marfanoid habitus, subluxation of lens, pseudo-xanthoma and cardiac murmurs of aortic regurgitation. Ophthalmoscopic examination in these patients may show angioid streaks.

Hereditary platelet defects may sometimes be associated with oculocutaneous albinism, ataxia and oculocutaneous telangiectasia. Severe epistaxis, haemoptysis may occur in patients with hereditary haemorrhagic telangiectasia. In these patients telangiectatic blood vessels may be seen in the palm, nasal septum or tongue. Similar lesions when present in the lungs may produce continuous murmurs and may be imaged using magnetic resonance imaging/high definition computed tomography.

Acquired cause of bleeding involves chronic diseases involving liver, kidneys, obstructive jaundice, acute liver failure, use of anticoagulants or aspirin-like drugs. Haematological disorders like aplastic anaemia, myelodysplastic syndrome (MDS), acute leukaemias (especially acute promyelocytic leukaemia) may be associated with bleeding.

Disseminated intravascular coagulation (DIC) is an important cause of acute bleeding due to diverse insults (physical injury like burns, septicaemia, snake bite, malignancies) that leads to systemic activation of blood coagulation and consumption of coagulation factors. Often this kind of bleeding is associated with multi-organ failure. Causes of DIC and their management have been discussed elsewhere.

Drugs are very important cause of bleeding. Anticoagulants and antiplatelet drugs like aspirin, clopidogrel causing bleeding is easily understood but many drugs can lead to thrombocytopaenia, aplastic anaemia or may cause development of antibodies to coagulation factors resulting in bleeding. Hence, taking history of drugs is an extremely important aspect in the assessment of bleeding disorders. Autoimmune disorders and various vasculitides can cause bleeding tendency either by producing severe thrombocytopaenia, inhibitors to coagulation factors, immune complexes or leucocytoclastic vasculitis or by a combination of all the causes.

Generally, antiphospholipid antibodies associated with systemic lupus erythematosus or occurring *de novo* can cause thrombotic tendency but occasionally it may lead to severe hypoprothrombinaemia causing severe bleeding.

PHYSICAL EXAMINATION

Look for signs of systemic diseases, anaemia, hepatosplenomegaly, and lymphadenopathy, etc. Examine the joints for haemarthrosis, chronic arthritis, muscle contractures, pseudocysts, etc. from the previous bleed. Assess bleeding sites like palate, fundi, size of cutaneous bleeds, e.g. petechiae (pinhead); purpura (~1 cm); bruises and ecchymoses (measure them).

LABORATORY EVALUATION

The first step is to do screening tests as described in **Table 3**. Depending on the defects found in screening tests proceed for correction studies, i.e. see whether mixing normal and patient's plasma in equal proportion corrects the test abnormality. If abnormality is corrected then the patient has deficiency of one or more factors, if not then the presence of an inhibitor to blood coagulation (heparin, antibody, fibrin degradation predict) is indicated. When a factor deficiency is indicated on a screening test and correction studies, relevant factor assays can establish severity of the deficiency. It is to be noted that screening coagulation test (e.g. activated partial thromboplastin time) may be normal in moderate and mild factor deficiency; hence if the patient has strong bleeding history then even if screening coagulation is normal, more detailed investigations are indicated. Factor XIII deficiency, vWF assay and platelet function tests are indicated in the context of relevant clinical presentations. Finally if a patient who has bleeding diathesis and cause is not found out, referral to a specialised coagulation laboratory should be strongly considered. DIC is a very common problem in medical, surgical and gynaecological set-up. Apart from screening coagulation studies which in addition to providing the severity of coagulation disturbances also suggest a rational order of blood components to be replaced, D-dimer assay confirms systemic generation of thrombin and cross-linking of fibrin monomer to dimers or the presence of a big thrombus. In post-operative patients, D-dimer may be weakly positive.

Table 3: Screening Tests for Assessing Bleeding Disorders

Test	Abnormality Detected
Complete blood count including smear exam	Anaemia, pancytopaenia, leukaemia severe thrombocytopaenia, microangiopathy
Platelet count	Thrombocytopaenia
Prothrombin time	Prolonged in deficiency of fibrinogen, prothrombin, factors V, VIII and X, liver disease, oral anticoagulants, isolated deficiency of above-mentioned clotting factors.
Activated partial thromboplastin time	Defects in intrinsic and common pathways. Prolonged in deficiency of factors involved in intrinsic and common pathways of blood coagulation, i.e. haemophilias, von Willebrand disease. Circulating Inhibitors to coagulation like heparin, antibodies to coagulation factors and antiphospholipid antibodies.
Thrombin time	Prolonged in heparin therapy, hypofibrinogenaemia, high levels of FDP in DIC (confirmed by D-dimer assay).

FDP = Fibrin degradation product; DIC = Disseminated intravascular coagulation.

MANAGEMENT

Management of a bleeding patient depends on understanding the cause of bleeding. A patient who is bleeding severely may need supportive therapy in the form of blood transfusion. If non-blood product treatment stops the bleeding, they are to be used first, i.e. DDAVP (Desmopressin) for moderate vWD, moderate and mild haemophiliac patients. Relevant factor concentrates

(plasma-derived and recombinant) for the given factor deficiency, FEIBA (Factor VIII inhibitor bypass activity) or recombinant activated factor VII for a patient with inhibitor who is bleeding should be considered. High levels of heparin in blood causing bleeding can be controlled by protamine sulphate injection. Offending drugs need to be stopped immediately.

Various blood components can be replaced depending on the need of that particular product e.g., platelet concentrates for low platelets or functional defects in platelets, cryoprecipitate to replace factor VIII, vWF and fibrinogen. Fresh frozen plasma for chronic liver disease and for other factor deficiency. No intramuscular injection or non-steroidal anti-inflammatory drugs should be given to a patient with congenital bleeding disorder.

Over anticoagulated (oral) patients who are bleeding can be managed by stopping oral anticoagulation and depending on availability of small dose (1 mg) of vitamin K may be added and if it does not stop bleeding then prothrombin complex/ recombinant activated factor VII/FEIBA and if they are not available then fresh frozen plasma may be used.

15.16 Platelet Disorders

SK Bichile

PHYSIOLOGICAL CONSIDERATIONS

Platelets are the smallest component of the blood cells in the peripheral blood. On peripheral blood film from normal uncoagulated blood stained with Ramonavsky stain they appear as anucleate, granular structures of about 2 µm diameter, distributed throughout the film and some of them forming platelet clumps.

They originate from megakaryocytes in the bone marrow. The microstructure of platelet, as revealed by electron microscopy, is complex. Major function of platelets is to form platelet plug at the site of injury. Platelet plug is formed within seconds of injury and it plays crucial role in achieving haemostasis.

Platelet counts are done by using electronic cell counters (manual methods are less accurate). Normal range of platelet count is 1.5 to 4 lakhs/mm^3 (150 to 400 x 10^3/µL). Life span of platelets *in vivo* is estimated to be 9 to 12 days. Old platelets or damaged platelets are phagocytosed in the spleen by macrophages of phagocytic system. The number of platelets in circulation is maintained fairly constant. The major regulator of platelets production is a colony stimulating factor called thrombopoietin.

CLASSIFICATION OF PLATELET DISORDERS

Disorders of platelets are broadly of three types, i.e. thrombocytopaenia (low platelet count), thrombocytosis (high platelet count) and thromboasthenia (normal platelet count with defective function).

THROMBOCYTOPAENIAS

Basically thrombocytopaenia is produced by one of the three mechanisms, i.e. reduced platelet production, excessive peripheral destruction and increased platelet sequestration in spleen. Thrombocytopaenia can occur as an isolated phenomenon or along with suppression of other formed elements of blood (bicytopaenia or pancytopaenia). **Table 1** enumerates causes of thrombocytopaenia.

Clinical Manifestations

Typical clinical manifestation of thrombocytopaenia is skin (dry) and mucous membrane (wet) purpura. The bleeding occurs spontaneously or after trivial trauma. Bleeding gums, epistaxis, menorrhagia and gastrointestinal bleeding are commonly encountered. Severe thrombocytopaenia can lead to life-threatening bleeding such as intracranial bleeding. Severity of bleeding is dependent on the platelet count (**Table 2**).

Clinical and Laboratory Evaluation

Clinical evaluation of thrombocytopaenia should include information on duration of bleeding manifestations, presence or absence of fever, high-risk behaviour, joint pains, symptoms suggesting systemic illness and history of all or any drug. Physical examination should record presence of pallor, lymph node enlargement, hepatosplenomegaly, malar rash, examination of joints and fundoscopy. Laboratory evaluation should include full blood count, peripheral blood film examination for abnormal cells and platelet morphology, prothrombin time, partial thromboplastin time, screening test for human immunodeficiency virus (HIV), test for antinuclear antibodies and bone marrow examination.

Table 1: Causes of Thrombocytopaenia

- **Acquired Thrombocytopaenia**
  - Increased destruction
    - Immune mechanism
      - Idiopathic thrombocytopaenic purpura
      - Drug induced
      - Systemic lupus erythematosus
      - Lymphoproliferative disorders
      - HIV-1 associated
      - Mononucleosis
      - Sarcoidosis
      - Autoimmune thyroiditis
      - Isoimmune thrombocytopaenia
        - Congenital
        - Post-blood transfusion
    - Non-immune mechanism
      - Disseminated intravascular coagulation
      - Thrombotic thrombocytopaenic purpura
      - Haemolytic uraemic syndrome
      - Bacterial infections
      - Massive blood transfusion
      - Thrombocytopaenia of pregnancy
  - Reduced production
    - Vitamin B12 and/or folic acid deficiency
    - Viral infections
    - Hypoplastic/aplastic anaemia
    - Bone marrow infiltration
    - Paroxysmal nocturnal haemoglobinuria
    - Thrombopoietin deficiency
  - Increased sequestration
    - Hypersplenism
    - Hypothermic anaesthesia
- **Hereditary Thrombocytopaenia**
  - Wiskott-Aldrich syndrome
  - May-Hegglin anomaly
  - Bernard-Soulier syndrome

Table 2: Severity of Thrombocytopaenia and Clinical Manifestations

Platelet Count (x 10^3/µL)*	Clinical Manifestation**
>100	Asymptomatic
50 to 100	Haemorrhage after injury
20 to 50	Skin purpura
<20	Spontaneous bleed from mucous membrane, intracranial bleeding

** Pseudothrombocytopaenia is false low platelet count (platelets are not counted accurately); it is suspected when there is no bleeding despite very low platelet count.*

*** Presence of fever or coagulation factor deficiency adversely affects severity.*

Immune Thrombocytopaenic Purpura

Immune thrombocytopaenic purpura occurs due to excessive destruction of platelets by reticuloendothelial system due to autoantibodies or immune complex deposition on platelet membrane. They are broadly classified in two categories: idiopathic thrombocytopaenic purpura (ITP) in which no known aetiological factor is found, and secondary immune thrombocytopaenia seen in systemic lupus erythematosus, lymphoproliferative disorders, drugs and infections.

Idiopathic Thrombocytopaenic Purpura

Pathophysiology of ITP is summarised in **Figure 1**.

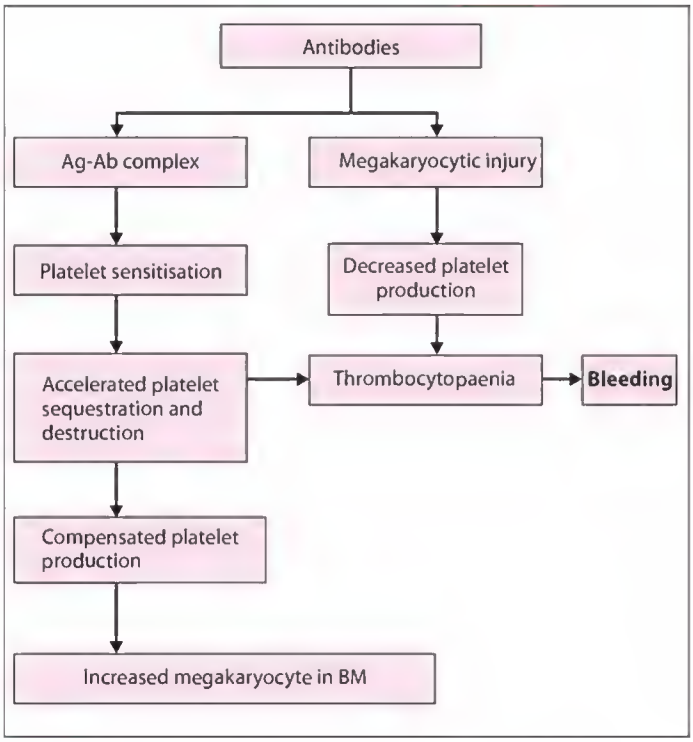

Figure 1: Pathophysiology of idiopathic thrombocytopaenic purpura.

Typically ITP presents with purpuric lesions (red, flat haemorrhages of pin-head size which do not blanch on pressure) or ecchymosis (large purple lesions) on skin and mucous membrane, no symptoms suggestive of systemic illness, absence of lymph node enlargement and absence of hepatosplenomegaly. Bleeding gums, epistaxis, menorrhagia and haematuria are common manifestations. Sometimes bleeding can occur in intracranial site which may be fatal. Clinically ITP is of two types, i.e. acute ITP and chronic ITP. These types differ as regards their clinical characteristics, prognosis and therapeutic strategies (**Table 3**).

Laboratory features

Thrombocytopaenia, large platelets in peripheral blood film, normal total and differential white blood cell count, normal screening coagulation tests and bone marrow aspiration revealing normal or increased megakaryocytes are typical laboratory features of ITP. There can be anaemia proportional to blood loss. In some patients Coombs' test is positive (Evans syndrome). Diagnosis of ITP is by exclusion of causes that produce secondary immune thrombocytopaenia. Decision to skip bone marrow examination in children should be taken in consultation with haematologists.

Table 3: Clinical Characteristics of Acute and Chronic Idiopathic Thrombocytopaenic Purpura (ITP)

	Acute ITP	Chronic ITP
Occurrence	Common in children	Common in adults
Sex	None	Female preponderance
Antecedent infection	1 to 3 weeks prior	Unusual
Bleeding onset	Abrupt	Insidious
Platelet count	<20,000/mm^3	30/mm^3 to 80,000/mm^3
Duration	Usually 2 to 6 weeks	Months to years
Spontaneous remission	80% (6 to 12 months)	Uncommon
Initial treatment approaches	Palliative Keep patient trouble-free Avoid splenectomy	Oral prednisolone High recurrence rate Often require other drugs and splenectomy

Treatment

Although treatment modalities available are similar, different treatment strategies are adopted for ITP in children and ITP in adults. Commonly used initial therapies are described below:

Prednisolone: Prednisolone can be administered orally in an initial dose of 1 to 2 mg/kg daily for 2 to 4 weeks and then gradually tapered over 8 to 12 weeks or more. Oral prednisolone can be effective but it is frequently associated with unacceptable side-effects.

Intravenous immunoglobulin: Immunoglobulins can be administered intravenously in a dose of 400 mg/kg per day for 5 days or 1000 mg/kg for 2 days can be done. Both regimens are equally effective in raising platelet count especially when rapid increase in platelet count is required, e.g. life-threatening bleeding or before surgery. The disadvantages are high-cost and need for repeated administration.

Intravenous anti-D: It can be used as an alternative to intravenous immunoglobulin and has an advantage of lower cost. It can result in an increase in platelet count after 48 hours. Patients have to be monitored for drop in haemoglobin.

Platelet transfusion: It is not required or recommended for initial therapy except in severe life-threatening bleeding. Platelet transfusion must be preceded by a single dose of intravenous immunoglobulin.

Childhood ITP is usually a self-limiting disorder. Patients with mild thrombocytopaenia (no bleeding or minor purpura) are kept under observation. Majority of these patients recover spontaneously over few weeks. The indications to initiate therapy in childhood ITP are platelet count less than 20,000/mm^3 and/or bleeding from multiple sites, impending intracranial or life-threatening bleeding and thrombocytopaenia persisting for more than 6 months.

ITP in adults is insidious in onset and often a chronic disease. It rarely remits spontaneously; however these generally do not have bleeding manifestation if platelet count is between 20,000 to 30,000/mm^3. The natural course of adult ITP varies with periods of exacerbations of thrombocytopaenia and bleeding episodes. Therefore, treatment options are highly individualised and subjective. Patients with mild thrombocytopaenia are kept

under observation without any drug therapy. Those in whom platelet count is less than 20,000/mm^3 and/or have bleeding are given oral prednisolone (1 mg/kg/day). Adult patients require prednisolone for longer periods. Decision of maintenance dose administered is decided by side-effects of chronic steroid administration *versus* its effectivity to maintain target platelet count of 20,000 to 30,000/mm^3.

In patients with chronic and recurrent bleeding manifestations the choice of therapy revolves between off and on steroids, intravenous immunoglobulins, intravenous anti-D, methyl-prednisolone, danazol, immunosuppressive therapy and splenectomy. Other modalities available for such patients are intravenous vincristine, oral dapsone, cyclosporine, interferon-alpha and anti-CD20 antibodies.

Thrombotic Thrombocytopaenic Purpura and Haemolytic Uraemic Syndrome

TTP and haemolytic uraemic syndrome (HUS) are characterised by microangiopathic thrombosis. In TTP the thrombotic process is diffuse whereas in HUS thrombotic process is localised in kidneys.

TTP is a syndrome characterised by pentad of haemolytic anaemia, thrombocytopaenia, fluctuating neurological symptoms, fever and renal dysfunction. It occurs due to disseminated thrombotic occlusion of micro-circulation (terminal arterioles and capillaries). The thrombi are composed of platelets, von Willebrand factor and fibrin is only in small amount.

TTP can occur in previously healthy individuals or associated with disorders such as HIV, *Escherichia coli*, antineoplastic drugs, collagen vascular disease, malignancies and bone marrow transplantation.

TTP is a clinical diagnosis and it requires to be differentiated from HUS. HUS typically occurs in children, associated with localised thrombosis in kidney and often preceded by infection. Clinically HUS is characterised by anaemia, renal failure, abdominal pain and absence of neurological manifestations.

Treatment

TTP carries a high-risk of mortality unless promptly treated. The main modality of treatment is plasma exchange or therapeutic plasma pheresis after which patients respond dramatically and laboratory abnormalities disappear. Plasma exchange of a single plasma volume is done daily up to 10 days. Antiplatelet drugs and corticosteroids are of unproven benefit.

THROMBOCYTOSIS

Thrombocytosis refers to high platelets count (platelet count of 5 to 10 lakhs/mm^3). The term thrombocythaemia is used for a clonal disorder of multipotent stem cells in which platelets count generally, higher than 10 lakhs/mm^3.

Aetiology of thrombocytosis is given in **Table 4**.

Table 4: Causes of Thrombocytosis

Primary Thrombocytosis
Chronic myeloid leukaemia
Myeloproliferative disorders
Polycythaemia vera
Essential thrombocythaemia
Myelofibrosis
Secondary or Reactive Thrombocytosis
Blood loss
Infections
Neoplasms
Post-splenectomy

The differentiation between reactive thrombocytosis and essential thrombocythaemia (ET) is important. In essential thrombocythaemia symptoms are frequent due to disturbances in the micro-circulation. Common clinical features of essential thrombocythaemia are erythromelalgia (red and congested extremities which are warm), central nervous system (headache, giddiness, ringing in ears) and splenomegaly.

Diagnosis of essential thrombocythaemia is by excluding causes of reactive thrombocytosis and myeloproliferative disorders. Treatment of essential thrombocythaemia includes oral anagralide 0.5 mg thrice a day, which effectively controls increased platelet count but it is expensive. Other treatment which has been used is busulfan, hydroxyurea or radioactive phosphorus.

PLATELET FUNCTION DISORDERS

Platelet function disorders are suspected in individuals with history of purpura and having normal platelet counts, absence of platelet clumps in peripheral blood film and prolonged bleeding time. Diagnosis is confirmed by platelet aggregation studies. Platelet function disorders are of two broad types: hereditary and acquired (**Table 5**).

Hereditary platelet disorders present at early age with easy bruisability, bleeding gums, epistaxis, menorrhagia and post-operative bleeding.

Table 5: Causes of Thromboasthenia

Acquired Thromboasthenia
Uraemia
Paraproteinaemia
Drugs: acetyl salicylic acid, ticlopidine, nonsteroidal anti-inflammatory drugs, clopidogrel, tricyclic antidepressants
Myeloproliferative disorders
Hereditary Thromboasthenia
Glanzmann's thromboasthenia
Bernard-Soulier syndrome
Storage pool disorders

Treatment of thromboasthenia includes supportive measures such as local pressure, application of local agents, e.g. fibrin glue, and antifibrinolytic agents (tranexamic acid, epsilon amino caproic acid). Use of 1-desamino-8D-arginine vasopressin (DDAVP) has been shown to shorten the bleeding time. Intravenous administration of recombinant factor VII has been shown to be effective in Glanzmann's thromboasthenia. Patients with severe disease have been successfully treated with allogenic bone marrow transplantation.

15.17 Disorders of Coagulation

Jina Bhattacharyya

INTRODUCTION

Disorder of coagulation results because of a defect in any of the processes of coagulation. To know about the defects and the resulting disorders we must have a basic understanding of the steps of coagulation.

MECHANISM OF COAGULATION

The process of coagulation or haemostasis involves a series of proteolytic enzymatic reactions. The reactions that govern haemostasis may be divided into 5 distinct phases:

1. Initiation of coagulation
2. Propagation of α-thrombin formation
3. Termination of the procoagulant response
4. Elimination of the fibrin clot
5. Tissue repair and regenerations

The essential features of the haemostatic response are speed, amplifications, regulations and localisation. The response to injury must be rapid. Initiation of coagulation occurs whenever the vascular milieu is perturbed and antithrombotic nature of the endothelium turns to prothrombotic. The membrane surface and tissue factors are exposed, setting the stage for next phase of coagulation.

There is rapid burst of α-thrombin which activates platelets, pro-cofactors V and VIII, the zymogen factors VII and XI and also factor XIII (F XIII). This cleaves fibrinogen to fibrin clot which is stabilised by F XIII. The activated thrombin activable fibrinolysis inhibitor (TAFIa) protects the fibrin clot from proteolysis. Thus, the propagation phase stops blood loss by forming a stable clot. The termination phase limits the coagulation process and prevents excessive clot formation through plasmin dependent process. The enzyme plasmin cleaves fibrin clot to produce soluble fibrin peptide. This whole process of solubilisation and removal of fibrin clot is coordinated with processes of tissue repair and regeneration.

All these steps of coagulation must occur rapidly and in a precise choreographed manner and must be located at the site of injury. This localisation is controlled at several levels. Unperturbed endothelial cells actively inhibit coagulation; the surface of undamaged cells is not conducive to the assembly and function of procoagulant protein complexes.

There are two distinct procoagulant pathways. The primary or extrinsic [tissue factor (TF)] pathway consists of the intrinsic and extrinsic tenase complexes and prothrombinase complex whereas accessory or intrinsic pathway is composed of F XII – high molecular weight kininogen (HMWK) – Prekallikrein complexes. Both pathways lead to activation of F IX and converge at the intrinsic tenase complex. Finally, prothrombinase complex is formed with generation of α-thrombin. Classical coagulation tests differentiate between the two pathways; activated partial thromboplastin time (APTT) initiates coagulation through accessory pathway and prothrombin time through primary pathway. The procoagulant response is triggered upon by the interaction of activated factor VIIa (F VIIa) and TF when TF is expressed as a result of vascular perturbation. The resulted extrinsic tenase complex activates F IX and F X; F IX combines with F VIIa to form the intrinsic tenase complex to accelerate activated factor X (F Xa) generation. The burst of F Xa overcomes the inhibition and initiates maximal levels of prothrombinase complex activity which in turn leads to burst of α-thrombin generation and propagation of the procoagulant response (**Figure 1**).

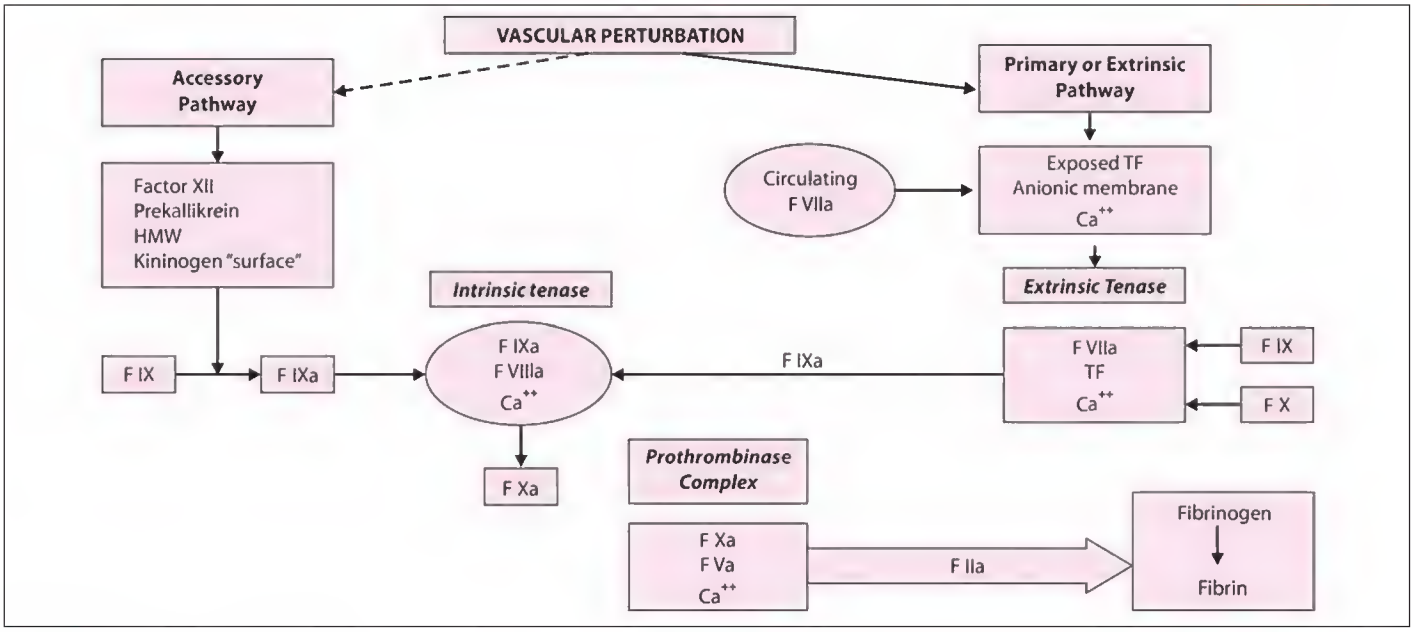

Figure 1: Basic pathways of coagulation.

HMW = High molecular weight; TF = Tissue factor.

The role of intrinsic or accessory pathway is not clearly defined and it appears that this pathway is not essential for haemostasis, because it has been seen that persons deficient in the factors needed in accessory pathway do not have any bleeding manifestation even after surgical challenge.

INHERITED DISORDERS OF COAGULATION

Disorders of coagulation may be inherited or acquired. Inherited disorders of coagulation usually result from a deficiency or abnormality of a single plasma protein. **Table 1** shows different types of inherited disorders of coagulation. Haemophilia A and von Willebrand disease (vWD) are the two most common inherited coagulation disorders. Diagnosis of these disorders is based on clinical pointers as to the pattern of bleeding and laboratory tests as shown in **Table 2**. Immunologic assays available for coagulation factor are expressed as positive or negative for cross reactive material (CRM). A CRM positivity means the disorder is qualitative and CRM negativity means it is a quantitative disorder.

Table 1: Inherited Disorders of Coagulation

X-linked Recessive Traits
- Haemophilia A
- Haemophilia B (i.e. CRM^+ and CRM^- variants; haemophilia B_m, B Leyden, etc.)

Autosomal Recessive Traits
- von Willebrand disease
- Dysfibrinogenaemias

Combined Abnormalities
- Associated with factor VIII deficiency (i.e. factor V deficiency, haemophilia B, factor XI deficiency, factor VII deficiency, von Willebrand disease, dysfibrinogenaemias, platelet dysfunction)
- Involving vitamin K-dependent factors (i.e. factors II, VII, IX, and X; factors IX and XII; others)

Miscellaneous
- Prekallikrein deficiency
- High molecular weight kininogen deficiency
- Deficiency of physiologic inhibitors [i.e. α_2-antiplasmin, abnormal α_1-antitrypsin (antithrombin Pittsburgh)]

Haemophilia A and B are X-linked with bleeding manifestation in male homozygote, vWD is autosomal dominant and the rest of the disorders are autosomal recessive where bleeding manifestation occur in homozygotes or complex heterozygotes.

Table 2: Basic Diagnostic Evaluation of Coagulation Disorders

Clinical pointers like mucosal bleed versus bleeding into joints and muscles, delayed bleeding, family history, age of onset, sex, etc.

Screening coagulation test including platelet count and morphology, bleeding time, prothrombin time, activated partial thromboplastin time and factor XIII assay

Correction studies of prolonged coagulation times, with pooled normal plasma, absorbed and aged plasma and/or factor deficient plasma

Factor assays to confirm the deficiency and establish its severity—functional/antigenic.

The treatment of these disorders is replacement for each bleeding episode. The dose depends on the level of haemostasis required based on the severity of bleeding. The activity of various coagulations factor are expressed in units, defined as the activity present in 1 mL of fresh plasma from a normal donor. Thus, the concentration of all coagulation factors in normal pooled plasma is 1 IU/mL or 100 mg/dL or 100% activity; in the blood bank the level is 80 IU/dL because of dilution with anticoagulants. Common inherited disorders will be discussed briefly here.

HAEMOPHILIA

It can be haemophilia A (deficiency of factor VIII) or haemophilia B (deficiency of IX). Haemophilia A is more common; the incidence of the disease can be as high as 1 in 10,000 person. In India, the estimated prevalence of Haemophilia A is ~50,000 and 1,300 new cases are born per year. It is inherited as X- linked recessive disorder. However, in one-third of the patients there is a lack of family history which suggests that one-third would result from spontaneous mutation. The molecular defect can be a point mutation, deletion or inversions. Approximately 5% of patients with haemophilia A have deletions in the F VIII gene; 40% severe haemophilias are secondary to major inversion of section of the tip of long arm of X chromosome (intron 22 inversion). Haemophilia in females is rarely seen; most common form is seen in a minority of heterozygous female where X chromosome inactivation occurs at an early stage of embryogenesis and the second form is seen in homozygous female as a result of mating between a haemophilic male and a heterozygous female.

Patients with haemophilia have prolonged and excessive bleeding with minor trauma. Bleeding into joints and soft tissues is the hallmark of the disease. The severity and frequency of the bleeding episodes depend upon the factor level. Based on severity a consensus committee has classified haemophilia into 3 categories as shown in **Table 3**. Earliest manifestations of the disease are subcutaneous haematomas when the child starts crawling and as the child starts walking bleeding into joint starts appearing. Haemarthrosis is the most common, most painful and most physically, economically and psychologically disabling manifestation of these disorders. It results from bleeding into the joint cavity or its epiphysis or diaphysis from the synovial vessels. The retained blood results in chronic inflammation. Recurrent haemarthrosis leads to progressive thickening of the synovium resulting in chronic proliferative synovitis. In the terminal stage, chronic haemophilic arthritis sets in which is a form of fibrous or bony ankylosis of the joints. The knee joint is the most commonly affected joint and most often is permanently crippled. Besides bleeding into joints, a patient can have subcutaneous and intramuscular haematomas, which may compress vital structures. Psoas and retroperitoneal haematomas, gastrointestinal and genitourinary bleeding and intracranial bleeding, are different forms of bleeding episodes.

Table 3: Severity of Haemophilia and Clinical Manifestations

Severe	Factors VIII or IX level is less than 1% Spontaneous joint and soft tissue bleeding several times every month.
Moderate	Factors VIII or IX level is 1% to 5% Spontaneous bleeding is uncommon but occurs after minor trauma or surgery.
Mild	Factors VIII or IX level is 5% to 30% Bleeding occurs only after significant trauma or surgery.

Replacement of the deficient factor is the principal treatment. The objective is to achieve a haemostatic level. This depends on severity of bleeding and availability of factor concentrate. Dose can be calculated on the basis of body weight or plasma volume. One unit of factor per kilogram would raise F VIII level by 2% and F IX level by 1%. **Table 4** shows replacement doses for different bleeding episodes. Factor can be replaced on demand, at the onset or premonition of bleed or as regular prophylaxis 2 to 3 times a week to maintain factor level of more than or equal to 1%. The goal of the treatment is to maintain a normal life. The patient and family members should be counselled about the disease, its implications and its management. They should be able to recognise the onset of bleeding early and be aware of its management.

VON WILLEBRAND DISEASE

It is the most common bleeding disorder affecting 1% of population. The name derived from von Willebrand who had recognised the disease in 1926 amongst the inhabitants of Aland Islands. It is a very heterogeneous disorder and multiple variants have been recognised. However, all of these variants are either due to insufficient amounts of von Willebrand factor (vWF) or defective function of this protein. Broadly, the disease is divided into 2 parts: quantitative which can be partial or severe deficiency and qualitative deficiency. However, as per the revised classification the diseases are sub-grouped into 3 variants as shown in **Table 5**. Type 1 vWD accounts for 70% of all cases.

Table 4: Replacement Therapy in Haemophilia A and Haemophilia B

Disorder	Therapeutic Product	Minor bleeding (i.e. uncomplicated haemarthroses; haematomas in noncritical areas; haematuria; dressing changes; arthrocentesis; removal of sutures and drains)		Major bleeding (haematomas in critical locations; traumatic injuries; multiple tooth extractions; major surgical procedures)	
		Loading Dose	Maintenance Dose	Loading Dose	Maintenance Dose
Haemophilia A (factor VIII deficiency)	Cryoprecipitate	Not required	1.25 to 1.75 bags/10 kg every 12 h for 1 to 3 days	3.5 bags/10 kg	1.75 bags/10 kg every 8 h for 1 to 2 days; every 12 h thereafter
	Purified factor VIII	Not required	10 to 15 IU/kg every 12 h for 2 to 4 days	30 to 40 IU/kg	30 to 40 IU/kg every 12 h
Haemophilia B (factor IX deficiency)	Prothrombin complex	20 to 30 IU/kg	15 IU/kg every 24 h for 2 to 4 days	40 to 60 IU/kg	20 to 25 IU/kg every 24 h
	Purified factor IX	20 to 30 IU/kg	15 IU/kg every 24 h for 2 to 4 days	60 to 70 IU/kg	20 to 40 IU/kg every 24 h for 2 to 4 days

The replacement therapy requires a large quantity of factor concentrate which is very costly. It becomes very difficult for the patients and families to bear the cost, especially in India. Due to lack of treatment, therefore, many patients in India become crippled.

Anti-fibrinolytic agents like tranexamic acid and ε-epsilon amino-caproic acid (EACA) are used mostly in mucosal bleeds and also bleeding into central nervous system. These agents bind fibrinogen and thus, inhibit fibrinolysis. These should not be used in patients with haematuria.

Desmopressin (DDAVP; 1-desamino-1-D-arginine vasopressin) is used for mild bleeding episodes and mild haemophiliacs. It acts by increasing the release of stored factor VIII from endothelial cells. Hence, it is not useful for severe haemophiliacs. It is given as slow intravenous infusion or subcutaneous or intranasal route.

Additional measures include ice cold compression, analgesics, fibrin sealants, rest and physiotherapy. Physiotherapy is an important element of management and patient and family members must know its importance to have a normal quality of life. For complications like chronic haemophilic arthropathies, and pseudotumour, surgical management may be required.

Carrier detection helps in prevention of the disease by genetic counselling and antenatal diagnosis. Daughters of men with haemophilia and mothers with an affected son and another haemophiliac male relative are obligate carriers. Other females in the family from the same lineage are possible carriers. Carriers have reduced or low normal factor VIII/IX coagulant activity.

Table 5: Revised Classification of von Willebrand Disease

Revised type	Features
1	Partial deficiency of von Willebrand factor (vWF)
2	Qualitative vWF defects
2A	vWF variants with loss of high molecular weight multimers and decreased vWF-dependent platelet adhesion
2B	vWF variants with loss of high molecular weight multimers caused by increased affinity for platelet glycoprotein Ib
2M	vWF variants with decreased vWF-dependent platelet adhesion not associated with the loss of high molecular weight multimers
2N	vWF variants with decreased binding affinity for factor VIII
3	Severe deficiency of vWF

The basic defect is a deficiency or abnormality of vWF function. vWF is synthesised in the endothelial cells and megakaryocytes. It is required for normal platelet adhesion and it also acts as a carrier for factor VIII in the plasma. Whenever, vWF is deficient or aberrant, abnormalities in the early stages of primary haemostasis or F VIII deficiency result. Bleeding manifestations are heterogeneous. In mild forms, the manifestations may be skin and mucosal bleed due to defective primary haemostasis whereas in severe forms, haemarthrosis and dissecting intramuscular haematomas are seen. Epistaxis, easy bruisability, menorrhagia are amongst the different spectrum of disease manifestations.

Diagnosis of the disease may require repeated observations over a prolonged period of time. Both vWF and F VIII are acute phase reactants and increase in stress, pregnancy, trauma, oestrogen therapy, etc. Screening tests include bleeding time, platelet count, PFA-100, partial thromoboplastin time (PTT). Bleeding time is increased but may be normal; however, prolonged bleeding time adds to the diagnosis. Bleeding time is not recommended to monitor disease response to treatment. Plasma level of F VIII varies greatly from as low as ~3 µ/dL in patients with Type 3 vWD to normal levels in patients with mild type. vWF immunoassay is a quantitative measure of vWF. In patients with blood group O, the level is 25% lower. Ristocetin cofactor activity assay (vWF: RCo) is the most sensitive and specific assay for the diagnosis of vWD. Multimeric analysis is done to further characterise the disease.

Majority of the patients with vWD are mild, hence seldom need factor replacement. The goal of therapy is to stop active bleeding and prevent excessive bleeding during procedures, surgery and trauma.

DDAVP (Desmopressin) is the mainstay of treatment for mild forms of vWD. It raises the levels of vWF and F VIII by 2 to 4-fold over baseline. Response to treatment is variable between patients, and therefore, it is essential that therapeutic response is documented for each patient by a test dose at the time of diagnosis or before elective treatment or surgical prophylaxis.

DDAVP unresponsive patients need transfusion support; cryoprecipitate which can be obtained from the blood bank gives 80 to 100 units of factors per bag. Alternatively, intermediate purity F VIII concentrate with preservation of vWF multimers can be used.

Limited studies in India have reported a prevalence of approximately 10% of vWD among the cases with inherited bleeding disorders. In contrast to the Western countries Type 3 vWD has been shown to be more common; in a recent Indian Council of Medical Research study of vWD in Western India, it has been shown that Type 3 vWD is prevalent in ~ 60% of the cases. This may be because of low awareness and under-diagnosis of the mild cases.

OTHER INHERITED COAGULATION DISORDERS

Other inherited coagulation disorders like deficiencies of factor II, VII, IX, XI are rare and more commonly seen in populations that have consanguineous marriages. Afibrinogenaemia, dysfibrinogenaemia and factor XIII deficiency are also rare. Classically, in factor XIII deficiency there is history of bleeding from the umbilical stump, and spontaneous bleeding into the central nervous system is common. **Table 6** shows replacement therapy for this group of deficiency disorders. Inherited deficiency of multiple coagulation factors is very rare and only a few cases are reported. Congenital vitamin K-dependent coagulation factor deficiency (VKCFD) is one such form and has received increasing interest lately.

Table 6: Replacement Therapy in Other Inherited Coagulation Disorders

Disorder	Therapeutic product	Loading dose	Maintenance dose
von Willebrand disease	Hymate-P Cryoprecipitate	40 to 60 IU/kg Not required	40 to 50 IU/kg every 12 to 24 h;up to 7 days 1 bag/10 kg daily
Fibrinogen deficiency	Cryoprecipitate Purified fibrinogen	1 to 2 bags/10 kg 50 to 100 mg/kg	1 bag/10 kg every other day 20 mg/kg every other day
Prothrombin deficiency	Fresh frozen plasma	15 mL/kg	5 to 10 mL/kg daily
Dysprothrombinaemia	Purified prothrombin complex	20 IU/kg	10 IU/kg daily
Factor V deficiency	Fresh frozen plasma	20 mL/kg	10 mL/kg every 12 to 24 h
Factor VII deficiency	Fresh frozen plasma Purified prothrombin complex	20 mL/kg 30 IU/kg	5 mL/kg every 6 to 24 h 10 to 20 IU/kg every 6 to 24 h
Factor X deficiency	Fresh frozen plasma Purified prothrombin complex	15 to 20 mL/kg 15 IU/kg	5 to 10 mL/kg daily 10 IU/kg daily
Factor XI deficiency	Fresh frozen plasma	15 to 20 mL/kg	5 mL/kg every 12 to 24 h
Factor XIII deficiency	Fresh frozen plasma	5 mL/kg every 1 to 2 weeks	Not usually required

ACQUIRED COAGULATION DISORDERS

The acquired coagulation defects are usually characterised by multiple coagulation factor deficiencies, unlike congenital coagulation disorders which are because of a single factor deficiency. Acquired ones are usually associated with thrombocytopaenia, platelet functional defect and/ or vascular abnormalities. **Table 7** shows different forms of acquired coagulation disorders.

COAGULOPATHY DUE TO LIVER DISEASE

Liver disease can impair coagulation as a result of both biosynthetic and clearance dysfunction of liver. **Table 8** shows abnormalities of haemostasis and coagulation associated with liver disease. Even though numerous haemostatic abnormalities are associated with liver disease, majority of the patients do not bleed spontaneously. Most common bleeding manifestation is gastrointestinal haemorrhage and most commonly this originates from oesophageal varices, peptic ulcer, gastritis, etc. All patients with coagulation and liver disease do not require haemostatic correction. Patients with prolonged prothrombin thrombin time and high fibrin degradation products (FDPs) have a high-risk of bleeding.

Vitamin K supplementation can produce some improvement in coagulation abnormalities in ~30% of the patients. Replacement with fresh frozen plasma (FFP) is recommended only to patients with active bleeding and as surgical prophylaxis. Recombinant F VIIa may be used for hepatic coagulopathy. For

Table 7: Acquired Coagulation Disorders

Deficiencies of vitamin K-dependent coagulation factors

- Haemorrhagic disease of the newborn (vitamin K deficiency bleeding)
- Biliary obstruction (gallstone, strictures, fistulas)
- Malabsorption of vitamin K (sprue, idiopathic steatorrhoea, coeliac disease, ulcerative colitis, regional enteritis, gastrocolic fistulas, *Ascaris* infestation)
- Nutritional deficiency
- Drugs
  1. Pharmacologic antagonists of vitamin K (coumarins, indandiones, others)
  2. Those that alter gut flora (broad-spectrum antibiotics, sulphonamides)
  3. Miscellaneous (cholestyramine)

Liver Disease

Accelerated destruction of coagulation factors

- Disseminated intravascular coagulation
- Fibrinolysis (liver disease, thrombolytic agents, tumours, after surgery)

Inhibitors of coagulation

- Specific inhibitors (antibodies)
- Antiphospholipid-protein antibodies
- Miscellaneous (antithrombins, paraproteinemias)

Miscellaneous

- After massive transfusion
- After extracorporeal circulation
- Drugs (antibiotics, antineoplastic agents, others)
- Miscellaneous (polycythaemia vera, congenital heart disease, amyloidosis, nephrotic syndrome, Sheehan syndrome, Gaucher's disease, leukaemia, others)

Table 8: Abnormalities of Haemostasis and Coagulation in Liver Disease

Deficient biosynthesis

- Of fibrinogen; prothrombin; coagulation factors V, VII, IX, X, XI, XII, XIII; prekallikrein; high molecular weight kininogen
- Of antiplasmins, antithrombin, proteins C and S

Aberrant biosynthesis

- Of abnormal fibrinogen, factor V
- Of abnormal inhibitory analogue of prothrombin factors VII, IX, and X

Deficient clearance

- Of haemostatic 'products' [e.g. fibrin monomers, fibrin(ogen) degradation products, platelet factor-3]
- Of activated coagulation factors (IXa, Xa, XIa)
- Of plasminogen activators

Accelerated destruction of coagulation factors

- Disseminated intravascular coagulation
- Abnormal fibrinolysis

Thrombocytopaenia

- Hypersplenism (portal hypertension)
- Folic acid deficiency
- Chronic ethanol intoxication
- Disseminated intravascular coagulation

Platelet dysfunction

- Acute and chronic ethanol intoxication
- Effects of products of fibrinogen degradation
- Uraemia

Miscellaneous

- Inhibition of coagulation by products of fibrinogen degradation
- Loss or consumption of coagulation factors in ascitic fluid

thrombocytopaenia synthetic thrombopoietin or thrombopoietin mimetic agents are nowadays available, but yet unproven in controlled trials.

Disseminated Intravascular Coagulation

A consensus definition of disseminated intravascular coagulation (DIC) has been proposed:

'It is an acquired syndrome characterised by intravascular activation of coagulation with loss of localisation arising from different causes. It can originate from and cause damage to the microvasculature which if sufficiently severe can cause organ dysfunction.'

The pathophysiology of DIC is complex. The trigger acts on processes involved in normal haemostasis; thrombin is persistently generated and fibrin is formed in the circulating blood. Thus, fibrinogen and other coagulation factors are consumed. The fibrinolytic mechanism is activated and large numbr of FDP are generated.

The major clinical features of DIC are abrupt onset serious bleeding, shock out of proportion to blood loss, acute renal failure, and thromboembolic manifestations. There is a marked heterogeneity in clinical manifestations; it has been shown that DIC due to obstetric disorders manifests as bleeding in almost all whereas DIC due to sepsis are mostly associated with organ dysfunction.

Laboratory tests should be interpreted carefully as levels of many coagulation factors remain elevated in many of the conditions associated with DIC. Basic blood examination would show schistocytes on peripheral blood smear in ~50% of the cases which is suggestive of DIC. D-dimer is one of the important tests; level of more than 2,000 ng/mL is consistent with DIC, but is NOT specific.

The aim of replacement therapy in DIC is to replenish fibrinogen and is achieved by using cryoprecipitate which contain fibrinogen of ~250 mg per bag. Bleeding patients with platelet count of less than 50,000/cu mm should be given platelet transfusion; due to associated platelet function defect, DIC patients required a higher platelet count, for adequate haemostasis. Anti-fibrinolytic agents like EACA and tranexamic acid should be used carefully and only in selected cases where fibrinogenolysis, hypofibrinogenaemia, and adequate renal function is clearly documented. Heparin therapy has favourable result in patients with chronic DIC manifesting mainly with thrombosis, but is avoided in acute DIC with active bleeding.

ACQUIRED HAEMOPHILIA

Acquired haemophilia is seen as a result of autoantibodies to factor VIII in non-haemophilia persons. It can arise spontaneously or secondary to various diseases as shown in **Table 9**. In elderly persons it is most often idiopathic. The disease manifestations are like congenital haemophilia except that haemarthrosis is an uncommon presentation. Antibodies to F VIII that arise during pregnancy may cross the placenta. Prolonged APTT which does not correct on mixing with normal pooled plasma gives clue to the diagnosis which can be confirmed by factor

assay and inhibitor assays. Treatment includes replacement therapy with large doses of recombinant factor VIII concentrate, steroids, cytotoxic agents, intravenous immunoglobulin (IVIG), recombinant F VIIa and rituximab (monoclonal antibody to CD20).

Table 9: Different Causes of Acquired Haemophilia

Alloantibodies in haemophilia A
Autoantibodies in non-haemophilia patients
Autoimmune disease
Systemic lupus erythematosus
Rheumatoid arthritis
Dermatologic conditions
Psoriasis
Pemphigus vulgaris
Pregnancy (peripartum)
Malignancy
Lymphoproliferative disorders
Plasma cell dyscrasias
Non-haematologic
Medications: penicillin, sulpha antibiotics, chloramphenicol, phenytoin
Idiopathic

ACQUIRED DEFICIENCY OF SINGLE COAGULATION FACTOR

This is an uncommon phenomenon. Isolated F X deficiency is seen in patients with primary amyloidosis. Likewise, hypoprothrombinemia has been seen to be associated with lupus anticoagulant. In nephritic syndrome, deficiencies of prothrombin, F IX and F XII, plasminogen and antithrombin have been reported due to loss in urine. F XIII deficiency has been associated with inflammatory bowel disease.

CONCLUSION

Coagulation disorders are seen commonly in clinical practice. History of the pattern of bleeding, age of onset, family history and clinical examination (haematomas, haemarthrosis, joint deformity, petechia, ecchymosis, evidence of underlying clinical condition, etc.) are of utmost importance while evaluating such patients. Short screening is the first line of laboratory evaluation on the basis of which confirmatory tests are planned. Principal treatment of this disorder is replacement of the deficient factor. Most of the factors are commercially available; however cost is a concern especially in India. Transfusion transmitted infection, inhibitor formation and thrombosis are the major concerns of replacement therapy. Therefore, mild haemophilia and mild vWD should be treated with DDAVP or antifibrinolytic agents to avoid unnecessary exposure to factor concentrates or blood or animal products. Factor concentrates used for replacement should preferably be recombinant or otherwise be virus inactivated. Awareness amongst patients and family members and measures for carrier detection would go a long way for the prevention of common inherited disorders.

15.18 Hypercoagulable Disorders

Mammen Chandy

PHYSIOLOGY OF HAEMOSTASIS AND ITS REGULATION

There are three integral components of haemostasis—blood vessel wall, platelets and coagulation cascade, which lays down the fibrin clot. Haemostasis is always linked to fibrinolysis since the clot must be removed within the lumen of the vessel and blood flow restored. There is a finely tuned regulatory mechanism to balance the need to arrest haemorrhage and also prevent thrombosis.

The key initiator of coagulation is tissue factor VIIa which generates a small amount of thrombin through factors X and V and this then augments the process by activating factors XI, IX and VIII. More thrombin is generated, fibrinogen is converted to fibrin and this is stabilised by factor XIII. Tissue factor pathway inhibitor (TFPI) blocks the tissue factor/VIIa complex while antithrombin III (ATM) inhibits coagulation by blocking the action of thrombin and factor X while protein C and its co-factor protein S act by breaking down activated Factors VIII and V. Platelets are important in primary haemostasis as they play an important role in arterial thrombosis and atherosclerosis (**Figure 1**). The endothelial cell is not just the part of a conduit but it has important procoagulant and anticoagulant functions (**Figure 2**). Once a clot has been formed the intraluminal portion is broken down by plasmin which is formed by the action of activators on plasminogen within the clot, while any free plasmin is inactivated (**Figure 3**).

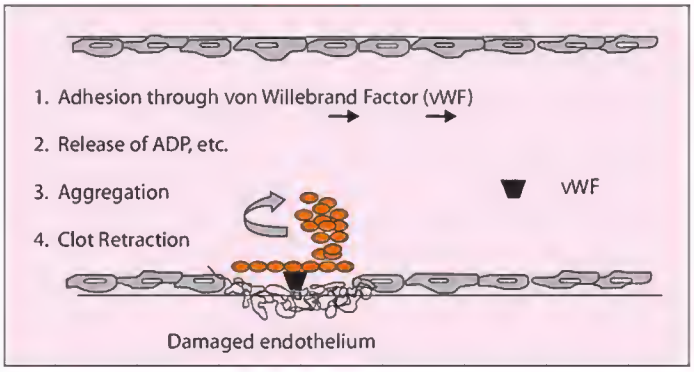

Figure 1: Role of platelets in haemostasis.

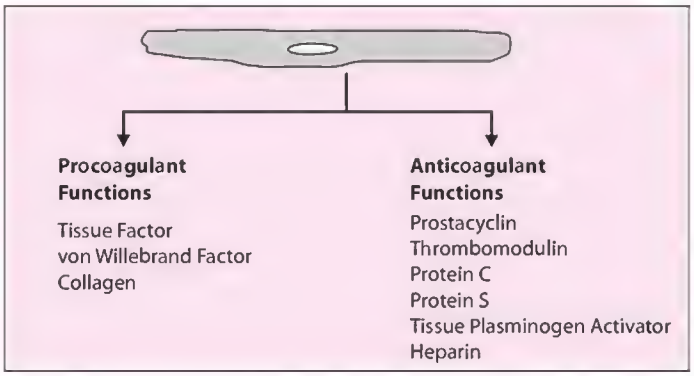

Figure 2: Endothelial cell in haemostasis.

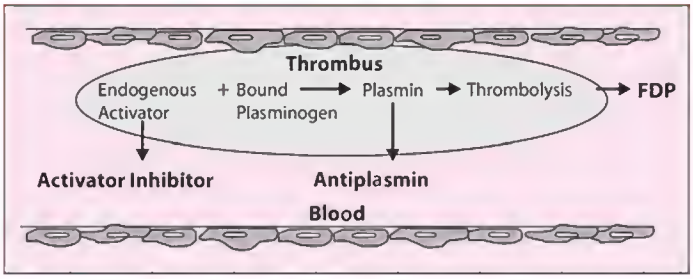

Figure 3: Normal fibrinolysis within a thrombus.

PATHOGENESIS OF THROMBOSIS

It is evident that any change in this finely balanced system can result in either thrombosis or haemorrhage; Rudolf Virchow was the first to suggest that there are three underlying precipitating factors in the pathogenesis of thrombosis: stasis, damage to the vessel wall and change in the composition of blood. Today the pathogenesis can be understood in terms of genetic risk factors and acquired factors and in a given patient these two could be operating together resulting in thrombosis (**Tables 1 and 2**).

Table 1: Acquired Causes of Thrombosis

Lupus anticoagulant syndrome
Malignancy
Drugs: oestrogen, prothrombin complex concentrates, heparin
L-asparaginase
Nephrotic syndrome
HUS, TTP
Paroxysmal nocturnal haemoglobinuria (PNH)
Myeloproliferative disorders: Polycythaemia, essential thrombocythaemia
Vascular damage due to diabetes, hypertension, atherosclerosis
Hyperlipidaemia
Congestive cardiac failure, hyperviscosity
Immobilisation

HUS = Haemolytic-uraemic syndrome; TTP = Thrombotic thrombocytopaenic purpura.

Table 2: Hereditary Causes of Thrombosis

Resistance to activated protein C-Factor V Leiden
AT III deficiency
Protein C deficiency
Protein S deficiency
Prothrombin gene mutations
Disorders of fibrinolysis
Dysfibrinogenaemia
Homocystinuria homozygous and due to methylene tetrahydrofolate reductase mutations
Sickle cell anaemia

Fifteen per cent of patients less than 45 years of age with venous thrombosis may have an inherited thrombotic disorder. Clinical features and diagnosis of venous and arterial thromboembolism are discussed in different sections of this book.

THROMBOPHILIA

This is a term used when an individual has a predisposition to thrombosis which can be inherited or acquired. Table 2 lists the hereditary causes and the probability of finding a genetic predisposition in patients with deep venous thrombosis (DVT). Deficiencies of AT III, protein C and protein S are rare with a frequency of less than 0.5% in the population. AT III deficiency is autosomal dominant and there is a high-risk of thrombosis. Homozygous protein C is very severe and presents as purpura fulminans. Acquired deficiencies of these anticoagulant proteins can occur in patients on L-asparaginase, those with nephrotic syndrome and vitamin K deficiency. The most common genetic cause for thrombosis among Caucasians is factor V Leiden where the mutation makes FV resistant to proteolytic cleavage by protein C. Mutations in the methylene tetrahydrofolate reductase gene are present in 20% of the population and this may produce a mild increase in the tendency to clot because of raised homocysteine levels. Clinical indications of a hereditary thrombotic disorder include: thrombosis occurring at an early age, family history of thrombosis, thrombosis at an unusual site, recurrent thrombosis, thrombosis while on anticoagulants and warfarin-induced skin necrosis.

Thrombophilia in Developing Countries

Data on thrombophilia from the developing world is scarce because of inadequate laboratory facilities for documentation and the denominator is different in published studies. There are no large epidemiological studies in the general population. However, it appears that in comparison with the incidence of DVT (48 per 100,000 admissions) and pulmonary embolism (23 per 100,000 admissions) in patients admitted to a hospital in the West, in India the incidence is much lower, DVT—7 per 100,000 and pulmonary embolism—6 per 100,000.

In a study done in the UK, the incidence of thrombophilia in patients attending an anticoagulant clinic was significantly lower in Asians when compared to Caucasians but in Asians with thrombosis there was a higher chance of finding a genetic cause.

Investigating the Underlying Cause in a Patient with Thrombosis

Detailed investigations are best avoided in the acute post-thrombotic phase since heparin therapy reduces AT III levels and oral anticoagulants reduce protein C and protein S levels. The algorithm showing the timing of different tests is given in **Table 3**.

Family members of the index patient should be studied. Management guidelines of hereditary thrombophilia are given in **Table 4**.

Antiphospholipid Antibodies and Lupus Anticoagulant

Antiphospholipid antibodies are acquired antibodies present in the circulation, seen commonly, but not exclusively, in patients with systemic lupus erythematosus. These antibodies are associated with the antiphospholipid syndrome, the clinical manifestations, diagnostic criteria, laboratory diagnosis and management of which are discussed in the chapter on 'Antiphospholipid Syndrome' (see chapter 10 of section 24).

Table 3: Investigation of a Patient with a Thrombotic Disorder

Step I tests: Initiate anticoagulation after sending blood for Step I tests
- Full blood count
- Blood film for schistocytes
- Haemoglobin
- White cell count
- Platelet count
- Prothrombin time
- Activated partial thromboplastin time
- Thrombin time
- Fibrinogen estimation

Step II tests: Can be done in the acute phase while on anticoagulants
- Sickle preparation
- Anticardiolipin antibody
- Lupus anticoagulant
- ANA, dsDNA
- Tests for paroxysmal nocturnal haemoglobinuria—Ham's test, sucrose lysis, urine haemosiderin, flow cytometry for CD55, CD59

Step III tests#: Can be done while on anticoagulants since they are DNA-based
- Factor V Leiden
- Prothrombin gene 20210 mutation
- Methylene tetrahydrofolate reductase mutation

Step IV tests#: To be done after stopping anticoagulants
- Antithrombin III#
- Protein C*
- Protein S*

*#can be done while on coumarin; *can be done while on heparin.*
ANA = Antinuclear antibody; dsDNA = Double stranded deoxyribonucleic acid.

Table 4: Management Guidelines for Patients with Hereditary Thrombophilia

High risk: Indefinite anticoagulation
- Two or more spontaneous thromboses
- One spontaneous thrombosis in the case of antithrombin deficiency or the antiphospholipid antibody syndrome
- One spontaneous life-threatening thrombosis (e.g., near-fatal pulmonary embolism; cerebral, mesenteric or portal vein thrombosis)
- One spontaneous thrombosis at an unusual site (e.g., mesenteric or cerebral vein)
- One spontaneous thrombosis in the presence of more than a single genetic defect predisposing to a thromboembolic event

Moderate risk: Vigorous prophylaxis during high-risk situations
- One thrombosis with a prothrombotic stimulus
- Asymptomatic family member

ANTITHROMBOTIC DRUGS

Broadly, these may be grouped as those used for preventing the formation of a clot (anticoagulants and antiplatelet drugs) and those used for clot lysis (thrombolytic agents).

Anticoagulants

Heparin

Unfractionated heparin is a mixture of heparins with molecular weights ranging from 3,000 to 30,000 Da. Only 30% of the administered dose contains AT III–binding sequences and

therefore the effects are variable. The activity is low compared to the purified low molecular weight heparin (LMWH). Heparin forms a complex with AT III which inactivates thrombin, factors Xa and IXa. Heparin also inhibits platelet aggregation.

Heparin may be administered as intravenous bolus, infusion, or subcutaneous. Heparin therapy is best monitored by checking the partial thromboplastin time (PTT), which should be kept at 1.5-2 times the normal level. Adverse side effects include bleeding tendencies in up to one-third of cases, allergic reactions, thrombocytopaenia, osteoporosis and hyperkalaemia. Thrombocytopaenia due to heparin can be associated with thrombosis Heparin-induced thrombocytopaenia/thrombosis (HITT) with life-threatening venous and arterial thrombosis and this is managed with direct thrombin inhibitors like hirudin. Heparin does not cross the placenta, and therefore, there is no risk of foetal haemorrhage or foetal malformation. Overdose of heparin is treated by withdrawal of further doses, fresh frozen plasma, and the specific antidote, protamine sulphate, which neutralises heparin at a ratio of 1 mg/100 units.

Low molecular weight heparin

LMWH (molecular weight 3,000 to 7,000 Da) has lower ability to inhibit thrombin, but 2 to 4 times greater ability to inhibit factor Xa than unfractionated heparin. LMWH also stimulates the release of an endogenous tissue factor pathway inhibitor (TFPI), enhancing the anticoagulant potential.

LMWH has higher bioavailability on subcutaneous injection and its half-life is greater, so that single or twice daily injections are sufficient. The antithrombotic effect manifests even without prolonging the PTT and therefore, *in vitro* tests are not essential to monitor the anticoagulant effect. LMWH is effective in the prophylaxis of DVT and pulmonary embolism. The dose is dependent on the preparation used (enoxaparin 1 mg/kg twice daily or 1.5 mg/kg once daily for therapy and 40 mg daily for prophylaxis). LMWH should not be used in renal failure and protamine is not effective as an antidote.

Newer Anticoagulants

Pentasaccharides

Fondaparinux exerts its anticoagulant effect solely via antithrombin-III mediated neutralisation of factor Xa and is devoid of IIa inhibition. It does not bind to platelet factor 4 and therefore should not produce Heparin-induced thrombocytopaenia/thrombosis (HIT/HITT). It is given as a single daily subcutaneous dose of 2.5 mg.

Hirudin

Hirudin is 10 times as potent than heparin. It does not produce thrombocytopaenia and can be used to treat HITT. Lepirudin is a synthetic analogue.

Oral Anticoagulant Drugs

Coumarins are the most commonly used oral anticoagulants which act by blocking vitamin K-dependent gamma carboxylation of coagulation factors II, VII, IX and X and the anticoagulant proteins C and S. Different coumarins and their dosing pattern is given in **Table 5**. It is usual to start heparin or a similar drug for immediate action and to simultaneously introduce the oral anticoagulant. After 4 to 5 days heparin is withdrawn and anticoagulation is maintained with the oral drugs indefinitely or for specified periods depending upon the clinical indications.

Table 5: Common Oral Anticoagulants

Name of Drug	Dose	Remarks
Warfarin	4 to 5 mg per day for 5 days followed by reduced doses based on required INR	72 hours half-life
Acenocoumarol	1 to 8 mg per day	24 hours half-life
Dicoumarol	25 to 200 mg per day	Slow and erratic absorption
Indanediones (phenindione)	50 to 100 mg per day	Rarely used, does not cause alopaecia but can cause agranulocytosis

INR = International normalised ratio.

Adverse Effects

Haemorrhage related mostly to the dose and concomitant administration of interacting drugs is the most common side effect and this risk is increased in older patients. These drugs cross the placenta and may lead to foetal malformations and foetal haemorrhage. Monitoring the level of anticoagulation is done by the prothrombin time with a target international normalised ratio (INR) ranging from 1.5 to 3.5 depending on the risk of thrombosis. The following drugs potentiate the action of coumarins: acetaminophen, allopurinol, antibiotics, clofibrate, tolbutamide, isoniazid, phenytoin and the following drugs reduce the action by stimulating cytochrome P450: barbiturates, carbamazepine, digitalis, alcohol, prednisolone, oral contraceptives, haloperidol. The specific antidote is vitamin K_1 at a dose of 1 mg intravenously. If immediate reversal of the bleeding tendency is desired fresh frozen plasma should be given. The indications and contraindications for the use of anticoagulation are given in **Table 6**. Dabigatran is a new oral anticoagulant which can be administered for prophylaxis of DVT without PT monitoring.

ANTIPLATELET DRUGS

Aspirin, dipyridamole, ticlopidine and clopidogrel are the main drugs used for inhibiting platelet aggregation. Among these, aspirin is the most widely used on account of its safety and low cost.

Table 6: Use of Anticoagulation

Indications
- Deep venous thrombosis
- Pulmonary embolism
- Myocardial infarction
- Unstable angina
- Acute peripheral arterial occlusion and embolism
- Mitral stenosis with atrial fibrillation
- Transient ischaemic attacks
- Mechanical prosthetic cardiac valves

Contraindications
- Recent neurosurgery or eye surgery
- Pre-existing bleeding disorders, e.g. chronic liver disease, haemophilia
- Peptic ulcer
- Recent intracerebral haemorrhage
- Uncontrolled hypertension

Note: Anticoagulation is initiated with heparin because of the rapid onset of action and because an occasional patient with protein C deficiency may develop skin necrosis if coumarins are given without heparin. Loading doses of coumarins are no longer given: start with 4 to 5 mg of coumarin, check PT in 3 days and when desired INR is reached, stop heparin.

Aspirin

At a dose of 75 mg per day it blocks the formation of thromboxane A_2 (TxA_2), preventing aggregation of platelets. The action on the platelet is irreversible and platelets remain non-functional for the whole life-span of 5 to 7 days. In larger doses (over 1 g/day) aspirin also inhibits the production of prostacyclin which normally inhibits platelet aggregation and induces vasodilatation, hence low dose aspirin is preferred for prevention of thrombosis. Adverse effects include gastric erosions and gastrointestinal bleeding. Maximal inhibition of platelet aggregation is seen in 3 to 5 days, a larger dose of 325 mg daily for 2 days may be started if rapid onset of action is required.

Dipyridamole

This drug acts by increasing the cellular concentration of cyclic adenosine monophosphate (AMP) and thereby inhibits platelet function. In cases of intolerance to aspirin, dipyridamole is a suitable alternative. The dose is 100 to 300 mg per day as oral tablets.

Ticlopidine and Clopidogrel

These are thienopyridines which inhibits platelet function by direct inhibition of adenosine diphosphate (ADP) binding to its receptor and of the subsequent ADP-mediated activation of the glycoprotein GPIIb/IIIa complex. It takes 2 to 3 days for full action to be established. The action persists for a few days even after stopping the drug. Ticlopidine has a higher risk (0.8%) of agranulocytosis and therefore, clopidogrel is preferred and the daily dose is 75 mg once.

DRUGS USED FOR THROMBOLYSIS

These are fibrinolytic agents which activate the endogenous plasminogen system or which have intrinsic fibrinolytic properties, streptokinase, urokinase and recombinant tissue plasminogen activator are examples. These are mainly used in the management of coronary artery thrombosis, pulmonary embolism, peripheral vascular occlusions and selected cases of non-haemorrhagic cerebral infarcts.

15.19 Transfusion Medicine

Neelam Marwaha

Transfusion medicine today is a multi-faceted discipline. Its scope extends from collection of blood units to preparation and standardisation of blood components, blood serology, testing for transfusion transmitted diseases, to direct patient care services based on aphaeresis technology for therapeutic plasma exchange, cytoreduction and cellular therapies. Historically, the discovery of ABO blood groups by Karl Landsteiner in 1900 laid the foundation of clinical practice of blood transfusion.

BLOOD GROUP SYSTEMS

Thirty blood group systems are presently recognised, though all are not clinically significant. The clinical importance depends upon: (i) frequency with which alloantibodies occur in response to red cell antigens, (ii) characteristics of the alloantibodies such as immunoglobulin (Ig) class; IgG or IgM, subclasses of IgG, (iii) thermal range of the antibody, and (iv) its ability to fix complement.

ABO Blood Group System

The ABO blood group system is most significant for transfusion. This is because of regular presence of naturally occurring reciprocal alloantibodies in individuals who had no exposure to that antigen (**Table 1**).

Table 1: ABO Red Cell Antigens and Alloantibodies

Group	Antigen on red cells	Alloantibodies in plasma
A	A	Anti B
B	B	Anti A
O	H	Anti A, Anti B
AB	A,B	None

Hence, transfusion of ABO incompatible blood leads to an acute haemolytic transfusion reaction (HTR). These antibodies are IgM in nature, fix complement and cause intravascular haemolysis. Group 'O' red cells have neither A nor B antigen and can, thus, be transfused to 'A' or 'B' individuals. Therefore, 'O' individuals are referred to as universal donors. The antigen present on 'O' group red cells is the 'H' substance which is the precursor of A and B antigens. Absence of 'H' substance leads to a rare blood group termed that is the Bombay blood group, designated as (Oh). These individuals have anti A, anti B and anti H antibodies, and thus can receive blood only from individuals with Bombay blood group. Transfusion of 'O' group red cells will lead to haemolysis due to presence of anti-H. Individuals with AB phenotype do not have ABO alloantibodies and are, thus, universal recipients.

ABO grouping consists of testing the red cells with anti-A and anti-B sera (cell or forward grouping) and testing the serum with A and B red cells (serum or reverse grouping). The two serve as a check on each other. In neonates and infants up to 4 months of age, no serum grouping is necessary since antibodies appear later. When the results of red cell grouping do not match with serum grouping, the individual has an ABO discrepancy which needs resolution before proceeding for transfusion.

The Rh System

The Rh system is next in importance for transfusion. About 49 antigens are known but D antigen is most immunogenic. Transfusion of D positive red cells to D negative recipient leads to alloimmunisation in 90% of the recipients. It is the most common cause of haemolytic disease of newborn (HDN) in Rh D negative mothers carrying an Rh D positive foetus. Presence of D antigen connotes Rh positive blood group while absence of D antigen leads to Rh negative phenotype. However, there are four other clinically significant antigens in the Rh system; C, c, E and e. Alloantibodies to these may appear in multiply transfused patients. Antibodies to Rh antigens appear only after exposure to the antigens, are usually IgG and lead to delayed HTRs due to extravascular haemolysis.

Other Clinically Significant Blood Group Systems

Kell, kidd and duffy systems

Kell antigen (K) is next in order of immunogenicity after ABO and Rh antigens. Anti-kell alloantibodies complicate the management in patients on regular transfusion therapy, such as thalassaemics. Two Kidd antigens, Jk^a and Jk^b are well characterised. Antibodies to these antigens disappear rapidly in alloimmunised patients, hence on subsequent transfusion with Kidd antigen positive red cells, there is anamnestic response and delayed HTR. Fy^a and Fy^b are the clinically significant Duffy antigens. The alloantibodies are IgG, cause delayed HTRs and can also cause HDN as they cross the placenta. The Duffy protein is also the receptor for *P. vivax* and Duffy negative inviduals are resistant to *P. vivax* infection. This phenotype is most common in black races.

MNS system

The important antigens are M,N,S,s and U. Anti-M and N may occur naturally, are IgM in nature and have been associated with acute HTR. Anti S, s and U usually occur following red cell transfusions and are IgG. Anti-U antibodies are problematic since it is difficult to find U negative donors.

Lewis and P systems

The Lewis system antigens are Le^a and Le^b. They are adsorbed onto red cells from plasma. Antibodies may form in Le (a-b-) individuals, are IgM in nature and can cause acute HTRs. P_1 negative individuals may contain naturally occurring IgM alloantibodies. In paroxysmal cold haemoglobinuria, the biphasic Donath Landsteiner autoantibody is directed towards P antigens. These also form receptors for many pathogens including *Escherichia coli* and parvovirus B19.

The I/i antigens and antibodies

Cold agglutinins which arise in lymphoproliferative disorders and cold agglutinin disease, usually have 'I' specificity, an antigen

found on adult red cells. Cold agglutinins which appear post-infection as in *Mycoplasma pneumoniae* or infectious mononucleosis have 'i' specificity, an antigen found on cord blood red cells.

PRE-TRANSFUSION TESTING

It commences with request for transfusion where the requisition form should have relevant clinical details,informed consent, number of blood units required and signature of the physician. This is followed by identification check of the patient's sample and requisition form in the transfusion services. Recipient's ABO and Rh(D) grouping and repeat donor unit blood grouping are performed. Hereafter, depending upon the facilities available, an antibody screen is performed on recipient's serum/plasma for any irregular antibodies. If antibody screen is positive, the alloantibody is identified and donor units typed for the corresponding antigen to find an antigen negative unit. Cross-match is then put-up with antigen negative donor red cells and recipient's serum. In case of non-availability of antibody screening and identification technology, the donor red cells are cross-matched with recipient's serum. In case of incompatibility, cross-match is repeated with other group specific units until compatible units are found. Cross-match is performed in the saline phase which detects IgM antibodies and in the antiglobulin or Coombs' phase which detects IgG antibodies. During urgent requisitions, only saline cross-match is performed by many transfusion services and this may fail to detect clinically significant IgG antibodies.

BLOOD COMPONENTS

Donor blood is collected in citrate phosphate dextrose adenine (CPDA-1) as anticoagulant preservative solution either as 350 mL or 450 mL volume. This unit is referred to as whole blood and has a haematocrit of 30% to 40%. It is stored at 4°C. At this temperature platelets rapidly lose their viability, granulocytes disintegrate and labile coagulation factors (F VIII) decline rapidly. Separation of whole blood into components helps to preserve functions and optimises blood usage. The components are prepared within 6 to 8 hours of whole blood donation. The various components which can be prepared are as follows:

Packed Red Blood Cells (PRBCs)

Haematocrit is 65% to 75% and volume almost half of whole blood. Shelf-life in CPDA-1 is 35 days, but can be increased to 42 days in additive solutions.

Platelets

These are platelet rich plasma, random donor platelet (RDP) concentrates, pooled buffy coat platelet concentrates and aphaeresis platelets. Aphaeresis platelets also known as single donor platelet (SDP) are equivalent to 5 to 6 RDPs. Platelets are stored at +22°C and have a shelf-life of 5 days.

Fresh Frozen Plasma (FFP)

It contains all coagulation factors and plasma proteins. Its shelf-life is one year at temperatures below –30°C.

Cryoprecipitate

It is prepared from FFP and is rich in F VIII, von Willebrand factor (vWF), fibrinogen and F XIII. Its shelf-life is one year at temperatures below -30°C.

Granulocytes

These can be obtained from buffy coat or granulocytaphaeresis. The former has granulocyte count less than 1×10^9 and can only be used in neonates. Aphaeresis product has 1×10^{10} granulocytes.

INDICATIONS FOR TRANSFUSION

Whole Blood

Whole blood, fresh or stored has no appropriate indication except perhaps in an acutely bleeding patient, especially trauma. However, in developing countries due to limited or no availability of blood components, whole blood continues to be used. No medication other than normal saline should be added to the intravenous line to avoid haemolysis.

Packed Red Cells

They are indicated in patients with symptomatic anaemia. In chronic anaemias, volume overload can be avoided. One unit raises haemoglobin (Hb) by 1 g/dL or haematocrit by 3%. In treatable anaemias like iron/B12/folate deficiency, transfusions are to be avoided unless there is evidence of severe oxygen deficit. There is no absolute transfusion trigger, but transfusion is recommended when the Hb is less than 6 g/dL and between 6 to 10 g/dL, as per the clinical situation. In older patients and those with cardiac disease, a higher threshold of 10 g/dL is recommended.

PRBCs can be modified to reduce adverse events. These can be plasma reduced by adding additive solutions and washed to remove plasma in patients with allergic reactions. Once washed the shelf-life reduces to 24 hours. These are irradiated for prevention of transfusion-associated graft *versus* host disease (TA-GvHD) in susceptible patients. Leucofilters remove 99.9% white blood cells and decrease the risk of alloimmunisation and febrile non-haemolytic transfusion reactions. For rare blood groups, PRBCs can be frozen up to 10 years.

Platelets

Platelet transfusions are given prophylactically or therapeutically. For prophylaxis, the rationale is to prevent bleed when the platelet count reaches certain thresholds. The maximum numbers of prophylactic platelet transfusions are given in haemato-oncology patients on intensive chemo-radiotherapy. The transfusion thresholds are as follows:

- 5,000/µL for stable chronic thrombocytopaenic patients, e.g. aplastic anaemia.
- 10,000/µL for stable acute leukaemia patients
- 20,000/µL for patients with fever, sepsis
- 50,000/µL for invasive procedures
- 1,00,000/µL for brain/eye surgery

One unit of RDP raises platelet count by 5,000 to 10,000/µL. One aphaeresis unit raises platelet count by 30,000 to 60,000/µL. Therapeutic platelet transfusions are given in actively bleeding thrombocytopaenic patients. The threshold is 50,000/µL. Platelet transfusions are contraindicated in thrombotic thrombocytopaenic purpura (TTP), while in idiopathic thrombocytopaenic purpura, platelets may be given in life-threatening bleeds or just prior to splenectomy. Dosage in adults is one RDP unit/10 kg. Irradiated platelets are issued for immunosuppressed patients to prevent TA-GvHD.

Fresh Frozen Plasma

Appropriate indications are coagulation disorders like disseminated intravascular coagulation (DIC), liver disease,

congenital bleeding disorders where factor concentrates are unavailable and reversal of warfarin therapy. The dose is 10 to 15 mL/kg body weight. One unit of FFP causes an increment of coagulation factors by 8% to 10%. Therapy should be monitored by prothrombin time ratio, if it falls below 1.5 times normal FFP transfusions should be stopped.

Cryoprecipitate

In the developing countries it serves as a source of F VIII in haemophilia A, where F VIII concentrates are scarce. One unit contains 80 IU of F VIII. It is a good source of fibrinogen and is often used in DIC when fibrinogen level falls below 100 mg/dL. One bag of cryoprecipitate increases fibrinogen level by 10 mg/dL.

FFP and cryoprecipitate should be thawed immediately prior to use and transfused within 6 hours of thawing.

TRANSFUSION-ASSOCIATED ADVERSE EVENTS

Adverse events are classified as acute if they occur within 24 hours of transfusion or delayed. They may also be classified based on aetiopathogenesis. **Tables 2 and 3** depict the adverse events, their pathogenesis and salient clinical features.

Metabolic and haemostatic abnormalities can occur during massive transfusion (MT). MT is usually required in patients with trauma, obstetric haemorrhage, liver transplant or massive gastrointestinal bleeds. It is defined as replacement of whole blood volume within 24 hours or loss of 150 mL blood per hour. In neonates double volume exchange transfusion and transfusion for major surgeries constitutes MT. Metabolic complications like hyperkalaemia, acidosis and citrate toxicity leading to hypocalcaemia may occur. Hypothermia and dilutional coagulopathy and thrombocytopaenia may also develop. In such situations blood warmers, FFP, cryoprecipitate and platelet transfusions are of tremendous value.

HAEMOVIGILANCE

It is a surveillance system aimed to detect and analyse all serious adverse effects of blood transfusion in order to rectify their cause and prevent their occurrence. It may be through legislation as it happened in France or voluntary as exemplified by the UK [United Kingdom Serious Hazards of Transfusion (SHOT Project)]. However, confidentiality of patients, donors and reporting clinicians needs to be maintained. Haemovigilance

Table 2: Acute Adverse Events

Adverse Event	Pathogenesis	Clinical Features
Haemolytic transfusion reactions	Immune Preformed complement fixing alloantibodies in recipient Non-immune mechanical/osmotic/thermal damage to RBCs	Fever, chills, flank pain, hypotension, DIC, renal failure, haemoglobinuria
Febrile non-haemolytic transfusion reactions (FNHTRs)	Alloantibodies to WBCs in recipient Cytokine accumulation in cellular blood components	Fever (rise >1°C) chills, rigours
Urticarial reactions	IgE antibodies	Pruritis, rash
Anaphylaxis	Antibodies to donor plasma proteins	Hypotension, respiratory distress
Transfusion related acute lung injury (TRALI)	Anti HLA/neutrophil antibodies in donor plasma chemokine/bioactive lipids in cellular components	Respiratory distress, hypoxia, bilateral non-cardiogenic pulmonary oedema
Transfusion-associated circulatory overload (TACO)	Rapid large volume transfusion in elderly and neonatal patients	Respiratory distress, hypertension, increased levels of beta natriuretic peptide
Transfusion-associated bacterial sepsis	Bacterial contamination due to skin flora, asymptomatic donor bacteraemia More often seen with platelet concentrates due to higher storage temperature (22 °C)	Fever, chills, hypotension, shock

DIC = Disseminated intravascular coagulation; RBCs = Red blood cells; WBCs = White blood cells; Ig = Immunoglobulin; HLA = Human leucocyte antigen.

Table 3: Delayed Adverse Events

Adverse Event	Pathogenesis	Symptoms
Haemolytic transfusion reactions	IgG type of alloantibodies in previously sensitised patients	Unconjugated hyperbilirubinaemia, fall in Hb
Post-transfusion purpura	Antiplatelet HPA1 antibodies, destroy allogeneic and autologous platelets	Purpura within 7 to 10 days of transfusion
Iron overload	Regular transfusion therapy with inadequate iron chelation. Each unit contains 200 mg of iron, appears after 100 RBCs units	Cardiac, hepatic, endocrine dysfunction
Transfusion transmitted viral infections	Window period transmission (pre-seroconversion phase)	HIV, hepatitis B, C, parvovirus B19, CMV in susceptible recipients
Transfusion transmitted malaria	Merozoites in donor erythrocytes (asymptomatic)	Malaria symptoms within 7 to 14 days
Transfusion-associated graft versus host disease (TA-GvHD)	Recognition of host antigens as foreign by donor T-lymphocytes	Skin, gastrointestinal and hepatic symptoms, pancytopaenia
Transfusion related immuno-modulation (TRIM)	Increased cytokine stimulation by donor leucocytes, still not completely understood	Increased renal allograft survival but infection and tumour recurrence
Prion's disease	Asymptomatic infected individuals	vCJD

Ig = Immunoglobulin; Hb = Haemoglobin; RBCs = Red blood cells; HIV = Human immunodeficiency virus; CMV = Cytomegalovirus; vCJD = Variant Creutzfeldt-Jakob disease.

data is of enormous value for improving transfusion practices. Some of the initiatives taken are universal leucodepletion to prevent alloimmunisation, febrile non-haemolytic transfusion reactions and cytomegalovirus transmission, irradiation to prevent TA-GvHD, methods to reduce bacterial contamination, avoiding use of plasma components from parous females to avoid transfusion related acute lung injury and methods to check mismatched blood/component transfusions.

HOSPITAL TRANSFUSION COMMITTEE

Hospital Transfusion Committee should be constituted in all health care facilities to evaluate all aspects of transfusion in the hospital and to ensure compliance with various national/international guidelines on good transfusion practices. Members should comprise major clinical users of blood and the consultant in-charge of the blood transfusion services.

THERAPEUTIC PLASMA EXCHANGE

Therapeutic plasma exchange constitutes an extra-corporeal blood purification technique designed to remove high molecular weight substances from plasma, implicated in disease causation in the patient, using aphaeresis technology. The most commonly removed macromolecules are immunoglobulins/immune complexes and low density lipoproteins (hyperlipidaemia). Therapeutic plasma exchange is the standard first-line therapy in certain neurological disorders (Guillain-Barré syndrome and chronic inflammatory demyelinating polyneuropathy), haematological disorders (TTP, hyperviscosity syndrome) and autoimmune disorders (Goodpasture's syndrome). Therapeutic cytapheresis helps in reducing cellular load prior to chemotherapy in leukaemic patients with hyperleucocytosis. Therapeutic thrombocyte apheresis provides symptomatic relief in extreme thrombocytosis.

15.20 Haematopoietic Stem Cell Transplantation

Velu Nair

INTRODUCTION

Haematopoietic stem cell transplantation (HSCT) is a life-saving procedure for a number of malignant and non-malignant diseases which were considered incurable in the past. The term bone marrow transplantation is used synonymously with HSCT. Technically HSCT is the correct nomenclature as stem cells can be sourced from the bone marrow for bone marrow transplantation, from peripheral blood stem cell (PBSC) for peripheral blood stem cell transplant (PBSCT) and umbilical cord blood for cord blood transplant. Stem cells are immunophenotypically labelled as CD34+ cells. In allogeneic (allo) HSCT, the stem cells are harvested from an human leucocyte antigen (HLA) matched donor, either related or unrelated. In autologous (auto) transplants, the patients own stem cells are harvested. In HSCT, the diseased marrow is ablated using chemotherapy or/and radiotherapy which is referred to as 'conditioning' followed by stem cell rescue. There is high incidence of relapse in auto-HSCTs because it is difficult to achieve 100% ablation of the malignant clone. The relapse rates are lower in allo-HSCT due to the added immunological effect of 'graft *versus* tumour' or '*versus* leukaemia (GvL)' effect which is lacking in auto-HSCT. Complications encountered during HSCT are graft-rejection, graft *versus* host disease (GvHD), veno-occlusive disease (VOD), infections and haemorrhagic episodes.

HISTORICAL BACKGROUND

The first use of bone marrow in the present context of HSCT was done by Schrezenmeier in 1937. Following the Hiroshima and Nagasaki disaster in 1945, radiation biologists, Jacobson and Lorenz pioneered the mice model demonstrating effect of radiation on bone marrow and spleen. They also showed that infusion of spleen cells prevented bone marrow aplasia. 1954 was the benchmark year when Lorenz elegantly demonstrated using chromosomal markers, that the new cells produced by the recovering marrow following infusion of splenic cells contained the same chromosomal marker as that of donor spleen. This stimulated further experimental work in the field of stem cell biology and HSCT.

E. Donnell Thomas, in a series of carefully planned experiments in dogs, for the first time defined the radiation doses, marrow harvesting procedures, regimen for GvHD prophylaxis and supportive care required for HSCT for which he was awarded the Nobel Prize in 1990. However, it was another Nobel laureate, Jean Daussett who discovered the HLA system which revolutionised the field of HSCT and the first HLA identical sibling transplant was done in the Netherlands in an infant with severe combined immune deficiency disease. In the 1970s, the Centre for International Blood and Marrow Transplant Research (CIBMTR) and the European Group for Blood and Marrow Transplantation (EBMT) was set up. The 1980s saw the entry of new drugs, such as ciclosporine for GvHD prophylaxis, newer generation of antivirals, antifungals and antibiotics which helped reduce transplant related morbidity and mortality due to infections. In the 1990s, discovery of PBSC and Cord blood stem cells was a landmark in establishing stem cell sources other than the bone marrow. In India more than 3,000 transplants (auto- and allo-HSCTs) have been performed at various centres, the first being done in Tata Memorial Hospital, Mumbai in 1983.

INDICATIONS FOR HAEMATOPOIETIC STEM CELL TRANSPLANTATIONS

The indications have been rapidly expanding over the years (**Table 1**). HSCT is indicated for all refractory or high-risk

Table 1: Indications for Allo- and Auto-Haematopoietic Stem Cell Transplantation (HSCT)

Indications for Allogeneic HSCT

- Malignancy
  - Acute myeloid leukaemia
  - Acute lymphoblastic leukaemia
  - Chronic myeloid leukaemia
  - Chronic lymphocytic leukaemia
  - Myelodysplasia
  - Hodgkin's disease
  - Non-Hodgkin's lymphoma
  - Multiple myeloma
- Immunodeficiency
  - Severe combined immunodeficiency
  - Wiscott-Aldrich syndrome
  - Adenosine deaminase deficiency
  - X-linked lymphoproliferative syndrome
  - Cartilage hair hypoplasia
- Defective haemopoiesis
  - Aplastic anaemia
  - Acquired severe aplastic anaemia
  - Congenital aplastic anaemia (Fanconi's anaemia)
  - Post-radiation Injury
  - Thalassaemia major
  - Sickle cell disease
  - Kostmann syndrome
  - Chronic granulomatous disease
  - Chediak-Higashi syndrome
  - Adhesion molecule deficiencies
  - Platelet disorders
  - Glanzmann thromboasthenia
  - Bernard-Soulier syndrome
  - Metabolic storage disease
  - Osteopetrosis
  - Familial haemophagocytic syndrome

Indications for Autologous HSCT

- Lymphoma and Hodgkin's disease
- Multiple myeloma
- Acute myeloid leukaemia, Acute lymphoblastic leukaemia
- Chronic myeloid leukaemia
- Neuroblastoma
- Breast cancer, germ cell tumour
- Autoimmune disorders
- Scleroderma, multiple sclerosis, rheumatoid arthritis, systemic lupus erythematosus

haematological malignancies, various genetic disorders and for bone marrow failure syndromes. In addition, it is also being offered of late for autoimmune disease.

Autologous Haematopoietic Stem Cell Transplantation

This is useful in myeloma, lymphoma, acute and chronic leukemias and solid tumours (breast, neuroblastoma and lung neoplasms). Bone marrow or PBSC is harvested from the patient itself, while the disease is in remission. This graft is then cryopreserved at –80 °C (freezers) or at –180 °C (liquid nitrogen). The harvested graft is stored in a cryoprotectant bag after mixing with dimethyl sulphoxide which is a cryoprotectant. Following this marrow is myeloablated with high dose chemotherapy and/or radiotherapy followed by reinfusion of the cryopreserved bone marrow or PBSC.

Allogeneic Haematopoietic Stem Cell Transplantation

Allo-HSCT involves stem cells being sourced from a related or unrelated donor [matched unrelated donor (MUD)]. The chances of finding a related donor (ideally a sibling) is 25% to 30% while it increases to 50% to 70% in case of MUD transplants where a donor is sought from a web-based registry. Earlier allo-HSCTs were myeloablative but of late, non-myeloablative transplants are being done increasingly in older patients. This is the treatment of choice for all high-risk/refractory haematological malignancies, several genetic disorders (thalassaemia major, Diamond Blackfan syndrome, etc.) and also for bone marrow failure syndromes (severe aplastic anaemia).

SOURCE OF HAEMATOPOIETIC STEM CELLS

Bone Marrow

In bone marrow transplantation, the haematopoietic stem cells (HSCs) are collected from the pelvic bone (posterior iliac spine) of the donor using bone marrow harvest needles under general anaesthesia.

Peripheral Blood Stem Cells (PBSCs)

PBSCs represent the richest source of stem cells and engraftment has been noted to be earlier compared to bone marrow or cord blood. As the lymphocyte content is higher in PBSC the incidence of GvHD (especially chronic GvHD) is higher in PBSCT compared to bone marrow transplantation or cord blood transplant. The advantages and disadvantages of PBSCT are listed in **Table 2**.

Table 2: The Advantages and Disadvantages of Peripheral Blood Stem Cell Transplantation

	Advantages	Disadvantages
Recipient	Faster neutrophil recovery Faster platelet recovery Faster immunologic recovery Less intravenous antibiotics Shorter hospitalisation Lower cost More GvL (?)	Higher incidence of chronic GvHD
Donor	No general anaesthesia No marrow harvest No hospitalisation	Venepuncture or central line Side-effect from growth stimulating factors and citrate used for PBSC harvest

Umbilical Cord Blood

Cord blood has a higher concentration of HSCs than in adult blood. They are naïve and less immunogenic, thereby causing less GvHD. They bear an immature phenotype and lack perforin expression. Cytotoxic cells seem to comprise mostly of a NK cell subset. Newer techniques using *ex vivo* expansion of cord blood units or the use of two cord blood units from different donors are being explored to allow cord blood transplants to be used in adults.

Engraftment

It takes 2 to 3 weeks for stem cells to re-grow (engraft) in the bone marrow. Haematopoietic growth factors, such as G-cerebrospinal fluid (G-CSF) and GM- CSF are used post transplant to enhance engraftment. The engraftment is monitored by chimerism studies. The presence of deoxy-ribonucleic acid (DNA) pattern of the donor type in the blood and bone marrow cells of the recipient confirms engraftment. Reconstitution of the immune system takes several months pre-disposing these patients to infections. Factors affecting engraftment are depicted in **Table 3**.

Table 3: Factors Affecting Marrow Engraftment

Haematological
- Stem cell dose
  - $>10^6$ CD34+ cells/kg associated with better engraftment
- Stem cells quality
  - Previous chemotherapy decreases, take
- Normal recipient environment
  - No fibrosis; no splenomegaly
  - Adequate intensity of preparative regimen

Immunological
- Donor/recipient human leucocyte antigen compatibility
- Increasing incompatibility decreases the chance of 'take'
- Recipient sensitisation to donor through transfusion strongly increases rejection risk
- Recipient immunosuppression
- Low-intensity preparative regimen increases rejection risk

STEPS INVOLVED IN HAEMATOPOIETIC STEM CELL TRANSPLANTATION

The various steps involved in allo-HSCT are described as under and depicted in **Figure 1**.

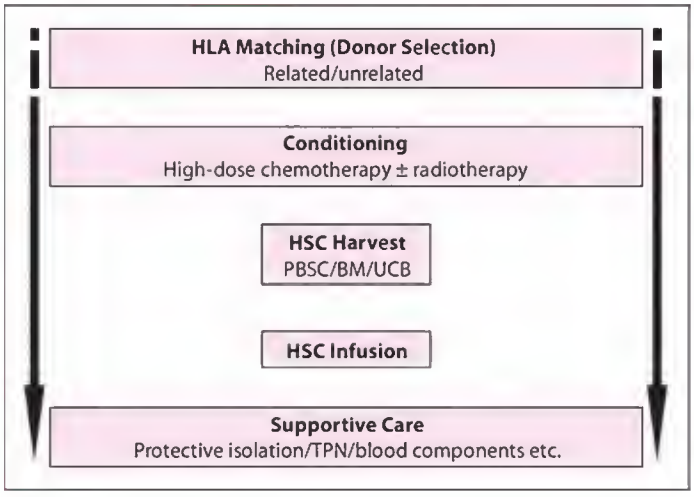

Figure 1: Steps involved in allo-HSCT.

HLA = Human leucocyte antigen; HSC = Haematopoietic stem cell; PBSC = Peripheral blood stem cell; BM = Bone marrow; UCB = Umbilical cord blood; TPN = Total parenteral nutrition.

Donor Selection and HLA Matching

The outcome of allo-HSCT is dictated by a set of immune response genes clustered together as the HLA system which is

analogous to the major histocompatibility complex (MHC) in animals. Ideally a sibling donor with matched major HLA loci stands the best chance for a successful HSCT. However, minor histocompatibility loci are not matched and this can lead to GvHD and graft-rejection. Initially, HLA was done by serology and later by molecular typing using sequence specific primers (SSP) which is a low resolution DNA based typing for HLA using polymerase chain reaction (PCR) technology. HLA loci A, B and DR are done for all related transplants and in addition HLA C, DP and DQ are also done for unrelated transplants.

Establishing a venous access

Since a long-term venous access is required for several weeks, a double or triple lumen central sialistic flexible catheter can be used, double lumen being preferred. This is introduced through a subcutaneous tunnel in the pectoral region and then inserted into the internal jugular or subclavian vein as shown in **Figure 2**. There are dedicated lines for blood component infusion, intravenous drugs and parenteral nutrition. Blood sampling is also done using these lines. Meticulous care of these central lines is required to prevent catheter sepsis.

Figure 2: Double lumen Hickman catheter.

Conditioning

Myeloablative: Conditioning or preparatory regimens containing high dose chemotherapy ± radiotherapy are used to ablate the abnormal clone of cells and create space in the bone marrow for engraftment of the new graft. It also suppresses the patient's immune system to prevent rejection of the new graft. Immunosuppression is achieved by irradiating lymphoid system ± cyclophosphamide (Cy) or combining fludarabine, Cy ± anti-thymocyte globulin (ATG). Myeloablation is achieved using busulfan (Bu) or melphalan. Total body irradiation achieves both; immunosuppression and myeloablation. In auto-HSCTs the main aim of conditioning is to achieve specific anti-tumour effect.

Non-myeloablative: Reduced intensity conditioning, using lower doses of chemotherapy and radiation, is an evolving approach of treatment which is less intensive and less toxic, minimising the risk of regimen related toxicity and transplant related mortality (TRM). The tumour kill is achieved by preparatory regimen and also by the GvL.

Graft *Versus* Host Disease Prophylaxis

For GvHD prophylaxis various protocols using combinations of immunosuppressive drugs are in use. A combination of cyclosporine A (CSA) with methotrexate (MTX) is a commonly used protocol. Intravenous (IV) CSA is administered beginning day 3 and continued till mucositis settles and oral fluids are tolerated, following which oral CSA is started (usually double the dose of IV-CSA). CSA levels are done weekly, targeting a level of 250 ng/mL. In cases of CSA intolerance, mycophenolate mofetil/tacrolimus can be given.

Stem Cells Harvest and Infusion

A target cell dose of total nucleated cells of 3 or more x 10^8 cells/kg or CD34 (stem cells) of 3 or more x 10^6 cells/kg is harvested followed by infusion into the patient either directly, if done within 48 hours (stored at 4°C) or following cryopreservation when infusion is done later than 48 hours.

Supportive Care

Success of a transplant programme relies heavily on an efficient support system, which includes blood bank for blood component support, good microbiological laboratory, molecular laboratory for HLA typing and well-trained transplant team of medical and nursing staff. In tropical conditions, protective isolation is important because of high-risk of infections when neutropenia occurs following myeloablation. However, in many centres in the West, HSCT has been successfully done without isolation. The nutritional status is often poor because of the underlying disease, occurrence of GvHD, sepsis and psychosocial issues like depression. Parenteral nutrition is resorted to, once the patient develops mucositis and is unable to take oral feeds.

ABO INCOMPATIBILITY

Unlike solid organ transplantation, HSCT can be performed despite ABO incompatibility. Major ABO incompatibility consists of the presence of ABO antibodies in the recipient directed against ABO antigens of the donor, e.g. O group recipient and A, B or AB donor. This can cause delayed erythroid engraftment and rarely red cell aplasia which is minimised by depleting donor red cells from the graft. In addition the ABO antibodies in the recipient can be neutralised by infusing donor specific fresh frozen plasma (FFP) and by plasmapheresis to reduce the antibody titre to less than 1:16. Minor ABO incompatibility is the presence of ABO antigens on recipient's red cells which are lacking in the donor, who has antibodies against the recipient's red cells, e.g. group O donor into group A, B or AB recipient. It is referred to as major and minor or 'bidirectional incompatibility' if group A donor and group B recipient or vice-versa is transplanted (**Table 4**).

Table 4: Selection of Blood Components in ABO Incompatible Allo-Haematopoietic Stem Cell Transplantation

	Recipient / Donor	Major ABO Incompatibility	Minor ABO Incompatibility	Mixed Major + Minor ABO Incompatibility	Rh^+ / Rh^-	Rh^- / Rh^+
Pre-transplant regimen	Red cells	Recipients type	Recipients type	Recipients type	Rh^+	Rh^-
	Platelets	Recipients type	Recipients type	Recipients type	Rh^+	Rh^-
	Fresh frozen plasma	Recipients type	Recipients type	Recipients type	Rh^+	Rh^-
Post-transplant regimen	Red cells	Recipients type/ Group O	Donor type/ Group O	Group O	Rh^-	Rh^+
< 8 weeks or until DAT is negative	Platelets	Donor type	Recipients type	Group AB	Rh^-	Rh^+
	FFP	Donor type	Recipients type	Group AB	—	—
Post-transplant regimen	Red cells	Donor type	Donor type	Donor type	Rh^-	Rh^+
	Platelets	Donor type	Donor type	Donor type	Rh^-	Rh^+
> 8 weeks or once DAT is negative	FFP	Group AB +ve for 12 weeks	Group AB +ve for 12 weeks	Group AB +ve for 12 weeks	—	—

Blood Component Support

Haemolysis of donor red blood cells (RBCs) by isoagglutinins in the recipient can cause immediate haemolysis. Formation of isoagglutinins by donor lymphocytes against recipient's ABO antigens can produce haemolysis after engraftment in ABO mismatched transplants as lifespan of residual recipient RBCs following allo-HSCT is about 40 days, whereas, circulating recipient's IgG and IgM antibodies have a half-life of approximately 20 days and 6 days respectively.

COMPLICATIONS

The first 100 days of post-HSCT is referred to as the early post-transplant period. Considerable morbidity and mortality is noted during this period, especially in allo-HSCT. These early complications are often related to the conditioning regimen, metabolic, fluid and electrolyte disturbances, microbial infections secondary to the neutropaenic state, haemorrhagic episodes secondary to underlying thrombocytopaenia, hepatic veno-occlusive disease (VOD) and acute GvHD. Some of the complications, listed in **Table 5**, will be discussed in more detail.

Infections

The HSCT recipient is immunocompromised both for humoral and cell-mediated immunity. There are 3 phases for opportunistic infections to occur in a transplant patient.

Pre-engraftment phase (2-4 weeks post-HSCT)

Febrile neutropaenia is commonly due to Gram-positive and negative bacteria followed by *Candida* and *Aspergillus* fungal infections. Herpes simplex virus (HSV) viral reactivation is known to occur during this period.

Early post-engraftment phase (< 100 day post-HSCT)

During this phase, viral [CMV (cytomegalovirus), HSV] and fungal infections are common, besides bacterial infections.

Late post-engraftment phase (> 100 day post-HSCT)

During this period infection with encapsulated bacteria, fungi and viruses are known to occur. This phase technically is a late complication of HSCT. However, for the convenience, it has been included under the category of infection.

Hepatic Veno-Occlusive Disease

VOD is a clinical syndrome, presenting with elevated levels of bilirubin, hepatomegaly and fluid retention. There is now a greater appreciation of obstruction in the hepatic venus sinuses, hence it is also referred to as sinusoidal obstruction syndrome. In VOD, endothelial damage due to the intensive conditioning leads to a local hyper-coagulable state with initiation of a 'cytokine storm' interleukin (IL)-1, tumour necrosis factor (TNF) which is responsible for hepatocyte necrosis. Signs of severe VOD include renal failure, thrombocytopaenia unresponsive to platelet transfusion and hepatic encephalopathy. VOD occurs in the first 20 days post-HSCT and 30% to 50% of patients undergoing HSCT develop VOD of varying severity and approximately 5% of these are life-threatening.

Table 5: Early Post-Transplant Complications

- **Infections**
  - Bacterial
  - Viral
  - Fungal
  - Protozoal
- **Gastrointestinal**
  - Nausea, vomiting
  - Mucositis, oesophagitis and gastroduodenitis
  - Diarrhoea and typhilitis
  - Pancreatitis and cholecystitis
- **Hepatic veno-occlusive disease**
- **Interstitial pneumonitis**
- **Renal and urinary tract complications**
  - Acute renal failure
  - Haemolytic uraemic syndrome
  - Acute tumour lysis syndrome
  - Haemorrhagic cystitis
- **Cardiovascular complications**
  - Pericarditis
  - Endocarditis
  - Hypertension
- **Metabolic complications**
  - Syndrome of inappropriate antidiuretic hormone secretion
  - Fluid and electrolyte imbalance
- **Neurological complications**
  - Encephalopathy
  - Seizures
  - Central nervous system haemorrhage
  - Thrombotic thrombocytopaenic purpura
- **Graft-*versus*-host disease (GvHD)**
  - Acute GvHD
  - Chronic GvHD

Prophylaxis has been attempted using low-molecular-weight heparin (LMWH), AT-III concentrates, prostaglandin E2,

pentoxyfilline, and ursodeoxycholic acid. Of these, though, ursodeoxycholic acid and LMWH have shown some benefit, besides supportive care there is no specific therapy for managing VOD. Prostaglandin-E, tPA and AT-III concentrates have been tried with mixed results. Liver transplantation has been carried out successfully but is clearly an unlikely option for the majority of cases. Defibrotide, an adenosine receptor agonist with antithrombotic and fibrinolytic properties, is being used with good results improving survival.

Pulmonary Complications

The pulmonary complications commonly encountered in HSCT are elaborated in **Table 6**.

Table 6: Causes of Pulmonary Complications of Post-Haematopoietic Stem Cell Transplantation

Infection
Bacterial
Viral
Fungal
Protozoal
Pulmonary oedema
Fluid overload
Cardiac dysfunction
Acute respiratory distress syndrome (ARDS)
Sepsis
Drug toxicity (e.g. cyclosporine A (CSA) and cytosine arabinoside)
Idiopathic (toxic)
Pulmonary embolism
Pulmonary graft-*versus*-host disease

Haemorrhagic Cystitis

This is characterised by frequency, dysuria and haematuria soon after administration of Cy. When severe it can pose a serious therapeutic challenge. This occurs primarily due to damage brought about by acrolein (a metabolite of Cy) to the uroepithelium of the urinary bladder. Prevention of haemorrhagic cystitis secondary to use of high dose Cy is done by administering continuous infusion of MESNA (2-mercaptoethanesulfonic acid sodium salt) starting 12 hours prior to and continuing 12 hours following cessation of Cy along with hydration.

Graft *Versus* Host Disease

GvHD is an inflammatory condition, unique to allo-HSCT, wherein, the donor immune cells attack the recipient's tissues. It is mainly, mediated by T-cells, when they react to foreign peptides presented on the MHC of the host.

Acute graft versus host disease

It typically appears in the first 3 months after allo-HSCT. Billinghan in 1966 defined the essential elements for the occurrence of acute GvHD.

1. The graft must contain immunologically competent cells.
2. The recipient must express tissue antigens that are not present in the transplant donor.
3. The recipient must be unable to mount an effective response to destroy the transplanted T-lymphocytes.

It is known that these immunocompetent cells are T-lymphocytes. However, there is no clear evidence as to which specific subsets are involved in acute GvHD. The CD8+ lymphocytes act against class-I HLA antigens and CD4+ against class-II HLA antigens. GvHD is understood to be a multi-step process. Step one causes tissue damage in the recipient which is cytokine (IL-1, IL-6 and TNF-α) mediated. Skin (**Figure 3**), gut and liver ducts are the target organs as they exhibit an increase expression of HLA molecules, adhesion molecules and other products with pro-coagulant activity. The next step involves activation of individual T-cells and expression of IL-2 receptors and production of interferon-gamma (IFN-γ) and IL-2. Activated T-lymphocytes undergo clonal proliferation and

Figure 3: Acute skin graft-*versus*-host disease (grade IV) in a patient with chronic myelogenous leukaemia after allo-HSCT.

differentiation, elaborating IL-2 which stimulates mononuclear cells which in turn secretes IL-1, TNF-α and IFN-γ producing a cytokine storm. In addition the lymphocytes also have a cytolytic action.

Glucksberg's scale is used to stage acute GvHD. The clinical grading of acute GvHD is shown in **Tables 7 and 8**.

Chronic graft versus host disease

Chronic GvHD is a late complication which occurs 100 days post-HSCT with clinical manifestations closely mimicking autoimmune disease, such as skin dyspigmentation, xerosis, erythema, scleroderma (**Figure 4**), lichen planus, xerostomia, ocular keratitis, jaundice, pulmonary obstruction/restrictive defects. Corticosteroids such as prednisone is the standard treatment for chronic GvHD with other drugs, such as mycophenolate mofetil (MMF), CSA, tacrolimus and thalidomide being used singly or in combination.

Table 7: Acute Graft *Versus* Host Disease Grading

Stage	Skin: Maculopapular Rash	Liver: Bilirubin	Intestinal Tract: Diarrhoea
+	< 25% of body surface	2 to 3 mg/dL (34 to 50 μ/L)	>500 mL/24h
++	25% to 50% body surface	3 to 6 mg/dL (51 to 102 μ/L)	>1000 mL/24h
+++	Generalised erythroderma	6 to 15 mg/dL (103 to 255 μ/L)	>1500 mL/24h
++++	Generalised erythroderma with bullae and desquamation	>15 mg/dL (>255 μ/L)	Severe abdominal pain with or without ileus

Figure 4: Scleroderma like skin chronic oral lesions due to chronic GvHD in a patient with allo-HSCT for CML.

Table 8: Clinical Grading of Acute Graft *Versus* Host Disease

Grade	Degree of Organ Involvement
I	+ to ++ skin rash; no gut or liver involvement; no decrease in clinical performance
II	+ to +++ skin rash; + gut or liver involvement (or both); mild decrease in clinical performance
III	++ to +++ skin rash; ++ to +++ gut or liver involvement (or both); marked decrease in clinical performance
IV	Similar to grade III and profound decrease in clinical performance

HSCT PROGRAMME IN INDIA

The institutes running HSCT programme in India are outlined in **Table 9**. Many more transplant centres are expected to open all over India as there is a lot of scope for this procedure considering the patient load of various haematological disorders.

There is no functional donor registry in India, while this is well-established in Europe, North America and Japan. These registries improve the chances of finding a fully matched, unrelated, HLA donor to 60% to 80%, whereas, it is only 25% to 30%, when siblings form the donor pool.

Table 9: Haematopoietic Stem Cell Transplantations (HSCTs) done in Various Centres Across India

Centres (period for which HSCT data is available)	No. HSCT	Allo-HSCT	Auto-HSCT
Christian Medical College, Vellore (1986-Dec 2009)	1002	767	235
AIIMS, New Delhi (1992-Dec 2009)	458	126	332
Tata Memorial Centre, Mumbai (1983-Jun 2010)	439	249	190
Sahyadri Speciality Hospital, Pune (1999-Mar 2010)	314	216	98
Apollo Cancer Hospital, Chennai (1995-Dec 2009)	249	151	98
Jaslok Hospital and Research Centre, Mumbai (2000-May 2010)	224	79	145
Army Hospital, Delhi (1998-Jun 2010)	207	137	70

SGPGIMS, Lucknow (1999-Dec 2009)	34	24	10
Prince Aly Khan Hospital, Mumbai (2007-Jun 2010)	32	01	31
Manipal, Bangalore (2004-Dec 2009)	28	8	20

FUTURE PROSPECTS IN HSCT

HSCT has revolutionised the treatment of many, hitherto, incurable diseases. However, because of significant peri and post-transplant morbidity and mortality (5% to 30%) further research and trials are required to refine and optimise conditioning regimens and supportive care. Stem cell manipulation and T-cell depletion to improve transplant outcomes and minimise incidence of GvHD is another area of research. Gene therapy using

haematopoietic stem cells is an exciting prospect. Adult stem cells and mesenchymal stem cells have been used in various trials for treatment of type 2 diabetes mellitus, neurodegenerative, heart and peripheral vascular diseases exploiting the potential of stem cell plasticity (or trans-differentiation).

Other developing areas which would help improve transplant outcomes and minimise complications are given below:

1. Non-myeloablative and cord blood transplantation
2. Matching for minor HLA antigens
3. *Ex vivo* expansion of HSCs
4. New immunosuppressive agents and monoclonal antibodies to minimise GvHD risk
5. Improving GVL without worsening of GvHD
6. Positive selection of CD34 cells and negative selection of allo-reactive T-cells responsible for GvHD

INTRODUCTION

The acquired immunodeficiency syndrome (AIDS) was first recognised among men who have sex with men (MSM) in the United States in 1981. The causative agent, human immunodeficiency virus (HIV) was discovered in 1983 by Luc Montagnier and Francoise Barre-Sinoussi at the Pasteur Institute, Paris, France and were awarded the 2008 Nobel Prize in Medicine for this discovery.

Molecular studies have revealed that HIV originated from the cross-species transmission to man of the simian immunodeficiency virus (SIV), which naturally infects non-human primates in Africa and has very close genetic similarity to HIV. The HIV viruses are broadly classified into HIV 1 and HIV 2 and it is further subdivided into groups and subtypes (**Table 1**).

Table 1: The Classification of HIV

Type	Group	Subtype (clades)	Distribution
HIV 1	M (major)	A1, A2, A3, A4, B, C, D, F1, F2, G, H, J, and K	Global Subtype C prevalent in India most
	O (outlier)		Limited to equatorial West Africa
	N (non-major and non-outlier)		Limited to equatorial West Africa
HIV 2			Limited to West Africa

The major routes for HIV transmission are:

1. Unprotected sexual intercourse with an HIV-infected partner.
2. Exposure to HIV-infected blood and blood products (e.g. blood transfusion, sharing of infected needles, needle-stick injuries, etc.).
3. Peri-partum (vertical) transmission from an HIV-infected mother to her child.

GLOBAL AIDS SCENARIO

HIV infection has evolved to become the greatest pandemic in human history. Since the beginning of the epidemic, almost 60 million people have been infected and 25 million people have died of HIV-related causes. Sub-Saharan Africa and Asia are the regions most affected by the HIV epidemic. India accounts for roughly half of Asia's HIV prevalence. **Table 2** shows the summary of United Nations AIDS global report for the year 2009.

BURDEN OF HIV EPIDEMIC IN INDIA

The first cases of HIV infection in India were documented in 1986 among female sex workers (FSWs) in Chennai, Tamil Nadu. Subsequently, cases of HIV infection have been reported from every state. The HIV epidemic in India has followed the 'type 4 pattern', where new infections occur first among the most vulnerable populations (such as FSW and injecting drug users [IDU]), then spread to 'bridge' populations (clients of sex workers and sexual partners of drug users) and then finally enter the general population. **Table 3** summarises the AIDS epidemic in India.

Table 2: Global Summary of the AIDS Epidemic

Number of people living with HIV in 2009	Total	33.3 million (31.4-35.3 million)
	Adults	30.8 million (29.2-33.6 million)
	Women	15.9 million (14.8-17.2 million)
	Children under 15 years	2.5 million (1.6-3.4 million)
People newly infected with HIV in 2009	Total	2.6 million (2.3-2.8 million)
	Adults	2.2 million (2.0-2.4 million)
	Children under 15 years	370 000 (230 000-510 000)
AIDS-related deaths in 2009	Total	1.8 million (1.6-2.1 million)
	Adults	1.6 million (1.4-1.8 million)
	Children under 15 years	260 000 (150 000 – 360 000)

Table 3: Summary of AIDS Epidemic in India

Number of people living with HIV infection	Total	2.40 million (1.9-3.0 million)
	Males	61%
	Females	39%
	Children	3.5%
Prevalence among adults	Overall	0.31%
	Males	0.44%
	Females	0.23%

These estimates are derived from sentinel surveillance (unlinked, anonymous HIV testing of consecutively collected samples from designated sites across the country for different target populations) conducted annually and is complemented by population-based surveys (e.g. National Family Health Survey).

A critical review of the HIV epidemic in India reveals the following trends:

- Young adults (15-49 years) account for 89% of the burden of HIV infection.
- The male to female ratio is 3:2.
- The states of Andhra Pradesh, Maharashtra, Karnataka, West Bengal, Tamil Nadu, Gujarat and Uttar Pradesh together account for 80% of the burden in India (**Figure 1**). The prevalence is <1% the north-eastern states of Nagaland and Manipur.
- India has a 'concentrated epidemic', the prevalence being significantly higher among various high-risk groups (MSM, IDU, FSW and STD clinic attendees) than among antenatal clinic (ANC) attendees (**Figure 2**).
- There is considerable variability in the spread of HIV infection in the country. At the district level, 87 districts had HIV prevalence <1% among ANC attendees and 47 had <5% prevalence among FSW in 2007. Several of these districts are in moderate and low prevalence states like Bihar, Chhattisgarh, West Bengal, Gujarat, etc.

- The predominant mode of transmission is heterosexual exposure (**Figure 3**), while it is injecting drug use in north-eastern states.
- HIV prevalence has been stable from 2002 to 2007 (**Figure 4**).
- HIV prevalence among women attending antenatal clinic (ANC) has declined from 2000 to 2007 (**Figure 5**), indicating a decrease in the incidence of new infections.

National Response to the HIV Epidemic

The first phase of the National AIDS Control Program (NACP) was launched in 1992 and the third phase (NACP-III) in 2007. The overall goal of NACP-III is to halt and reverse the HIV epidemic in India over the next 5 years. Since <99% of the population in the country is free from HIV infection, NACP-III places the highest priority on preventive efforts, and also seeks to integrate prevention with care, support and treatment. Populations that have the highest risk of exposure to HIV (FSW, MSM, IDU) will receive the highest priority in the prevention and comprehensive management. All infected persons will have access to treatment.

16.2 Virology, Immunology and Diagnosis

V Ravi, Anita Desai

More than a quarter of a century has passed since the discovery of human immunodeficiency virus (HIV), which is the causative agent of acquired immune deficiency syndrome (AIDS). While HIV-1 is responsible for majority of the infections, HIV-2 occurs in a small minority of HIV infections in some countries including India.

CLASSIFICATION OF HIV

Human immunodeficiency viruses (HIVs) belong to the family *Retroviridae* and subfamily *Lentivirinae*. This subfamily has two types HIV-1 and HIV-2. **Table 1** shows the subgroups.

Table 1: Subgroups of HIV

	Subgroups		
HIV	HIV-1	M major (clades A—K)	
		N new	
		O outlier	
	HIV-2	clades A—H	

Both differ in geographical distribution, biological and molecular characteristics as well as the extent of transmissibility. These subtypes have envelope gene sequences that vary by 20-50% or more between subtypes. The subtypes also differ in geographical distribution, biological characteristics and major modes of transmission. HIV-1 subtypes O and N are more distantly related genetically to all other HIV-1 subtypes but less so compared to HIV-2. Studies of HIV-2 genomes showed that there is a remarkably close relationship between HIV-2 and SIV strains that infect sooteymagabey monkeys (SIVsm). HIV-2 has also been reported from other countries other than Western Africa and has been subclassified into clades A-H.

HIV STRUCTURE

As depicted in **Figure 1**, HIV is an enveloped positive stranded RNA virus that measures 120 nm in diameter and consists of a lipid bilayer with uniformly arranged 72 spikes or knobs of glycoprotein – gp 120 and gp 41 (HIV-1)/gp 36 (HIV-2). The virion gp120 located on the virus surface contains the binding site for cellular receptor(s). The two plus stranded RNA molecules are embedded in a protein capsid (p24) together with certain viral enzymes (viral RNA-dependent DNA polymerase (Pol, also called the reverse transcriptase, RT (p66, p51) and nucleocapsid proteins (p9, p7). The capsid (p24) is surrounded by a matrix layer (p17) that in turn is enclosed in lipid bi-layer, the envelope.

Genome Organisation

The genome of HIV-1 measures about 9.8kb while that of HIV-2 measures 10.3 kb (**Figure 2**). Long terminal repeats (LTRs) of

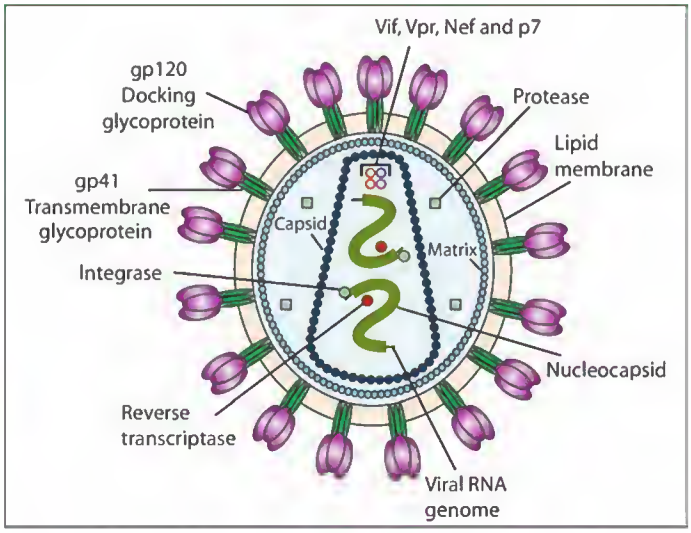

Figure 1: A diagram depicting the structure of human immunodeficiency virus.

nucleotides flank the structural and regulatory genes. Both HIV-1 and HIV-2 have similar genetic organisations encoded in a single positive-stranded RNA. The accessory gene vpu is unique for HIV-1 and is replaced by vpx in HIV-2. The primary transcript of HIV is a full length viral mRNA, which is translated into the gag and pol proteins. The *gag* gene codes for the proteins p24, p17, p9 and p7. The *pol* gene codes for the reverse transcriptase (RT), the protease (PR), and the integrase (IN) proteins. The *envelope* gene codes for the gp120 and gp41 proteins which are made from a precursor gp160. One of the regulatory proteins is *Tat*, a transactivating protein, which along with certain cellular proteins, interacts with an RNA loop structure formed in the 3' portion of the viral LTR and upregulates HIV replication. The other viral regulatory proteins include, *Rev* (Regulation of viral protein expression), which is needed for the synthesis of viral proteins, *Nef* (Negative factor), whose actual function remains unclear is believed to downregulate viral expression. The accessory HIV viral gene products and *vif, vpr, vpu/vpx* appear to influence events such as assembly and budding, as well as infectivity involved in the production of infectious viruses.

REPLICATION OF HIV

HIV enters the body when an individual comes in contact with infected blood, semen and/or vaginal secretions. The CD4 receptor is the principal target site for HIV, however specific chemokine receptors appear to serve as important secondary cellular receptors for HIV. HIV-1 strains have been divided into T-tropic (preferring to replicate in T-lymphocytes) and M-tropic (macrophages) viruses. The chemokine receptor usage is different for each of these viruses, with T-tropic viruses making use of CD4 and CXCR4 (or fusin, the receptor for SDF-1), and M-tropic viruses making use of CD4 and CCR5 (receptor for

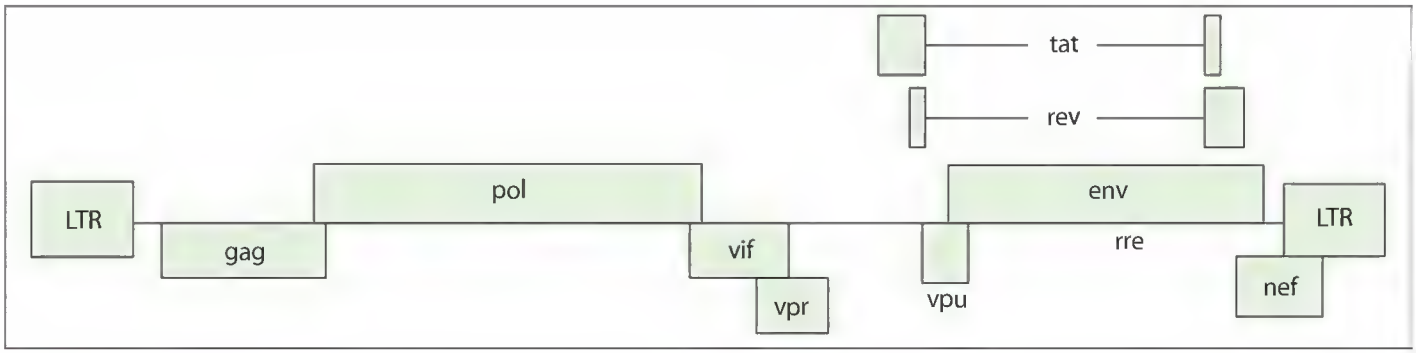

Figure 2: A diagram depicting the genome of HIV and the genes encoded in a single positive-stranded RNA.
Note that both HIV-1 and HIV-2 have similar genetic organisations except the accessory gene vpu is unique for HIV-1 and is replaced by vpx in HIV-2.

RANTES). After attachment of CD4, gp120 is displaced leading to uncovering of domains on the envelope gp41 needed for virus cell fusion. Gp41 is involved in infectivity as well as syncytium formation.

Shortly after the viral capsid enters the cell, an enzyme called *reverse transcriptase* liberates the single-stranded RNA genome from the attached viral proteins and copies it into a complementary DNA (cDNA). The cDNA and its complement form a double-stranded viral DNA which is then transported into the cell nucleus where it is integrated into the host cell's genome by the enzyme called integrase. During viral replication, the integrated DNA provirus is transcribed into mRNA, which is then spliced into smaller pieces. These small pieces are exported from the nucleus into the cytoplasm, where they are translated into the proteins. The final step of the viral cycle, assembly of new HIV-1 virion, begins at the plasma membrane of the host cell where the various structural components then assemble to produce a mature HIV virion. This cleavage step can be inhibited by protease inhibitors. The mature virus is then able to infect another cell. Schematic representation of HIV replication is depicted in **Figure 3**.

IMMUNOLOGY OF HIV INFECTION

The principal impact of HIV infection on the immune system is destruction of the CD4 T-lymphocytes. During primary infection, HIV and HIV-infected cells reach the lymph nodes and other lymphoid tissues. The virus rapidly disseminates during this early phase of HIV infection. As a result, there is a significant fall in CD4 cells and viral levels may be as high as 10^6-10^7 viral copies/ml. The next stage is downregulation of viraemia. This coincides with a robust, intense immune response by the host (**Figure 4**). Both effective cellular immune response mediated by HIV specific cytotoxic T-lymphocytes (CTLs) and humoral response mediated by complement fixing and neutralising HIV specific antibodies comes into play. As a result, the viraemia drops and CD4 levels bounce back to values slightly lower than the normal levels. However, active and continuous virus replication continues in the lymph nodes and lymphoid organs. There is a gradual reduction in the number of CD4 cells with a steady increase in viral load during the long asymptomatic stage. Humoral immunity is intact during the asymptomatic stage and specific antibodies are produced against different viral proteins, but the antibodies are not protective and unable to interfere with cell to cell transmission. This period on average lasts for 8-10 years. The advanced stage of HIV infection is characterised by increase in all the virological parameters (virus load, p24 antigen, etc.) in both peripheral blood and lymph nodes. Lymphoid tissue is totally destroyed and replaced by fibrous tissue. Consequently, there is profound immune suppression and a variety of opportunistic infections set in, which may prove fatal. The CD4 count at this stage is usually less than 200 cells/μl and progressively declines.

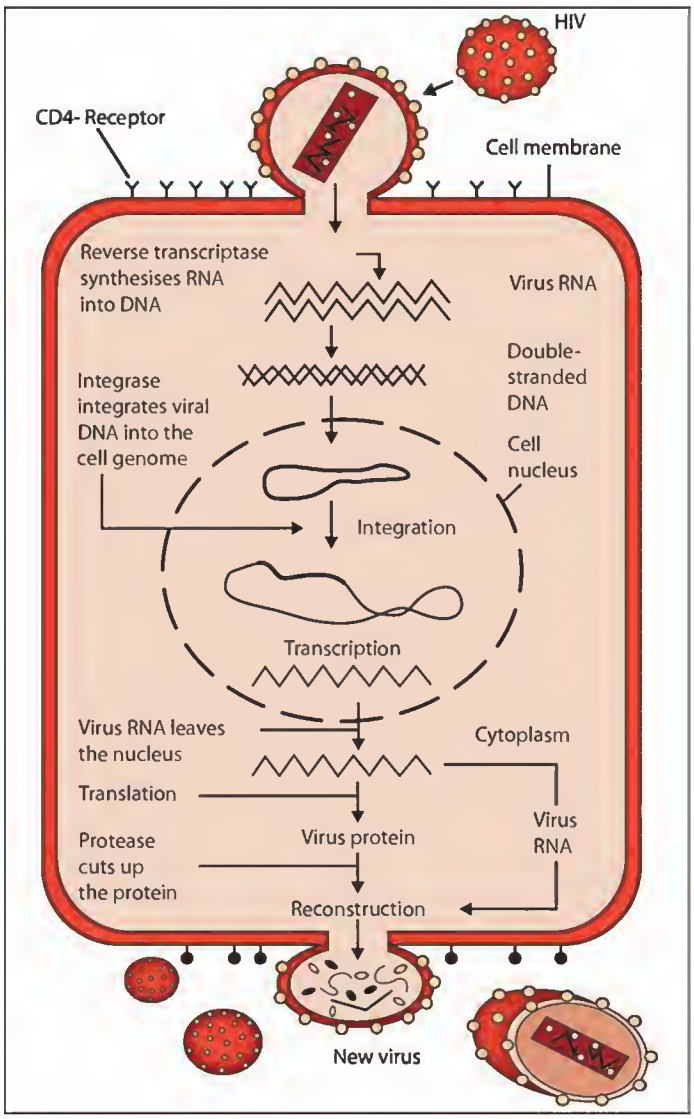

Figure 3: A schematic representation of the various steps in the replication of HIV.

LABORATORY DIAGNOSIS OF HIV INFECTION

Diagnosis of HIV infection can be achieved by the detection of: (a) antibodies in blood and body fluids; (b) antigen in blood and body fluids; (c) viral nucleic acid by polymerase chain reaction (PCR); and (d) virus isolation from blood and tissues. World over, the diagnosis of HIV infection is largely based on the detection of antibodies to HIV in the patient's serum sample. According to NACO, a three-tiered strategy is adopted for diagnosis of HIV infection in clinical settings. Initially, a sample is tested by an ELISA/rapid test. If it is found reactive it is subjected to second and third ELISA/rapid assay using different antigen or principle of testing. If the entire three tests are reactive, the samples are considered positive for antibodies against HIV. Samples that are negative in the first and second levels of testing are considered negative while samples that are positive in the two tests and negative in the third are considered equivocal and subjected to western blot for confirmation.

Detection of HIV Specific Antibodies

Immunoassays for the detection of a serological response to HIV-1 infection were developed in a series of stages, called generations. The first generation assays were very sensitive but not specific and the technology was improved by using recombinant and synthetic peptides as antigens (2nd and 3rd generation kits). More recently, 4th generation ELISA tests have been developed that detect both antibody and p24 antigen simultaneously. The different HIV-1 antibody detection tests available currently are ELISA, rapid immunoassays such as HIV spot tests, immuno Combs' tests, dot blot immunoassays and agglutination assay (Capillus). Antibodies to HIV-2 in clinical samples were detected by ELISA with synthetic gp36 (TM portion of the HIV-2 envelope) antigens.

Detection of Viral Antigen in Blood and Body Fluids

The p24 antigen assay detects the viral capsid (core) p24 protein in blood which is detected earlier than HIV antibody during acute infection. The most commonly used HIV p24 antigen test procedure is a basic antibody-sandwich ELISA. This test has limited diagnostic potential because antigenaemia is restricted to two stages of HIV infection: early in the illness during the latter half of the window period and late in the illness (end-stages) when immune collapse has set in.

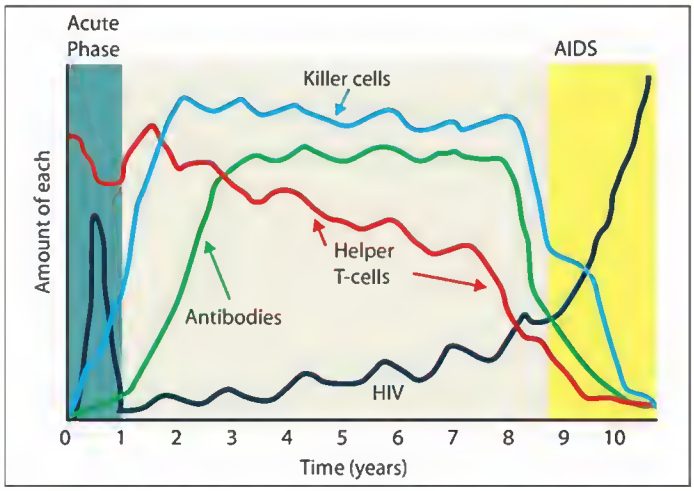

Figure 4: Immune events in relation to natural course of HIV infection.

Detection of Viral Nucleic Acid

Detection of HIV nucleic acid in plasma/serum is used in clinical practice for diagnosis of HIV infection in children aged less than 18 months (early infant diagnosis or EID) and estimation of viral loads. The detection of HIV nucleic acid can be achieved by either polymerase chain reaction (PCR), nucleic acid sequence based amplification (NASBA) or branched DNA (bDNA) technique. However, the most widely used test is the polymerase chain reaction (PCR). For EID, the NACO recommends the use of a HIV DNA PCR using dried blood spot specimens.

16.3 Pathophysiology and Clinical Features

UL Wagholikar

INTRODUCTION

'Human immunodeficiency virus' (HIV) is a human-specific retrovirus. Types HIV-1 and HIV-2 are identified by their unshared antigens.

Figure 1 depicts viral genes. **Table 1** summarises gene encoded products and their actions. Viral components, *proteins*, RNA, enzymes and structural proteins and *glycoproteins* are indicated by letters 'p' and 'gp' and allotted numbers, as per molecular weight in 'micro-daltons'. Together, they determine viral characters. Components are antigenic to man. Antibody responses to them differ from antigen to antigen, person-to-person and time-to-time (in a person). Some antigens resemble human components (e.g. p17 and thymosin, gp120 and neuroleukin, etc.). Anti-HIV antibodies may cross react with host tissues to cause autoimmune lesions in HIV disease.

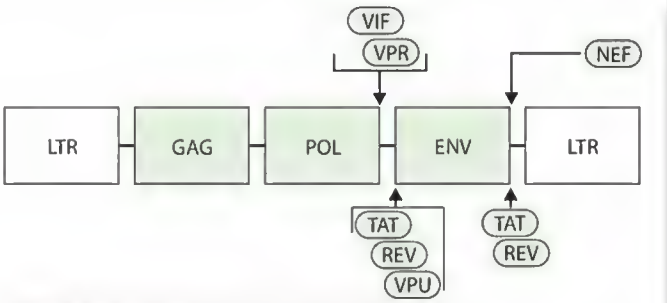

Figure 1: Human immunodeficiency virus genes.

INVASION OF TARGET CELLS

'CD4' molecules on cells and 'gp120' molecules on HIV have affinity for each other. A chance contact leads to firm bondage and lays the foundation for cell invasion. T-helper lymphocytes (including immature, mature and derived cells), monocytes, macrophages, dendritic cells (DCs) [in epidermis (Langerhans cells), mucosal surfaces of alimentary and genital tracts, lymphoid depots and tissues], epithelial cells lining mucosae of the said tracts and microglial cells of the central nervous system (CNS) carry CD4 molecules. HIV targets them for replication.

Just establishment of 'gp120↔CD4' bond does not ensure successful cell-invasion, gp120 must also bind with one or more cytokines on the surfaces of target cells, which act as co-receptors. Two co-receptors, essential for HIV, are CCR5 and CXCR4. Due to minute differences in gp120 molecules, strains

Table 1: HIV Genes, Products Encoded by Them and Actions of the Products

Gene	Products encoded by it	Action of the product
LTR	Transcription control factors	Initiates transcription process
GAG	GAG protein p55, a complex macromolecular poly protein, which is cleaved by 'protease', into smaller proteins, listed below:	p6 participates in terminal stages of building the viral particle p24 and p17 are used to form proteinous membranes around the core
	Core proteins (p6 and p24) Matrix protein (p17) and Nucleocapsid proteins (p7 and p9)	 p7 and p9 bind RNA to p24 to form nucleocapsid
POL	RNA (p31), Enzyme protease (p10), POL protein (p150), which is cleaved by 'protease' into 3 enzyme molecules:	p31 is the template for synthesis of proviral DNA p10 cleaves p55, p15, p150 and gp160 into smaller fragments, as mentioned in middle column
	Reverse Transcriptase (p64), Integrase (p32) and Ribonuclease H (p66/51)	p64 catalyses manufacture of proviral DNA p32 brings about integration of proviral DNA into cell genome p66/51 hydrolyses (remnant) RNA (p31) after synthesis of proviral DNA
ENV	ENV antigen p92 is formed first. It is glycosylated to gp160, which is further cleaved by 'protease' into 2 separate glycoproteins gp41 and gp120	gp120 selects the target cell and binds to it gp41 brings about fusion of viral envelop with target cell and manoeuvres viral entry into it
TAT	Transcriptional activator protein (p13/14)	Enhances (1000 times) transcriptional activity
REV	Regulator of gene expression protein (p19)	Regulates gene expression of virus
VIF	Viral infectivity factor (p23)	Overcomes inhibition from the host cell
NEF	Negative effector protein (p27)	Enhances viral infectivity
VPR	Viral protein R (p15)	Facilitates infection of macrophages
VPU	Viral protein U (p16)	Influences virus release from cell

First four genes are common to all retroviruses. Last 6 are HIV specific regulatory genes.

of HIV differ in their affinity to them. Other co-receptors (CCR2b, CCR3, STRL33 and GPR15) have also been identified.

After binding with CD4, the configuration of gp120 is changed. New sites are opened on it for binding with co-receptors. After "CD4↔gp120↔CCR5/CXC4" binding, gp41 also undergoes changes. It emerges on the surface, by the side of gp120. Now, gp41 can establish contact with the target cell membrane. Molecules of 'fusion' peptides (FPs) are inserted on the exposed ends of gp41. FPs cause fusion of viral envelope with the cell membrane. An opening is thus created. Viral genome then enters the target. This opening is sealed after viral entry. Only one virus can infect a cell. The infected cell cannot get rid of HIV.

FACTORS INFLUENCING REPLICATION

Interplay, between regulatory factors of the virus and of the host cell, determines when, in which cell and how much the virus replicates.

Virulence, mutations and tropism of HIV are significant viral factors. HIV-1 is more virulent than HIV-2. Group M is most virulent. Infections by more virulent strains are more prevalent and progress at a faster pace. Arguably, differences in virulence are related to efficiency of replication. HIV-1 (M) is the most common isolate all over the world. Clade B is the most common in USA and Europe, Clade E in Thailand. Clade C is emerging as the fastest spreading subtype in India, Ethiopia and South Africa. Isolates from different cases of HIV infection (even when of same type, group or clade) are seldom identical, on account of mutations. Mutations are clustered in POL, ENV and regulatory genes. Some mutations favour viral replication. Some act the other way (**Table 2**).

Table 2: Effects of HIV Mutations

Gene	Nature of mutation	Effect on virus
POL	Enzyme deficient mutant	Poor replication of virus → Diminished virulence
	Enzyme altered mutant	Replication, even in presence of ART drugs → Drug resistant virus
ENV	gp120 defective mutant	Poor binding with CD4 → Diminished virulence
	gp120 variant mutant	No effect of anti-gp120 antibodies → Immune escape of virus
VIF	p23 negative mutant	Cannot overcome effect of APOBEC 3G → Non-replicating impotent virus
TAT	p13/14 deficient mutant	Poor transcriptional activity → Diminished virulence
REV	p19 deficient mutant	Poor capacity to express genetic properties → Diminished virulence
NEF	p27 deficient mutant	Poor infective capacity → Diminished virulence
VPR	p15 deficient mutant	Incapability to target macrophages → Diminished virulence
VPU	p16 deficient mutant	Defect in release of virus from cell → Diminished virulence

Mutations 1 to 4 have been encountered, 5 to 10 are (to the best of author's knowledge) theoretical possibilities (as of today).

APOBEC 3G: apolipoprotein B mRNA-editing, enzyme catalytic, polypeptide-like 3G.

Cells have an inherent mechanism of protecting themselves against any viral invasion. They produce 'APOBEC 3G', a factor which inhibits viral replication. Its effect is counter-acted by p23, encoded by the gene VIF. By corollary, 'VIF negative' mutants will be impotent.

Strains which bind only with CXCR4 are called X4 strains. CXCR4 is present only on T-lymphocytes. Thus, X4 strain is 'T tropic'. Strains with affinity for CCR5 are R5 strains. Since, CCR5 co-receptors are predominant on macrophages and monocytes (MM series), R5 strain is 'M tropic'. Strains with affinity for both receptors are 'dual tropic'.

Besides MM series, CCR5 is present on DCs and T-lymphocytes also. So, M tropic strain has a wider range of target cells. Usually, in the early phase of infection, M tropic strains predominate in viral isolates from patients. In the later phases, T tropic strains predominate. It is likely that M tropic virus, with many targets at the portal of entry, establishes infection with greater ease and success. Later, it mutates to T tropism and switches on to the most susceptible target.

T tropic strains, with 'syncytium inducing' (SI) capacity on targets, are more devastating.

Other retroviruses can replicate only in cells capable of multiplication. But HIV has the capacity, *albeit* limited, of replication, even in terminally differentiated non-dividing macrophages. Viral protein R (p15) makes this possible.

Activation status, co-receptor profile and nature are significant cell related factors.

In targeted cells, proviral deoxyribonucleic acid (DNA) (free/integrated) remains transcriptionally inactive (latent) if the cell is in a resting state. Activation of the cell initiates viral replication. In a HIV patient, presence/acquisition of any sexually transmitted diseases (STDs) enhances HIV replication. Cytokines from inflammatory lesions of STD trigger activation of virus-infected cells. Lesions of tuberculosis (TB) and other viral infections (HBV/ HCV/EBV/CMV) also have a similar effect. Any such infection converts latent into active virus. Some cytokines, e.g. IL-10, also exert a minor anti-HIV influence.

In an individual, co-receptor production (quality and quantity) is genetically controlled. Co-receptor produced in excess, may be shed by the cell. Co-receptors floating in the micro-environment around a cell can hinder meeting of gp120 and cell-bound co-receptor and protect it partially. Delta-32 chromosomal mutation causes a homozygous defect in the gene responsible for expression of CCR5 in about 1% of population in Western European Caucasians and their American descendents. M tropic HIV-1 cannot replicate in them. In individuals with a heterozygous defect, the virus cannot replicate rampantly; in them the disease progresses slowly.

Replication is not equally efficient in all cells. T-helper cells and MM series are the principle targets. T-helper and T-memory cells are more easily infected by HIV. In the replication cycle, all target cells may not synthesise viral components in the proper proportion. Deficient production of any component will adversely affect replication. Viral proteins and

nucleoproteins, synthesised in excess, accumulate in the cell in cytotoxic proportion.

EFFECTS OF VIRUS ON CELLS

Interactions between HIV and the host cell are summarised in **Table 3**.

Table 3: Interactions between HIV and Host Cells

Peaceful co-existence of cell and virus
- When virus is non-replicating, the infected cell is unharmed
- Latent virus retains its viability. It can start replicating at opportune time

Pathogenetic virus-cell relationship
- When virus replicates, host cell is always damaged
- Cell may be killed by direct or indirect effects of the virus
  - Direct cell death of infected cells: due to enormous replication of virus
    - By 'fragmentation' of cell due to excess 'budding'
    - By 'lysis' of cell due to cytotoxic protein components of virus
    - By 'causing fusion' of cells (only by 'X4' strains of HIV)
    - (It is also called syncitium inducing (SI) effect of virus)
  - Indirect cell death of infected as well as non-infected cells:
    - Due to apoptosis
    - Due to IgM and IgG antibodies and cytotoxic lymphocytes
- When viral replication is not sufficient to kill the cell, it causes dysfunction
  - Functional damage
    - Reduced normal function
    - Abnormal function

CD4+ T Lymphocytes

Infected cells suffer most and by various mechanisms. Even non-infected cells suffer 'accelerated apoptotic death' (AAD), induced by excess, prolonged activation. Molecular basis of AAD is not clear. Non-infected cells, carrying viral antigens on the surface, are sequestered by anti-viral IgM/IgG antibodies and killed by cytotoxic lymphocyte (CTL) T-cells. Cells with lesser viral loads may not die; these get functionally impaired. Deficient antigen-induced proliferation and cell-mediated immune (CMI) response are the major defects.

In active phase of infection, CD4+ loss can be up to 2 million cells per day. Sometime loss of non-infected cells can be more than that of infected cells. In the initial phases of infection, enormous loss does not reflect as an immediate, proportionate drop in their blood count, due to compensatory proliferation of precursor cells. CD4+ counts start dropping, when the virus kills lymphoid precursor cells and replenishment of lost cells becomes increasingly inadequate. Not all research workers accept this as a satisfactory and complete explanation of drop in count.

Cells of MM Series and DCs

They are comparatively resistant to cytopathic effects of HIV because the extent of budding and fragmentation is low in them and because toxic products of viral replication are enclosed in vacuoles. Besides, M tropic virus does not express 'SI' effect. DCs, by carrying virus on their surfaces, minimise contact between their cytoplasm and viral chemicals. Loss of these cells is far less than that of CD4+ T-cells. Monocyte counts of blood do not drop.

Viral replication in these cells is less profound but not less significant. Migratory monocytes transport HIV to many organs, including CNS. Tissue macrophages establish viral reservoirs in gonads, kidneys, genital mucosa, etc. In transmucosal (rectal/vaginal/oral) infections, DCs get infected first. They carry the virus on the surfaces of their processes, migrate and present it to susceptible cells in the regional lymph nodes. Cell-to-cell transfer is a more efficient mechanism of cellular infection than random contact between the free virus and receptors on cell.

When CD4+ T counts drop, MM series and DCs act as virus supplying factories.

These infected cells show significant functional defects. Their microbicidal activity is reduced, response to chemotactic agents is decreased and capacity to present antigens to T-cells is poor. Secretion of useful IL-1 is reduced. They produce harmful IL-6.

B-cells

These are not infected, but are functionally affected by viral replication in other cells. IL-6 and gp 41 molecules instigate proliferation of B-cells and synthesis of abnormal immuno-globulins (IG) in excess quantity (hypergamma-globulinaemia). Abnormal Igs form immune-complexes (ICX) with other microbial antigens. Circulating ICXs can initiate type III allergic lesions.

CD8+ Lymphocytes

These also, are 'indirectly' damaged. In the initial phases of infection, these produce CTLs, which minimise viral replication by killing infected CD4 lymphocytes and also by producing cytokines which inhibit viral replication. As infection prolongs, the number of CTLs tends to fall, due to AAD. In terminal phases, CD8+ cells get exhausted.

Adaptive Immune Response of the Host

In an immunologically normal adult, immune response, as in other infections, would be expected in HIV infection too. Immune control of any viral replication is achieved through virus specific CD4+ T-cells, antibody dependent cellular toxicity and by CTLs. But, in HIV infection CD4+ T-cells, themselves, are the viral targets. Due to the vagaries of HIV antigens, the magnitude and pattern of antibody response can be unreliable. Antibody levels may be high, but viral neutralisation, not proportionately so. Moreover, mutant strains can escape immune damage. CTLs are the body's major effective measure of inhibiting HIV replication. Efficiency of their action determines the future course of events. Initially, in HIV infection, they are variably successful but later on they fail. As infection continues, CTL counts fall, due to AAD. On exhaustion of CD8+ cells, CTL response gets suppressed (immuno suppression). Other reasons for lack of effective immune control of viral replications are magnitude of HIV reservoirs in body, functional defects in immunocompetent cells, lifestyle (intravenous drug abuse) of patient and his genetic make-up.

Balance of forces 'producing and killing HIV' sets a level of viral load in body. Higher the 'set point', worse is the prognosis. When CTL response declines, the 'set point' gets raised. Disease progresses faster. ART, aiming at lowering the load, has to be life-long.

PROGRESS AND CLINICAL STAGES OF DISEASE

Lymphocytes, MM series and DCs constitute the backbone of CMI. HIV affects almost all. The immune apparatus and function show the most obvious primary clinico-pathologic manifestations. Others which bear the primary brunt are the gastrointestinal tract (GIT) and CNS.

Pathogenesis of Immunodeficiency

Incubation period

After transmucosal (and also parenteral) transmission, HIV reaches and establishes in T-cell areas of lymph nodes. Mucosal and nodal changes and early viral replication are clinically silent. Viral release into circulation increases slowly. Viral antigens appear in blood. HIV infection clinically manifests in 3 to 6 weeks post-exposure in up to 90% cases.

Acute retroviral syndrome (ARVS)

Increasing viraemia makes the infection manifest as 'flu like' episode, called ARVS (sore throat, myalgia, fever, rash, fatigue, enlarged nodes, diarrhoea and vomiting). Proportionate to the viral load in blood, there is a downward spike in CD4 count. With virus dissemination to all lymph depots, the infection becomes multi-systemic and permanent.

Due to the host's immune response, viral replication is restrained. Symptoms abate in 2 to 4 weeks. CD4 count gets corrected. Patient is sero-converted. He may be diagnosable, also by virus/its components in blood. After recovery, the patient goes through a variable period of clinical latency. Two types of 'latent' phases are possible.

Virus non-productive latent (VNPL) phase

Persons with a strong immune response take care of total viral replication while the virus lurks in reservoirs, in peaceful co-existence, awaiting an opportunity to reactivate. This can continue for months to years. The patient is sero-positive, has no viral load in blood and has a normal immune profile. Cases in VNPL phase are clinically healthy and symptom-free. They may even be non-infective to sex partners but are not safe blood donors.

Virus low-productive subdued (VLPS) phase

If the initial immune response is not strong enough to restrain viral replication completely, virus is produced in minute amount, but not sufficient to produce continuous clinical manifestations. The virus keeps on infecting new CD4+ T-cells. Its replication steadily increases without causing a drop in their count. A period of apparent inaction continues over a variable period, depending upon the magnitude of viral replication. Patient is sero-positive. His viral load depends on the 'set point'. CD4 count, usually normal, shows a trend of gradual annual decline (25 to 60 cells per year).

Cases in VLPS phase are not totally symptom-free. They may have mild/moderate episodes of symptoms due to GIT lesions (see below). In between the episodes, they do not appear seriously ill. There may be 'non-alarming' weight loss. Their infectivity is proportional to viral load.

Persistent generalised lymph adenopathy (PGLA)

Some cases in VLPS phase have PGLA. Enlarged nodes show non-specific polyclonal hyperplasia of 'B' and 'T' cell areas. Abnormal antibodies and their effects may appear. Some cases may have few, mild symptoms (fever, rash, fatigue). Constitutional symptoms indicate that the next stage is imminent very soon.

Stage of Immunodeficiency (SIMD)

Viral replication continued over a long period, plays havoc with the immune apparatus. CD4+ T-cells play the role of an 'orchestra conductor' for humoral immunity as well as CMI. Dysfunction of humoral immunity is *indirect* due to influences on B-cells. Dysfunction of CMI is the direct result of loss of T-lymphocytes. Progressive, relentless loss and dysfunction of almost all subsets of immunocompetent T-cells are the major events. Lymph nodes, thymus, bone marrow, lymphoid depots in tissues and gastrointestinal tract get depleted of T-cells. They show structural disorganisation and atrophy. CD4 and CD8 cell counts in blood drop. SIMD invites opportunistic pathogens and activates the pre-existing latent ones.

CD4 count in peripheral blood is used as an indicator of immune function. It is however not a perfect guide. 2% of the total pool of CD4 cells is in blood; rest is in tissues. Even a minute change in the distribution can bring about a vast change in the count. In some studies, CD4 percentage was a better marker than CD4 count. As of today, CD4 count is used and has served as a useful practical guide.

Time required for progress from infection to SIMD is variable. It depends on the summation of dynamics of viral replication and the host's anti-HIV immune response. It can be prolonged by ART regime. Usually, the period cannot be predicted with certainty, except in cases in VLPS, showing decline of CD4 count at a steady rate. SIMD is reached in 2 to 5 years in 'rapid progressors'. 'Slow progressors' take more than 10 years. 8 to 10 years is the period required for majority of the cases. Hallmarks of SIMD are increasing viral load, increasing titer of viral components in blood and CD4 count below 300/mL. An ill-understood group consists of patients in whom CD4 counts are below 300/mL and yet who show no manifestations of immunodeficiency. Co-existing STD/TB/(enlisted) viral infections accelerate the onset of SIMD. SIMD aggravates these diseases. A vicious cycle is thus established.

Possible Co-Morbidities Associated with HIV

These are immune complex lesions, autoimmune lesions and hypergammaglobulinaemia.

ACQUIRED IMMUNODEFICIENCY SYNDROME (AIDS)

Development of opportunistic infections (OIs) due to immuno-deficiency, and/or tumours in HIV infection defines the status as AIDS. AIDS defining OIs and tumours are enlisted in **Table 4**.

Pathogenesis of GIT Lesions

It is claimed (but not unanimously accepted) that GIT houses 40% to 65% of total immune cells of th body. Immune cells of GIT (all subsets of T-cells, B-cells and plasma cells, DCs and antigen identifying and processing clusters of T-cells and DCs) are organised into Peyer's patches and lymphoid follicles. They are also scattered in the lamina propria and in between the lining epithelial cells. Specialised (micro-folded) epithelial cells also act as 'immune cells'; they can take-up and transfer antigens and some pathogens to DCs. Epithelial cells bear CD4 receptors and possess the capacity to synthesise viral components and cytokines. Histology of gut mucosa is similar

Table 4: AIDS Defining Lesions in HIV Infection

Type of lesion	Disease	Distribution
Protozoal and Helminthic infections	Cryptosporidiosis/Isosporiasis	Enteritis
	Pneumocystosis	Pneumonia/Disseminated
	Toxoplasmosis	Pneumonia/CNS
Fungal infections	Candidiasis	Oesophageal/Tracheal/Pulmonary
	Cryptococcosis	CNS
	Coccidioidomycosis	Disseminated
	Histoplasmosis	Disseminated
Bacterial infections	Atypical Mycobacteriosis	Disseminated/Extrapulmonary
	Mycobacterium tuberculosis	Pulmonary/Extrapulmonary
	Nocardiosis	Pulmonary/Meningeal/Disseminated
	Salmonellosis	Pneumonia/CNS/Disseminated
Viral infections	CMV disease	Pulmonary/Intestinal/Retinal/CNS
	Herpes simplex disease	Localised/Disseminated
	Varicella-zoster disease	Localised/Disseminated
	JC polyomavirus disease	Progressive multi-focal leucoencephalopathy
Tumours	Kaposi's sarcoma	Anywhere
	B-cell non-Hodgkin's lymphoma	Anywhere
	Primary lymphoma of brain	Brain
	Invasive cancer of cervix	Uterus

to that of a tissue harbouring low-grade inflammation. It reflects ongoing contact and conflict with intestinal flora.

Mucosal T-memory cells are perpetually in a state of activation. Mucosal CD4+ cells are both CCR5+ and CXCR4+. They constitute 80% of the co-receptor positive population of the total body. For these reasons, the GIT is highly susceptible to HIV.

Studies on Macaque monkeys and simian immunodeficiency virus (SIV) have shown that the kinetics of destruction of immune cells of GIT was same as in other parts of the body. Depletion of intestinal CD4+ cells was noticeable within days after infection. It was same, regardless of route of the infection. It continued throughout the course of the infection. By the time SIMD was reached, the mucosa, almost totally depleted of immunocompetent cells, was markedly thinned out. There was also direct HIV driven mucosal inflammation, a lesion called 'HIV enteropathy'.

Intestinal disease manifests with episodic diarrhoea, dehydration and anorexia. All patients do not exhibit these manifestations. When present, they may not be proportionate to the severity of the lesions. Other factors, contributory to GIT dysfunction include: fat malabsorption, bacterial overgrowth, bile salt excess and reaction to drugs. The patient is markedly emaciated.

Pathogenesis of CNS Lesions

This is the third primary feature of HIV disease, even when HIV cannot cross the blood-brain barrier (BBB) and target neurones. Infected monocytes carry HIV across the BBB. A pre-existing inflammatory focus in brain attracts HIV infested macrophages and facilitates CNS infection. M tropic strain is the main invader. CNS macrophages and microglial cells pick-up HIV and suffer.

About 10% of patients have short meningitic episodes at sero-conversion. Serious disorder, 'dementia' (insidious onset, progressive course, impaired memory and concentration, apathy, social withdrawal, slow movements, ataxia, etc.) is seen late, when patients are approaching SIMD. Incidence (80% to 90%, prior to ART) is now declining.

Virus and antibodies are present in cerebrospinal fluid (CSF). Damage is indirect, probably caused by soluble neurotoxic components (gp41 and gp120) of virus and toxic chemicals produced by infected microglia. Excess entry of calcium ions into neurones, triggered by toxic chemicals, is the postulated mechanism. The lesion is slowly destructive (focal glial necrosis) accompanied by reparative gliosis. The brain shows cerebral atrophy, widening of sulci and ventricles, microglial nodules, perivascular infiltrates and giant cell encephalitis. Clinical severity is out of proportion to the magnitude and extent of lesions. The major factor responsible for functional loss of brain is invisible: 'synaptodendritic injury (chemical injury that disrupts neuronal network function)'.

PAEDIATRIC HIV AND AIDS

About 2% of cases of AIDS occur in children. 90% of them are due to materno-foetal transmission (MFT), intrauterine (trans-placental), intranatal (by fluids in birth canal) or postnatal (by breast milk). Intranatal transmission is the most common. By any mode, MFT is directly proportional to the viral load in the mother. Its incidence (24% to 65%, as per earlier reports) has been brought down by ART regimes for HIV positive pregnant women.

Pathophysiology of paediatric HIV/AIDS is essentially the same as in adults. Transplacental transmission can cause intrauterine death or congenital HIV, which reaches SIMD before infancy is over. In neonatal disease, most children are about a year old at presentation. Over recent years, the trend is shifting to older age. Failure to thrive, fever, lymphadenopathy and respiratory and neurological manifestations are the most common presentations. In patients younger than 15 months, demonstration of virus (its component) is needed to establish the diagnosis.

Some differences between paediatric and adult lesions are prominent. All lesions described in adults occur in paediatric disease, but with different frequency. Following lesions, rare in adults, are more frequent and prominent in the paediatric group: thymic lesions, systemic lymphoreticular disorder (SLD), pulmonary lymphoid hyperplasia (PLH) and arteriopathy (APT).

Moreover, secondary infections in children are more often by pathogenic than by opportunistic microbes.

Thymic lesions: They include precocious involution, dysinvolution and thymitis. They occur in different combinations. SLD is similar to PGLA in adults, but it affects not only lymph nodes but also lymphoid depots in parenchymal organs. There is polyclonal hyperplasia of both B- and T-cell domains. There is hypergammaglobulinaemia. Cytomorphologically, lesions are on the borderline of malignancy. Many cases have accompanying B-cell lymphomas in other organs. The name PLH is self explanatory. Hyperplasia can be focal (nodular) or diffuse and extensive. This 'associated' lesion is probably EBV induced. Frequently, it is accompanied by desquamative interstitial giant cell pneumonitis. APT lesions (luminal narrowing due to disruption and calcification of elastic lamina and fibrosis of intima and media) are seen in small and medium sized arteries in multiple organs. Pathogenesis and significance of APT remain undetermined.

Stringent blood bank enforcements have reduced the incidence of parenteral transmission.

WHAT WE DO NOT KNOW

T-lymphocytes are very versatile. Their 'homeostatic control', in health/disease, is very efficient. Despite enormous daily turnover, their 'number' and 'proportion of subsets' in blood/tissues are constant. In other infections there are outbursts of increase in number, but homeostatic control brings the counts back to normal, once the antigen is cleared from the body. Their progressive depletion is the unique theme in HIV infection. Mechanisms of loss of lymphocytes in HIV disease are well understood. What is not equally well understood (and accepted) is: the reason why the destroyed cells are not replenished at the same rate, despite the remarkable capacity of CD4+ cells to self-replicate. Mechanism of progressive T-cell depletion is under shroud.

Further, in HIV infection, depletion of the CD4 pool is accompanied by activation of all the cellular elements of the immune system. In other infections, activation of immunocytes leads to heightening of their performance, which is favourable to the host. Paradoxically, in HIV infection, activation leads to reduced function of CD4+, CD8+, CTL and natural killer cells, increased AAD of even non-infected immunocompetent cells and elevated production of pro-inflammatory cytokines. Weak CTL response allows ongoing viral replication. Ongoing viral replication escalates the level of activation of immunocompetent cells.

It is conceptually acceptable that the level of immune activation (if it could be measured in numerical figures) would be a more accurate predictor of disease progress than the CD4 count. We do not know the cause and mechanism of HIV-induced widespread, progressive immune activation.

The two enigmas are better appreciated by an appraisal of the striking features of natural disease in monkeys. 'Sooty mangabeys' monkeys (SMM) are natural hosts to SIV. The magnitude and mechanisms of death of SMM CD4+ cells by SIV are identical to those of human CD4+ cells by HIV. And yet, there are fundamental differences between monkey disease and human disease. In infected SMM, CD4+ counts remain normal and there is no immune activation. SIV infected SMM do not get immunodepleted. Obviously, up its sleeve, HIV has secrets, we do not know.

16.4 Antiretroviral Therapy

BB Rewari, Sanjeev Sinha

INTRODUCTION

The advent of antiretroviral drugs in the early 1990s began a revolution in the management of HIV infection. Results from various trials involving different drug combinations showing their efficacy opened the opportunities to reduce the morbidity and mortality due to HIV/AIDS. The combination of at least three antiretroviral drugs from different groups is the current standard of care and is commonly referred to as highly active antiretroviral therapy (HAART) or simply as combination antiretroviral therapy (cART). There is enough epidemiological and clinical evidence that effective combinations of antiretroviral drugs inhibit the replication of HIV and reduce viraemia to undetectable levels. Treatment slows down the disease progression, improves the quality of life and increases the longevity. Success achieved by antiretroviral therapy (ART) has now transformed the common perception about HIV infection from being a 'virtual death sentence' to a 'chronic manageable illness'.

GOALS OF ANTIRETROVIRAL THERAPY

The primary goals of ART are maximal and durable reduction in plasma viral levels and restoration of immunological functions. The reduction in viral load also leads to reduced transmissibility. However, as yet there is no therapy to eradicate HIV from the body.

Antiretroviral (ARV) drugs can also be used to reduce the risk of vertical transmission. The ARVs can be used after exposure to HIV too, as in cases of accidental needle stick injury, and in cases of sexual assault and rape. It is called post-exposure prophylaxis (PEP).

Till date 26 antiretroviral agents have been approved by US-FDA, of which 19 are currently available in India. Considering the lifelong management, one has to sequence the drug therapy in view of easy and repeated viral mutability. Therefore, the management of HIV is becoming increasingly complex in view of long-term toxicity, drug-to-drug interaction and drug resistance. In addition, monitoring facilities such as CD4 counts, viral load estimation and drug resistance assay have become necessary for follow-up.

PRINCIPLES OF ANTIRETROVIRAL THERAPY

A continuous high level of replication of HIV takes place in the body right from the early stages of infection. At least one billion viral particles are produced and destroyed each day. The antiretroviral drugs act on various stages of replication of HIV in the body and interrupt the process of viral replication. Theoretically, these drugs can act at the following steps in viral replication. Most commonly used drugs target the virus mainly by inhibiting the enzymes reverse transcriptase (RT) inhibitors and protease inhibitors (PIs). **Table 1** lists the classes of various ARV drugs. **Figures 1A and B** depict the therapy targets.

Table 1: Classes of ARV Drugs

Non-nucleoside reverse transcriptase inhibitors (NNRTIs)	Protease inhibitors (PIs)	Fusion inhibitors (FIs)
Nevirapine (NVP)	Saquinavir (SQV)	Enfuvirtide (ENF)
Delavirdine (DLV)	Indinavir (IDV)	
	Amprenavir (APV)	
	Nelfinavir (NFV)	
Efavirenz (EFV)	Fosamprenavir (FPV)	*CCR5 co-receptor antagonists*
Etravirine	Lopinavir (LPV)	Maraviroc (MVC)
	Ritonavir (RTV)	
	Atazanavir (ATV)	*HIV integrase strand transfer inhibitors*
	Tipranavir (TPV)	
	Darunavir (DRV)	Raltegravir (RAR)

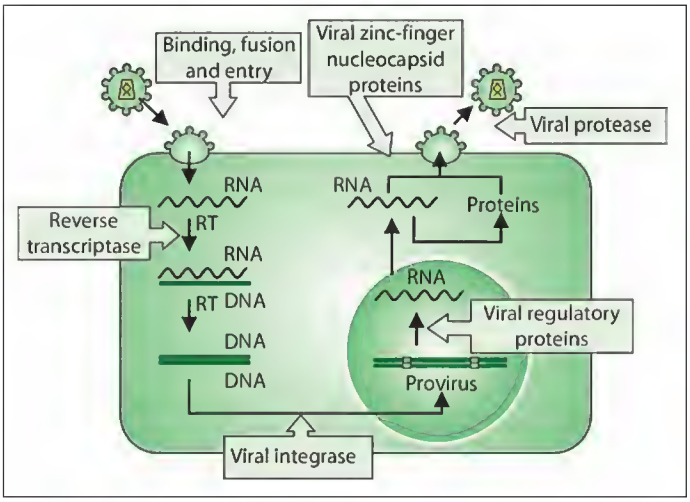

Figure 1A: Therapy targets.

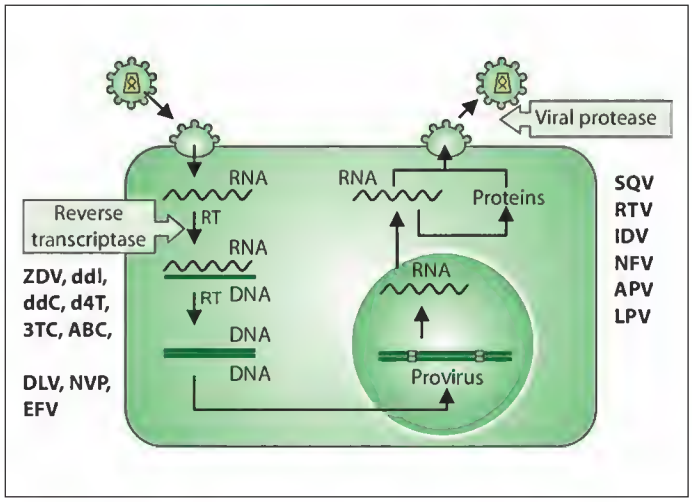

Figure 1B: Antiretroviral drugs.

Based on the scientific evidence, therapy guidelines have been developed by various international agencies such as WHO, DHHS, BHIVA, IAS (**Tables 2 to 4**). They define the optimum time, parameters and drugs to initiate and sequence treatment. Since, the drug therapy is lifelong, the selection of patients for therapy is based on clinical, immunological and viral parameters. Patients' preparedness for such a prolonged therapy and monitoring ensures their adherence. Oppurtunistic infections (OIs), if any, should be treated first. Patients should undergo therapy counselling. Along with detailed clinical evaluation, co-morbid conditions such as hepatitis B virus (HBV), hepatitis C virus (HCV) need to be evaluated for proper selection of ARVs considering the efficacy and drug interactions.

Table 2: Indications to Start Antiretroviral Therapy

WHO guidelines

Clinical	CD4 count available
Stage I or II	ART if CD4 <350/mm^3
Stage III and IV	ART regardless of CD4

Source: http://AIDSinfo.nih.gov, HIV Med 2008; 9: 563.
Guidelines by National AIDS Control Organisation and Department of Health and Human Services have been formulated with minor variations from WHO guidelines.

Table 3: Antiretroviral Therapy

WHO guidelines (Dec 2009)
Any one regimen to be initiated

Regimen
AZT+ 3TC +EFV
AZT+ 3TC +NVP
TDF+ 3TC +EFV
TDF +3TC + NVP
AZT to be avoided in patients with anaemia (Hb <8gm/dl)

DHHS guidelines (Dec 2009)

Preferred regimens	Alternative regimens	Acceptable regimens
EFV + TDF/FTC	EFV + (ABC/ZDV)/3TC	EFV + ddI + (3TC/FTC)
ATV/r + TDF/FTC	NVP + ZDV/3TC	ATV + (ABC/ZDV)/3TC
DRV/r + TDF/FTC	ATV/r + (ABC/ZDV)/3TC	
RAL + TDF/FTC	LPV/r + (ABC/ZDV)/3TC or TDF/FTC	
LPV/r + ZDV/3TC	SQV/r + TDF/FTC	

Source: Guidelines by National AIDS Control Organisation and Department of Health and Human Services have been formulated with minor variations from WHO guidelines.

Table 4: Treatment in Specific Situations

HIV and Tuberculosis (start Efavirenz-based regimen)

Pulmonary and extrapulmonary TB and HIV: Start ART for all patients irrespective of CD4 count (start TB treatment first and when it is tolerated start ART and within the first 8 weeks)

HIV and Pregnancy (Efavirenz not to be prescribed in first trimester)

a. WHO stages I and II: start ART at CD4 <350 cells/mm^3
b. WHO stages III and IV: start ART irrespective of CD4 count

MONITORING OF THERAPY

Frequent and regular follow-up especially during the initial months of the treatment is very important in order to ensure timely diagnosis and management of adverse events, to work with the patient on adherence issues and to diagnose any clinical manifestations like OIs and immune reconstitution inflammatory syndrome (IRIS). Generally, morbidity and mortality on ART occurs in the first 3 to 6 months of initiation of therapy. Once the patient is stable on ART, a quarterly review is recommended.

Regular CD4 count (and plasma viral load if possible) is desirable every 6 months. Clinical assessment and adherence monitoring should be done initially at 2 weeks and then regularly on a monthly basis.

ANTIRETROVIRAL DRUG TOXICITY

Antiretroviral drugs have a broad range of toxicities, ranging from low-grade intolerance which may be self-limiting to life-threatening side-effects (**Table 5**). Differentiating between complications of HIV disease and ART toxicity is very important. Considerations should also include intercurrent illness (e.g. hepatitis A, malaria, etc.) or reactions to medications other than ARVs, e.g. isoniazid-induced hepatitis or rash induced by cotrimoxazole. However, most of the toxicity/effects can be adequately co-managed with good clinical monitoring at all the levels of the health care system. As a general principle, mild toxicity does not require discontinuation of ART or substitution. Symptomatic treatment may be given. Moderate or severe toxicities may require substitution with a drug of the same ARV class but with a different toxicity profile. Severe life-threatening toxicity requires discontinuation of all ARV drugs until the patient is stabilised and the toxicity is resolved.

Treatment Failure: When to Change and What to Change

It is now well known, that even with good adherence levels, resistance occurs to ARV drugs over a period of time due to viral mutation and this requires change of ARV drugs. The virological failure appears first followed by immunological failure which finally leads to clinical failure. It is desirable to switch the entire regimen from first to second line as soon as virological failure is detected. Table 6 shows the guidelines for resource limited settings.

SPECIAL SITUATIONS

HIV Infection and Pregnancy

In case of pregnant women, an additional goal of ART is to prevent transmission of HIV infection from the mother to the child. It is recommended that all those pregnant women who have CD4 counts less than 350 cells/mm^3 should be initiated on ART. Some important considerations before initiating ARV therapy are:

- Zidovudine should be included in the regimen unless there is severe toxicity or anaemia.
- Efavirenz-based regimen should be avoided in the first trimester, because of teratogenic effects.
- It is recommended to closely monitor liver function tests if NVP containing ART is initiated in women with CD4 count >250.

The recent guidelines for usage of antiretroviral drugs for prevention of mother-to-child transmission (PMTCT) are available on WHO website http://www.who.int/hiv/pub/mtct/advice/en/index.html

Table 5: Toxicity of Commonly Used Antiretroviral Drugs

Occurrence	Zidovudine	Stavudine	Nevirapine	Efavirenz	Protease inhibitors
Short-term	Nausea, vomiting, diarrhoea	Nausea, vomiting	Hypersensitivity rash, Hepatotoxicity	Rash, hepatotoxicity, drowsiness, dizziness, confusion, vivid dreams	Abdominal pain, Abnormal stools or bowel movements, diarrhoea, nausea
Medium-term	Bone marrow suppression, anaemia, hyperpigmentation, Lactic acidosis	Lactic acidosis, Peripheral neuritis, Pancreatitis		Dyslipidaemia	Weakness/tiredness, Headache, Hyperglycaemia, Hypertriglyceridaemia, Hyperuricaemia
Long-term	Lipodystrophy	Lipodystrophy, Dyslipidaemia			Lipodystrophy

Table 6: Defining Antiretroviral Failure

Clinical failure	New or recurrent WHO Stage-IV condition, after at least 6 months of ART
Immunological failure	Fall of CD4 count to pre-therapy baseline (or below); or 50% fall from the on-treatment peak value (if known); or Persistent CD4 levels below 100 cells/mm^3
Virological failure	Plasma viral load >5,000 copies/ml

HIV/Tuberculosis Co-Infection

Initiation of treatment for active TB should always be on priority followed by initiation of ARV therapy as per the guidelines and should be started as soon as the patient is stabilised on ATT. In HIV-infected patients with TB who are not currently on ART, and who are provided rifampicin-based anti-TB treatment, initiate ART directly with EFV. No lead in dose is required for EFV. Nevirapine or PIs should not be administered along with rifampicin because of the enzyme inducing effect of rifampicin which renders NVP levels subtherapeutical. EFV blood levels are also decreased in presence of rifampicin, but remain at therapeutic levels. It is recommended to use the standard dose of EFV (usually 600 mg/day) in patients receiving EFV and rifampicin or use rifabutin if patient is on LPV/r based ART. Details on initiation guidelines have already been discussed.

HIV and Hepatitis B, C Co-Infection

Liver-related morbidity and mortality is very common in patients on ART. The common cause for liver related deaths is co-infection with hepatitis viruses. It is recommended that all HIV-infected patients should be screened for HBsAg, anti-HBcAb (if possible), HCV-RNA and HCV genotype at the baseline. It should be ensured that additional baseline investigations like LFTs, PT, serum proteins, HbeAg and HBV-DNA are also done.

1. HIV+HBV:
   - If treatment is not indicated for either infection, monitor the patient.
   - If treatment is indicated for HIV, then initiate with TDF+3TC/FTC-based regimen along with EFV.
   - If treatment is indicated only for HBV, pegylated interferon is recommended.
2. HCV treatment:

   HCV infection increases the risk of developing hepatic-toxicity with antiretroviral treatment. With regards to treatment, chronic HCV should be treated first if the patient does not qualify for anti-HIV treatment. Patients who qualify for anti-HIV treatment should be first initiated on ART and when the CD4 rises to more than 350 cells/mm^3, anti-HCV treatment may be considered. The treatment of choice for HCV is pegylated interferon and ribavirin. If the patient is also on anti-HCV treatment, care should be taken not to administer a regimen that has AZT or Didanosine (ddI) as they are contraindicated with ribavirin.

16.5 Drug Resistance

Alaka Deshpande

INTRODUCTION

Self survival and replication for propagation are the two main goals of every living organism. To achieve them, all organisms follow Darwinian model of continuous selection of the 'fittest'. Under adverse circumstances, including drug pressures which pose a threat to their survival, the microbes mutate and select those mutants which can survive in the presence of drugs.

HIV drug resistance can be broadly defined as any change that improves viral replication and survival in the presence of the inhibitors. It can appropriately be termed as 'altered drug susceptibility'. It is an altered phenotype resulting from a change in viral genotype.

HIV lacks the proofreading mechanism; therefore while replicating, the reverse transcription of viral RNA into DNA is error prone introducing on an average one mutation for each transcription. Some commonly used terms are defined here:

Gene

It is a unit of genetic information. Genes are encoded in the DNA.

DNA

It is a polymeric nucleic acid macromolecule composed of:

(a) Deoxyribose sugar

(b) Nitrogen containing two purine bases, namely adenine and guanine and two pyrimidine bases, namely thymine and cytosine

(c) A phosphate group

Nucleotides

They are composed of a base, phosphate and a sugar moiety which polymerise into long polynucleotide chains.

Codon

It is a code that relates specific amino acids to a combination of three adjacent bases along with mRNA.

Polymorphism

Variations in nucleotide sequence may produce different amino acid changes in the primary protein structure without producing a functional change.

Mutation

It is a change in nucleotide sequence resulting in functional change.

Primary/major resistance mutations

These are directly responsible for conferring drug resistance. They inhibit the drug action. In case of the Protease inhibitors (PIs), the terms are interchanged.

Secondary/minor mutations

These mutations include:

(a) Compensatory mutation, which aid in restoring the rate of viral replication despite presence of resistant mutation.

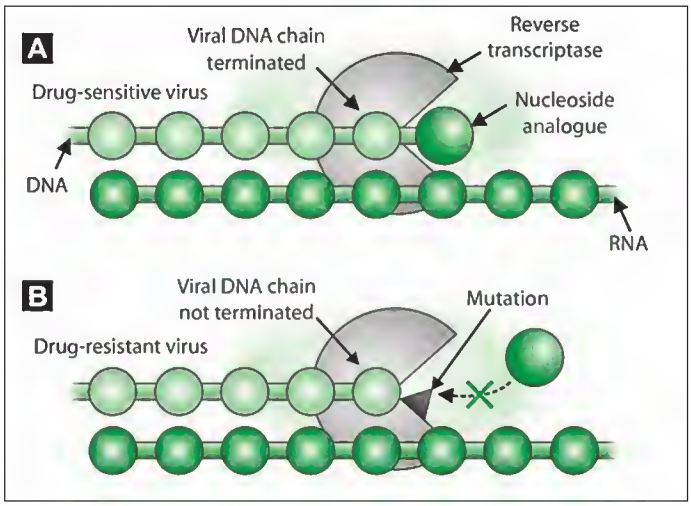
(b) Mutations that contribute to resistance in presence of primary mutations.

DETECTION OF RESISTANCE

Genotypic Assay

The various genes such as RT gene, Prot gene are sequenced. The observed mutations are compared with algorithms of large data base of Stanford, aNRS and IAS.

Phenotypic Assay



Phenotypic resistance of HIV is an *in vitro* test. HIV-1 isolates are cultured in the presence of serial dilutions of inhibitor drugs. The concentrations which are required to inhibit virus replication by 50%, i.e. Ic 50 or 90%, i.e. Ic 90, are the most commonly used methods. The process is expensive, cumbersome and time consuming.

MECHANISMS OF DRUG RESISTANCE

Two distinct mechanisms are involved in HIV resistance to NRTI drugs:

(a) Impairment of the Incorporation of the Analogue into DNA

Figures 1A and B shows the development of resistance by the incorporation of a nucleoside analogue into drug-sensitive viruses results in the termination of the viral DNA chain. Mutations in drug-resistant viruses prevent the incorporation of the nucleoside analogue into the growing viral DNA chain.

Figures 1A and B: Resistance by interference with the incorporation of nucleoside analogue.

(b) Pyrophosphorolysis

It is a removal of the analogue from the prematurely terminated DNA chain. **Figure 2** shows the mechanism of ATP-mediated excision of the nucleoside analogue.

ATP in drug-sensitive viruses does not have access to a reverse transcriptase that has formed a complex with a nucleoside analogue. Mutations that cause resistance to nucleoside analogues, referred to as thymidine analogue mutations (TAMs) allow ATP to bind reverse transcriptase near the 3' end of viral DNA terminated by the incorporation of a nucleoside analogue. ATP then excises the analogue from viral DNA, allowing reverse transcription to proceed normally.

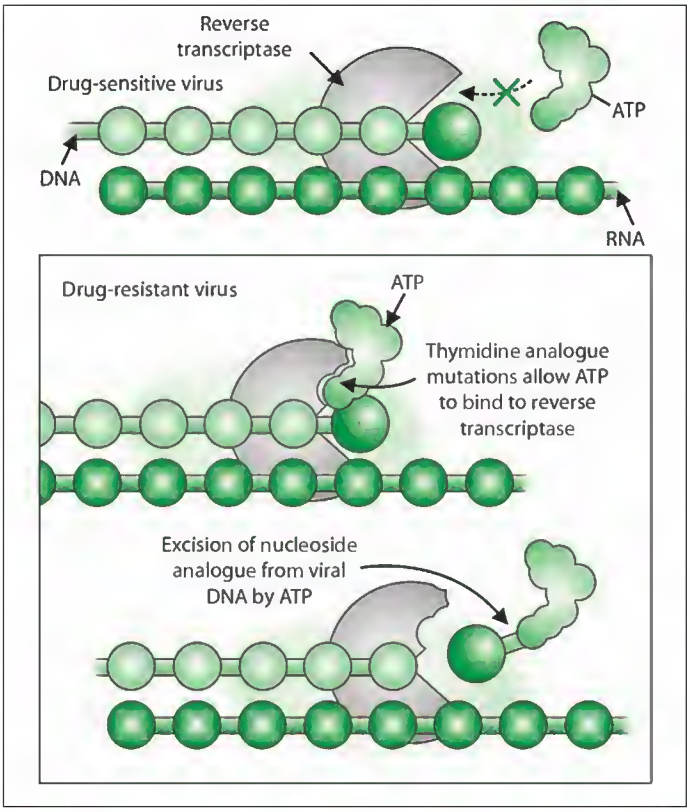


Figure 2: Resistance by ATP-mediated excision of the nucleoside analogue.

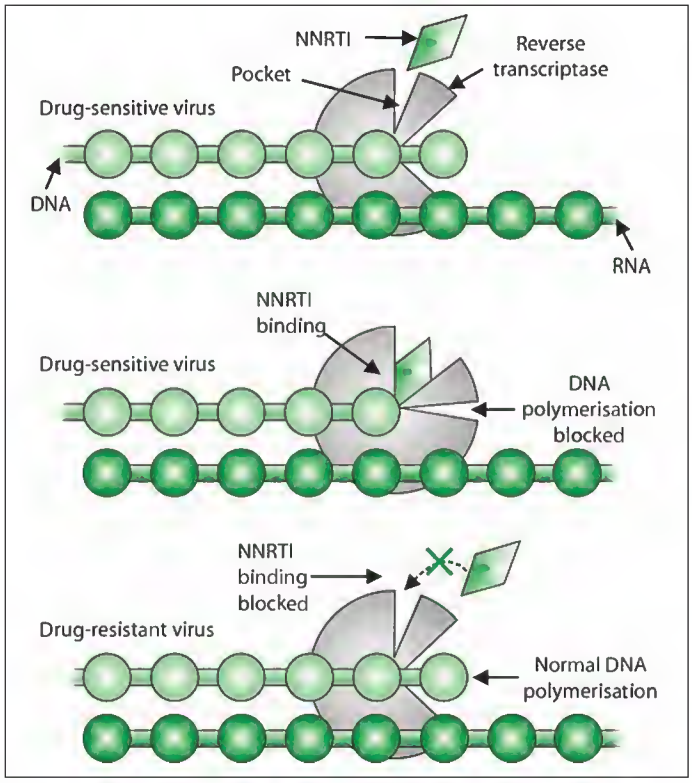
Thymidine Analogue Mutations

Mutations at positions 41, 67, 70, 210, 215 and 219 are referred to as TAMs because they are most often selected by ZDV and Stav containing regimens. These mutations occur gradually and their order of emergence can vary. TAMs promote ATP or pyrophosphate mediated removal of nucleoside analogue from 3' end of terminated DNA strand.

NON-NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS

Figure 3 shows non-nucleoside reverse transcriptase inhibitors (NNRTIs) have a strong affinity for a pocket next to the active site of reverse transcriptase. In drug-sensitive viruses, NNRTIs bind this pocket and block the polymerisation of DNA by reverse transcriptase. In drug-resistant viruses, mutations prevent the binding of NNRTIs, allowing DNA polymerisation to proceed normally.



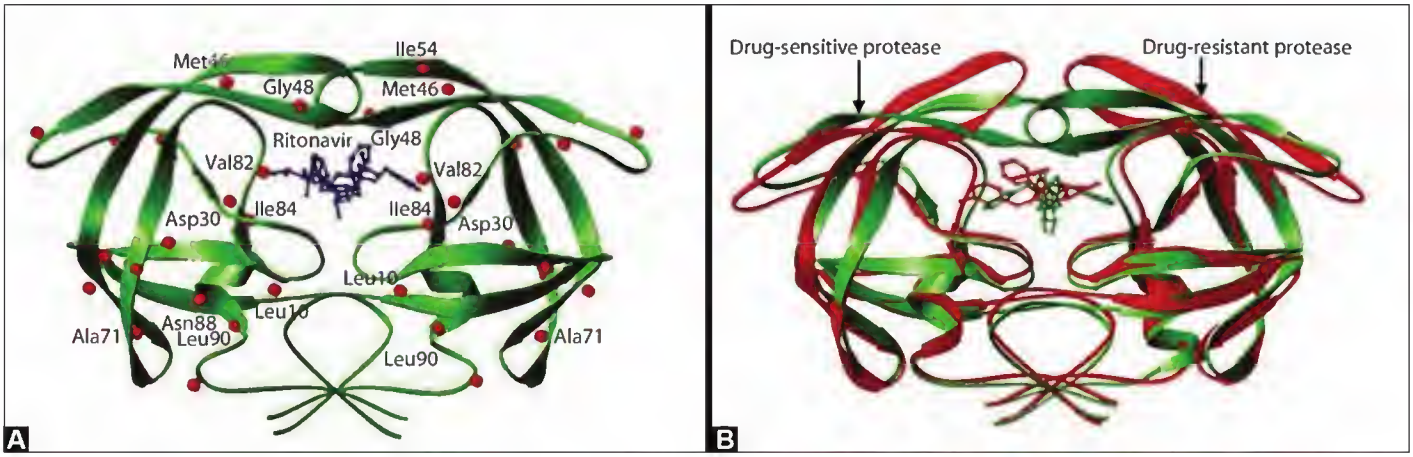


Figure 3: Mechanism of action of non-nucleoside reverse transcriptase inhibitors (NNRTIs).

Protease Inhibitors (PIs)

The three-dimensional structure of wild type HIV-1 is shown below (**Figures 4A and B**). The PIs bind to certain sites and block the protease activity.

Fusion Inhibitors

The fusion inhibitors destabilise the process of binding to hydrophobic region HR1, thus blocking the infectivity of HIV-1.

Figures 4A and B: Mechanism of action of protease inhibitors.

Viral resistance to fusion inhibitors results from mutations located in a stretch of 10 amino acids in HR1.

Convention for Describing Drug Resistant Mutation

Based on the amino acid sequences of RT and Protease, a standard numbering system has been developed in reference to wild type virus (mainly subtype B). For example, a change in genotype from ATG to GTG at codon 184 would be reported as a change from methionine to valine at residue 184 or as M184V. The resistant mutations to different drugs are shown in **Tables 1 and 2**.

Table 1: Resistant Mutants to Various Drugs

ARV	**NsRTI/NtRTI**	ARV	**NNRTI**
AZT	41L, 67N, 70R, 210W, 215Y/F, 219Q/E	NPV	100I, 103N, 106A/M, 108I,
		NVP	181C/I, 188C/L/H, 190A
d4T	41L, 67N, 70R, 210W, 215Y/F, 219Q/E	EFV	100I, 103N, 106M, 108I, 181I/C, 188L, 190S/A, 225H
3TC	65R, 184V/I		
FTC	65R, 184V/I		
ddI	65R, 74V		
ABC	65R, 74V, 115F, 184V		
TDF	65R, 70E		

The various factors which are responsible for drug resistant mutations are:

- Gastrointestinal intolerance
- Episodic compliance failure
- Poor adherence
- Drug toxicity
- High pill burden
- Drug interactions
- Irrational combinations
- Inadequate duration of therapy
- Infection with resistant strain

CONCLUSION

The effective pathway of therapy involves the following rational combination of therapy, adequate duration of treatment and adherence counselling. The therapy may be started only after the patients' preparedness for long-term antiretroviral therapy. The monitoring of therapy with the help of viral load is desirable. The viral load is suppressed to be less than 400 copies/mL in 16 to 24 weeks after successful therapy. The time when the viral load again starts rising after the initial viral suppression, indicates virological failure. This is the time viral resistance may be suspected.

Ideally, the genotypic assays should be performed before initiation of ARV therapy. Based on the viral drug susceptibility, the ARV may be selected.

Table 2: Resistant Mutants to Protease Inhibitors and Fusion Inhibitors

Drug	Major	Minor mutation
Protease inhibitors		
IDV and IDV/r	46I/L, 82A/F/T, 84V	10I/F/I/R/V, 20M/R, 24I, 32I, 36I, 54V, 71V/T, 73S/A, 76V, 77I, 90M

16.6 Non-Opportunistic Infections

Anil Kumar Tripathi, Shailendra P Verma

The presentation of HIV disease is mainly due to opportunistic infections (OIs) which become evident with advancing immunodeficiency. The present description will include variety of manifestations in HIV/AIDS patients which are not due to OI or malignancy.

ACUTE HIV SYNDROME

This acute clinical syndrome develops in about 50% to 90% persons after 3 to 6 weeks of primary infection with HIV. This phase corresponds with seroconversion phase of HIV infection. Acute burst of HIV viraemia leads to destruction and dysfunction of CD4+ T-cells. There is rise in CD8+ T-cells leading to reversal of CD4+/CD8+ ratio. Symptoms and their incidence in acute HIV syndrome are given in **Table 1**.

Table 1: Clinical Manifestations of Acute HIV Syndrome

Symptoms	Incidence (%)
Fever	96
Lymphadenopathy	74
Pharyngitis	70
Rash	70
Myalgias or arthralgias	54
Diarrhoea	32
Headache	32
Nausea/Vomiting	27
Hepatosplenomegaly	14
Weight loss	13
Thrush	12
Neurological manifestations	12

Maculopapular rashes which are painless, non-pruritic and erythematous are the usual lesions found on trunk, face and occasionally in extremities. Vesiculopapular rashes, oro-pharyngeal ulcers and penile ulcers can also occur in acute HIV syndrome. Neurological manifestations can be aseptic meningitis, encephalitis, myelopathy, Guillain-Barrè syndrome or peripheral neuropathy. Most symptoms of acute infection resolve after 2 to 4 weeks spontaneously with the development of antibodies to HIV virus.

Persons should be tested for HIV p24 antigen and HIV RNA levels by PCR which can detect infection in around 10 days and 7 days, respectively. Those who are negative should again be tested for HIV by ELISA after 3 months and 6 months of clinical presentation. No definitive recommendation about the use of ART are available. However, treatment in acute viraemia is recommended to curb the dissemination of the virus to various organs.

CARDIOVASCULAR MANIFESTATIONS

Prevalence of cardiac involvement in HIV disease varies from 5% to 50% but symptomatic involvement occurs in 5% to 7% of patients only. Most common clinically significant cardiac abnormality due to direct HIV infection is HIV-associated dilated cardiomyopathy. There is evidence of myocarditis and HIV has been isolated from myocardial cells. Diagnosis can be supported by chest radiograph and electrocardiogram and confirmed by echocardiography and elevated serum NTproBNP. CD4+ count in these patients is generally >200/cumm. HIV associated cardiomyopathy has poor prognosis.

Other findings on echocardiography may be diastolic dysfunction, pericardial effusion, right ventricular hypertrophy, pulmonary arterial hypertension and non-bacterial thrombotic endocarditis.

GASTROINTESTINAL MANIFESTATIONS

Manifestations of gastrointestinal tract can be due to HIV itself or drugs used in the treatment. Aphthous ulcers are generally found in posterior oropharynx and oesophagus. Ulcers produce dysphagia and severe odynophagia due to ulcerative oesophagitis. These lesions can be present in cases of severe immunodeficiency or during seroconversion. Several studies have demonstrated HIV infected inflammatory cells in the base of these lesions suggesting aetiological role of HIV. Endoscopically one or multiple ulcers of variable depth with normal intervening mucosa may be present, as seen in CMV infection. Short-term steroids or thalidomides are effective. Relapse rate of these ulcers is high. Other gastric problems are generally rare.

AIDS Enteropathy

Direct involvement of intestine by HIV can cause AIDS enteropathy or HIV enteropathy. Features include villous blunting, low mitotic figures and decrease in villous-crypt ratio. Patients usually present with chronic diarrhoea and weight loss. Stool studies, sigmoidoscopy and/or upper gastrointestinal endoscopy should be done to rule out other aetiologies. Tests of malabsorption are deranged. Treatment includes non-specific management like dietary fibre supplementation, antimotility agents, octreotide and oral rehydration solution.

HEPATOBILIARY MANIFESTATIONS

Direct involvement of liver parenchyma by HIV is not documented, and most common cause of hepatic involvement is co-infection with hepatitis B, C and antiretroviral therapy.

In India hepatitis B coinfection is present in 2% to 9 % cases and hepatitis C in 2% to 3%. Intravenous drug users may have HCV co-infection in up to 50% to 90%.

Drugs like nevirapine, protease inhibitors (atazanavir) can cause severe acute hepatitis or hepatic failure and their use should be properly monitored. Lactic acidosis syndrome occurs due to impaired mitochondrial DNA synthesis by NRTI'S such as AZT, ddI, and stavudine. It has high mortality and the only curative treatment is liver transplantation.

AIDS cholangiopathy is a syndrome resembling sclerosing cholangitis with papillary stenosis. Diagnosis is made by ERCP and papillotomy can relieve obstruction.

NEUROLOGICAL MANIFESTATIONS

Neurological diseases due to direct HIV infection occur throughout the course of infection and may be due to basic pathology like inflammation, demyelination or degeneration.

AIDS-Dementia Complex (HIV Encephalopathy)

It is an AIDS defining illness and usually occurs at CD4+ counts >200/cumm. If untreated, 15% to 20% of HIV patients will develop this entity. AIDS-dementia complex (ADC) or HIV encephalopathy (HIVE) is the term used to describe the advanced neurological involvement. HIV infects macrophages and glial cells in central nervous system. Release of various cytokines/neurotoxins such as interleukin (IL)-1β, tumour necrosis factor-α, IL-6 and TGF-β may be responsible for involvement of neuronal cells.

HIV encephalopathy is a slowly progressive subcortical dementia. Typical complaints are forgetfulness, poor concentration, slowing of reasoning, lack of energy drive, mild depression and emotional blunting. Patients look apathetic and slow and become socially withdrawn. Sexual dysfunction is common. Signs of HIV encephalopathy include impaired gait, slowing of rapidly alternating movements, tremor, brisk deep tendon reflexes, positive Babinski sign, slowed gaze saccades, sphincter impairment including incontinence and frontal release signs. Neuropsychological findings such as slowing of psychomotor speed, impaired short-term memory and mental flexibility, problem with recalling events in correct order, disorientation to time, place and person and finally mutism can occur.

MRI is preferred imaging modality. It reveals patchy or diffuse, hyperintense and relatively symmetrical lesions of white matter suggestive of leucoencephalopathy. Cerebrospinal fluid examination should be done to exclude alternative diagnosis. A systematic mental status examination is an important part of the examination. Quantitative neuropsychological tests can be done to see progressive decline in neurological functions. Metabolic disorders, depression and anxiety should be ruled out.

Antiretroviral therapy should be optimised. Highly CNS penetrant drugs should best be used from the list of lamivudine, zidovudine, nevirapine and indinavir. Outlook for prolonged independent life is guarded.

HIV Myelopathy

Myelopathy is present in 20% patients with AIDS. Vacuolar myelopathy is pathologically similar to subacute combined degeneration of cord. The histological hallmark are vacuoles and lipid laden macrophages most prominent is cervical and thoracic spinal cord. It is characterised by insidious onset of leg weakness and gait abnormalities. Vague leg discomfort and paraesthesias are main sensory symptoms. Bladder and bowel dysfunction is also common. Posterior columns of cord can also be separately involved producing pure sensory myelopathy and pure sensory ataxia. MRI of spinal cord is usually normal. Treatment of myelopathy with ART is not much rewarding.

Peripheral Neuropathy

It can present like acute inflammatory demyelinating polyneuropathy resembling GB syndrome. Chronic inflammatory demyelinating polyneuropathy (CIDP) with relapsing and remitting course has also been documented. Distal sensory neuropathy is most common type of neuropathy which can be due to HIV itself or nucleoside analogue drugs. Mononeuritis multiplex can also be present. Pregabalin, carbamazepine, gabapentin, tricyclic antidepressant and analgesics can provide symptomatic improvement.

HAEMATOLOGICAL MANIFESTATIONS

Anaemia is the most common haematological finding. Normocyctic normochronic anaemia is found in HIV-associated bone marrow suppression. Reticulocyte count is inappropriately low. Drugs like zidovudine is the other main culprit. It can block erythroid maturation earlier than other components of bone marrow. Mean corpuscular volume of RBC is increased. HIV-induced anaemia may respond well to ART therapy. Erythropoietin is also effective if its levels are less than that expected for severity of anaemia. Zidovudine should be replaced.

Neutropaenia is mostly mild but sometimes it can be severe. The cause of neutropaenia can be a direct effect or therapy-induced. Presence of neutropaenia generally indicates advanced disease. G-CSF or GM-CSF can be of use in increasing counts of neutrophils regardless of the cause. Myelosuppressive drugs should be removed.

Thrombocytopaenia can be due to decreased platelet survival probably by immunological mechanism and decreased platelet production due to infection of megakaryocytes with HIV. Treatment should be initiated in patients having platelet count <20000/cumm. IVIG and Anti Rh(D) are equally effective but sustained responses are few. Prednisolone 0.5-1.0 mg/kg is used cautiously. Splenectomy may be needed in relapsed/refractory cases.

Persistent generalised lymphadenopathy is an early clinical presentation of body response to HIV infection. The condition is defined as lymph node enlargement of 2 or more extrainguinal sites of size >1 cm for at least more than 3 months without obvious cause. Histologically follicular hyperplasia of lymph nodes is present.

RENAL MANIFESTATIONS

HIV-associated nephropathy (HIV-AN) is a true direct complication of HIV infection occurring in 2% to 10% of HIV infected individuals. Clinical presentations of HIV-AN consist of heavy proteinuria (90% have nephritic range), rapid deterioration of renal function, normal size of kidneys, no or minimal increase in blood pressure. End stage renal disease commonly occurs in 6 to 12 months. Kidney biopsy is diagnostic. Histology is similar to that of idiopathic focal segmental glomerulosclerosis (80%) and mesangial proliferation in 10% to 15% cases. HIV-AN also exhibits sclerosis of the whole glomerular tuft which is distinctly known as collapsing glomerulopathy. Majority of patients have CD4+ T-cell counts <200/cumm. ACE inhibitors and prednisolone with tapering dose have been effective in preventing progression of the disease. IgA nephropathy can also occur in HIV patients.

Acute tubular necrosis can result from nephrotoxic drugs, hypovolaemia, shock and sepsis. Drugs like pentamidine, amphotericin, adefovir, tenofovir, NSAIDs and radiocontrast

agents can cause acute tubular necrosis. Patient should be closely monitored and dose adjustments or stoppage of drug should be considered once renal dysfunction develops.

RHEUMATOLOGICAL MANIFESTATIONS

Rheumatological manifestations include Reiter's syndrome, non-specific reactive arthritis and septic arthritis. Myopathy, vasculitis and diffuse infiltrative lymphocytosis syndrome can also occur. Myopathy occurs in 1% to 2% of all HIV patients and can appear at any stage of the disease. Myopathy can be drug-induced, inflammatory or non-inflammatory. Drug notorious for causing myopathy is zidovudine probably due to mitochondrial toxicity. Inflammatory myopathy indistinguishable from idiopathic polymyositis can also be seen. Zidovudine should be replaced first, if no improvement, immunosuppressive drugs should be started.

Vasculitis should be considered in the setting of unexplained multi-system disease, unexplained myopathy or arthritis, unexplained organ ischaemia and in presence of mononeuritis multiplex.

DILS is presumably of autoimmune origin. Dryness of mouth, eyes and massive enlargement of parotids are common. Histopathological study of salivary gland shows infiltrating lymphocytes which are CD8+ cells.

METABOLIC MANIFESTATIONS

Hyperglycaemia can occur due to various drugs used in HIV disease treatment. Protease inhibitors, pentamidine and didanosine are main culprits. Hypercholesterolaemia is usually seen with protease inhibitors and efavirenz. In HAART era, HDL Cholesterol levels are reduced, total and LDL cholesterol levels are increased with concomitant severe hypertriglyceridaemia. HMG COA reductase inhibitors (statins) with diet modification and exercises should be used to treat these conditions. Lipohypertrophy and lipoatrophy can occur with PI's in long-term use. Mitochondrial toxicity is the probable mechanism.

HIV-Associated Wasting

It is an AIDS defining illness. Centers for Disease Control and Prevention (CDC) definition of HIV-associated wasting is a weight loss of $\geq$10% associated with intermittent or constant fever and chronic diarrhoea or fatigue lasting >30 days in the absence of a defined cause other than HIV infection. Dietary assessment and weight monitoring should be done. Key to prevention and management of HIV wasting is aggressive management of infection.

ENDOCRINE DISORDERS

Hypogonadism is common in HIV patients. Patients present with decreased libido, impotence, gynaecomastia or amenorrhoea. Production of GnRH is decreased or its release is abnormal. Diagnosis is made by low or normal levels of FSH and LH in response to GnRH. MRI of brain should be done to see pituitary gland. Management includes hormone replacement therapy. Hypothyroidism, hyperthyroidism and adrenal dysfunction are rare. Less than 5% of patients with AIDS have adrenal insufficiency.

PULMONARY MANIFESTATIONS

Most of the pulmonary manifestations are due to opportunistic infections and should be ruled out before attributing it to HIV disease. Lymphocytic interstitial pneumonia, non-specific interstitial pneumonia and increased incidence of pulmonary hypertension is seen as the non-OI manifestations of HIV disease.

16.7 Opportunistic Infections

Natasha Edwin, Dilip Mathai

Opportunistic infection (OI) is a disease caused by microbial agent(s) in hosts with defects in humoral and cell mediated immunity. Immunocompromised secondary to human immunodeficiency virus (HIV) infection, use of immunomodulatory agents (including steroids and anticancer drugs) are emerging predisposing factors to OI.

Opportunistic infections (OIs) may serve as indicators of underlying HIV infection. Mortality among HIV-infected individuals is due to improper awareness and consequent poor clinical management of OIs. HIV load increases in the presence of ongoing OIs, thus accelerating progression to clinical acquired immunodeficiency syndrome (AIDS). Changes in the CD4 lymphocyte count occur with the institution of highly active antiretroviral therapy (HAART) which in turn results in changes in OI epidemiology, clinical presentation and treatment outcomes. As HAART results in reconstitution of the immune system – certain OIs respond to HAART alone. However, the ensuing immune mediated inflammatory response may present as a paradoxical worsening of disease. It is, therefore, essential to be able to recognise and treat OIs prior to the institution of antiretroviral agents. OIs play a role in the clinical staging of HIV infection. OIs may present as indolent chronic infections (pyrexia of unknown origin), reactivation of latent infections, or as acute medical emergencies. They may affect single or multiple organ systems.

The incidence of OIs range from 10.7 to 69.7 /100 patient years. Among 28 OIs—tuberculosis (65%), candidiasis (57.5%) and diarrhoeal diseases (40%) are the most common OIs found in Indian patients (**Table 1**) [National AIDS Control Organisation (NACO), 2007] while OIs due to infection with *Rhodococcus equi, Blastomyces, Coccidioides, Bartonella* and Human Herpes Virus 8 have not been described in India. Various OI are seen to increase and organism with poor penetration and infectivity seem to become pathogenic. **Table 2** lists various OI with falling CD4 count.

Table 2: Correlation of OIs with CD4 Lymphocyte Count

CD4 cell count (/mm^3)	Infectious conditions
>500	Candida vaginitis
200 to 500	Pneumococcal pneumonia Pulmonary tuberculosis Herpes zoster Oropharyngeal candidiasis Cryptosporidiosis Self-limited Kaposi's sarcoma Oral hairy leukoplakia
<200	*Pneumocystis jiroveci* pneumonia Disseminated histoplasmosis Miliary/extrapulmonary TB Progressive multifocal leucoencephalopathy
<100	Disseminated herpes simplex Toxoplasmosis Cryptococcosis Cryptosporidiosis Microsporidiosis Candida oesophagitis
<50	Disseminated cytomegalovirus (CMV) *Mycobacterium avium* complex

TUBERCULOSIS (TB)

Tables 3 and 4 show the salient features of Koch's and the difference in tuberculosis in HIV positive patient and a normal immunocompetent patient.

Table 1: Common Opportunistic Infections (OIs) seen in India

Bacterial	Viral	Fungal	Parasitic	Other illnesses
Tuberculosis	Herpes simplex virus infection	Candidiasis	Cryptosporidiosis	Non-Hodgkin's lymphoma
Bacterial respiratory infections	Oral leukoplakia	Cryptococcosis	Microsporidiosis	Invasive cervical cancer
Bacterial enteric infection	Varicella zoster	*Pneumocystis carinii jiroveci* pneumonia	Isosporiasis	
	Cytomegalovirus infection	Penicilliosis	Giardiasis	
	Human papilloma virus infections		Strongyloidiasis Toxoplasmosis	

Epidemiology

Table 3: Epidemiology of Tuberculosis in HIV-infected and Immunocompetent Individuals

	Immunocompetent individuals	HIV-infected individuals
Risk of reactivation of latent tuberculosis	10% (lifetime)	10% per annum 50% (lifetime)
Disease recurrence after treatment	2-3%	14%

Clinical Features

Table 4: Differences between TB Infection in HIV-infected and Immunocompetent Patient

	Immuno-competent	Immunocompromised
Sputum AFB	Multibacillary disease—sputum positive	Paucibacillary disease—usually sputum negative
Pulmonary radiography	Upper lobe cavitatory lesions	Bilateral interstitial infiltrates usually lower zone Predominant extrapulmonary involvement – pleural effusion and hilar adenopathy
Extrapulmonary disease	10 to 20% of TB infection	40 to 80% of TB burden

Treatment

Antituberculosis therapy (ATT) must be administered according to the directly observed treatment-shortcourse (DOTS) regimen.

Institution of HAART is recommended 10-14 days after institution of ATT in patients with CD4 counts less than 200 cells/mm^3. In patients with CD4 counts over 200 cells/mm^3 HAART may be commenced 2-8 weeks after the institution of ATT. As rifampicin is known to enhance the metabolism of protease inhibitors and nevirapine, efavirenz based antiretroviral therapy (ART) is recommended while patients are on rifampin.

OROGENITAL CANDIDIASIS

Clinical features and management are shown in **Table 5**.

Table 5: Clinical Features and Management

Site of disease	Clinical features	Treatment
Oral	Cotton-like sensation in mouth	Clotrimazole troche 10 mg five times/day for 7-14 days Oral Fluconazole 100-200 mg once daily for 7-14 days
Oesophageal	Odynophagia with oesophageal ulcers	Tab Fluconazole 200 mg once daily for 14-21 days.
Vaginal	Curdy white pruritic vaginal discharge adhering to erythematous base	Tab Fluconazole 150 mg stat Tab Fluconazole 150 mg x 3 doses

DIARRHOEAL DISEASE

Epidemiology

The common infective organism which are usually responsible for diarrhoea in patients are depicted in **Table 6**.

Table 6: Common Pathogens Associated with Diarrhoea in HIV-infected Individuals

Infectious agent	Small intestinal pathogen	Large intestinal pathogen
Bacteria	*Mycobacterium avium intercellulare* *Salmonella* spp	*E. coli* *Campylobacter* spp *Aeromonas* spp *C. difficile*
Virus	Rotavirus Norovirus	Adenovirus *Herpes simplex virus* Cytomegalovirus
Protozoa	Cryptosporidium Cyclospora *Giardia lamblia* *Isospora belli* Microsporidiosis	*Entamoeba histolytica*

Clinical Features

Four distinct clinical syndromes exist:

- Small bowel diarrhoea—watery, large volume associated with bloating and weight loss.
- Large bowel involvement—frequent, small volume, painful stools.
- Anorectal involvement—associated with tenesmus, dyschezia and urgency.
- Disseminated infection—with fever is seen in Salmonellosis, atypical mycobacteria or CMV.

Treatment

Treatment of chronic diarrhoea is outlined in **Table 7**.

Table 7: Definitive Therapy of Chronic Diarrhoea

Organism	Drugs
Salmonella	Oral double strength Cotrimoxazole (800 mg sulphamethoxazole/160 mg trimethoprim) once daily for 10 to 14 days
Shigella	Oral Cotrimoxazole double strength tablet for five days
Giardia lamblia	Oral Metronidazole 200 mg thrice daily for a week
Entamoeba histolytica	Oral Metronidazole 400 mg thrice daily for a week
Cryptosporidium	HAART
Cyclospora	Oral double strength Cotrimoxazole every 6 hours for 10 days then twice a week indefinitely
Isospora belli	Single double strength Cotrimoxazole tablet four times a day for 10 days followed by thrice daily for 3 weeks
Microsporidiosis	Oral Itraconazole 400 mg once daily and Albendazole 400 mg once daily

CRYPTOCOCCOSIS

Cryptococcus neoformans is an encapsulated yeast-like fungus which produces meningitis, pneumonia, cutaneous abscesses among individuals with CD4 count <100 per mm^3.

Clinical Features

Cryptococcal meningitis begins as a subacute onset of fever, headache and malaise with seizures or altered mentation. Stiff neck, photophobia, and vomiting are seen in 25% patients. Symptoms suggesting disseminated disease such as cough, dyspnoea, and skin rash may be present.

Diagnosis

The gold standard for diagnosis of cryptococcal infection is a positive cerebrospinal fluid (CSF) culture. CSF India ink staining demonstrates the organism in 75% of patients. CSF and serum cryptococcal antigen have sensitivity and specificity ranging from 93 to 100%.

Treatment

The treatment of choice is amphotericin B 0.7 to 1 mg/kg/day, usually combined with flucytosine 100 mg/kg/day, for two weeks, followed by fluconazole 400 mg once daily for 8 weeks. Maintenance fluconazole 200 mg/day is recommended till patients begin HAART and maintain CD4 counts >200/mm^3 for more than 6 months.

Repeated therapeutic lumbar punctures may be required if CSF opening pressures are >250 mm CSF draining 20-30 mL CSF so as to decrease CSF pressures by 50%.

If new symptoms or signs develop after 2 weeks of treatment, repeat diagnostic lumbar puncture may be required to exclude coinfection with tuberculosis.

CYTOMEGALOVIRUS

Clinical Features and Diagnosis

Table 8 shows the clinical features of cytomegalovirus while **Table 9** charts the other common opportunistic infections.

Table 8: Clinical Disease Produced by Cytomegalovirus

Organ affected	Clinical features	Diagnosis
Retina infiltrates	Flashes, blurred central vision	Fundoscopy reveals perivascular fluffy yellow-white retinal and focal necrotising retinitis with or without intraretinal haemorrhage
Gastrointestinal tract	Fever and odynophagia with lower oesophageal ulcers Abdominal pain, diarrhoea (large bowel type), weight loss	Endoscopic visualisation of mucosal ulcers or erosions and histological evidence of tissue destruction with presence of viral inclusion bodies
Lung	Fever, cough and dyspnoea	Positive CMV culture of bronchoalveolar lavage fluid or histopathologic cytopathologic effect
CMV encephalitis	Delirium, confusion and focal deficits	MRI brain or spinal cord is useful in excluding other OIs
Myeloradiculoneuropathy	Ascending flaccid paralysis with bowel and bladder involvement	Positive CMV PCR from CSF is highly suggestive of CMV

Table 9: Other Opportunistic Infections

Disease	Pathogen	Clinical features	Diagnosis	Management
Pneumocystis jiroveci pneumonia	*Pneumocystis jiroveci*	Fever, cough dyspnoea with diffuse dry rales in individuals with CD4 count <100 cells/ microlitre	Demonstration of the organism in pulmonary secretions by immunofluorescence or methenamine silver staining	2 double strength tablets of Cotrimoxazole (800 mg sulphamethoxazole/160 mg trimethoprim) every 8 hours for 21 days PaO_2 <70 mm of Hg and alveoloarterial gradient greater than 35 mm Hg mandates steroids
Progressive multifocal leucoencephalopathy	JC virus	Subacute onset altered mentalstatus, motor deficits, limb ataxia, gait ataxia and visual symptoms	Asymmetric periventricular white matter foci of demyelination without oedema or mass effect sparing the optic nerves and spinal cord – confirmation by brain biopsy	HAART
Toxoplasmosis	*Toxoplasma gondii*	Encephalitis in individuals with CD4 count <50 cells/ microlitre	Identification of ring-enhancing intracranial mass lesions and detection of the organism on biopsy. Positive CMV IgG is suggestive. Therapeutic response in 2 weeks is confirmatory	Pyrimethamine (200 mg loading dose orally followed by 75 mg/ day) plus sulphadiazine (6 to 8 g/day orally in four divided doses)
Oral hairy leukoplakia	Epstein-Barr virus	Adherent white patches on lateral tongue and mouth	Clinical	Topical tretinoin or podophyllin
Herpes zoster	*Varicella zoster*	Grape-like clusters of clear fluid-filled blisters on red skin	Tzanck preparation showing multinucleate giant cells	800 mg oral Acyclovir 5 times a day for 7-20 days
Penicilliosis Histoplasmosis	*Penicillium marneffi Histoplasma capsulatum*	Fever, lymphadenopathy hepatosplenomegaly molluscum like skin lesions	Histopathology – yeast like organisms. Fungal culture from blood, bone marrow, lymph nodes confirmatory	Amphotericin B 0.6 mg/kg/day for 2 weeks followed by oral Itraconazole 200 mg twice daily for 10 weeks.

Table 10: Common Immune Reconstitution Inflammatory Syndrome (IRIS)

Disease	Clinical manifestations	Treatment
Tuberculosis Usually occurs in 10-180 days of institution of HAART	Fever, malaise, weight loss Worsening respiratory symptoms Increase in size of lymph nodes New pleural effusion Resurgence of fever with pulmonary symptoms Increase in size of tuberculomata	Continuation of ART unless life-threatening IRIS or localised symptoms threaten to cause permanent sequelae Prednisolone 1 mg/kg/day tapered over 14 days (adjunct) Appropriate antimicrobial therapy for the opportunistic agent
Cryptococcosis	Fever, increased headache, nuchal pain, eye pain	
Cytomegalovirus	Immune recovery vitritis – Uveitis, vitreous inflammation with or without cystoid macular oedema, epiretinal membrane or retinal neovascularisation	

Treatment

Oral Valganciclovir is recommended for CMV retinitis (900 mg twice daily for 3 weeks as induction followed by 900 mg once daily as maintenance – till CD4 count >100 cells/microlitre for 6 months while on ART). In patients with vision threatening disease, gastrointestinal, neurologic and pulmonary disease, intravenous ganciclovir 5 mg/kg every 12 hours for 21 days followed by the oral preparation (1,000 mg capsules thrice daily) for maintenance is recommended.

IMMUNE RECONSTITUTION INFLAMMATORY SYNDROME (IRIS) (Table 10)

IRIS refers to inflammatory reactions occurring at the site of pre-existing infection owing to reconstitution of the immune system in HIV-infected individuals following the initiation of HAART. Up to 30% of individuals responding to HAART manifest IRIS.

It may be possible to avoid IRIS by treating identified OIs that have an effective antimicrobial therapy for one to two months prior to initiation of HAART thereby reducing the microbial burden when ART is initiated.

PROPHYLAXIS OF OPPORTUNISTIC INFECTIONS

Primary chemoprophylaxis against OIs is recommended in all HIV-infected individuals who have WHO Stage III disease or Stage II disease with a CD4 count less than 200 cells/mm^3.

Primary prophylaxis may be ceased once the CD4 count is over 200 cells/mm^3 for over 6 months (**Table 11**).

Secondary prophylaxis may be discontinued when the CD4 count is above 100 cells/mm^3 for more than 6 months while patient is on HAART (**Table 12**).

Table 11: Primary Prophylaxis of OIs

Agent	CD4 count/ mm^3	Drug	Comments
Pneumocystis jiroveci	CD4 <200	Cotrimoxazole double strength tablet once daily	Cotrimoxazole is useful in the prevention of Toxoplasmosis, certain bacterial pneumonia, Nocardiosis and Isosporiasis
Mycobacterium avium intercellulare	CD4 <50	Azithromycin 1.2 g once a week	

Table 12: Secondary Prophylaxis of OIs

Agent	Drug
Cytomegalovirus	Valganciclovir 900 mg once daily
Cryptococcosis	Fluconazole 100 to 200 mg orally daily
Candidiasis

16.8 Non-Pharmacologic Interventions and Prevention

R Sajithkumar

INTRODUCTION

Human immunodeficiency virus (HIV) has a long incubation period and florid disease takes a long time before becoming clinically manifest. This, therefore, provides a unique window period to prevent its progression, and in case of disease, to reduce its morbidity. This chapter deals with interventions in asymptomatic and symptomatic PLWHAs (Persons Living With HIV/AIDS). Many alternative therapies (like yoga) have been occasionally reported as useful. Counselling is a useful tool right from the stage when the tests are being planned to crisis situations. Nutritional support is another well recognised intervention. Periodic screening and monitoring will assist in early detection and treatment of infections and malignancies. There are effective preventive vaccines for many infections which can be used in PLWHAs. HIV vaccine development is advancing. Many vaccines are being studied for their potential therapeutic efficacy (delaying progress) even when primary prevention is not possible.

The interventions in HIV disease can be grossly classified as follows:

1. Interventions for general public.
2. Interventions for vulnerable groups.
3. General interventions amongst PLWHAs.
4. Specific interventions at certain stages.

INTERVENTIONS FOR GENERAL PUBLIC

These include IEC (Information, Education and Communication) strategies, e.g. general education, sex education and health awareness programmes, etc. They aim at generating knowledge which leads to healthy attitudes, improved behaviour translating to better practices. The behaviour change must be regularly re-inforced with repeated attempts. Health issues and safe sex education at various levels have been found to be useful. IEC also generates healthy attitudes in infected persons, special categories, i.e. intravenous drug users (IVDUs), men having sex with men (MSM) and commercial sex-workers (CSWs). Across cultures this is the most commonly tried intervention and adjudged the most acceptable.

ABC OF HIV PREVENTION

A- Abstinence, B- Being faithful with an uninfected partner and C- Condom use, proper and consistent has been the cornerstone of prevention of sexual transmission of HIV. Such a strategy has been found to be useful and successful but the first practice is hard to follow and in the second, the HIV status of the partner has to be known, which at times is difficult. While effective use of condom is possible and quite useful.

INTERVENTIONS FOR SPECIAL GROUPS

Interventions in this category can be divided into two main groups: (1) those practicing high-risk sexual behaviour and (2) those indulging in IV drug use.

Reducing Sexual Transmission

The high-risk sexual behaviour includes: (a) male homosexuality with multiple partners, (b) multi-partner sex, (c) sex with casual (non-regular) sex partners. In heterosexual practice (sex between opposite sexes), the risk is graded differently as unprotected anal intercourse, unprotected vaginal intercourse, unprotected oral sex and as protected sex using condoms. The strategies aim at shifting a person from practices of higher risk to safer practices. Condom promotion plays a major role in all these modalities.

Syndromic Approach to Sexually Transmitted Infections (STIs) Management

Refer to chapter 16 of section 10.

Reducing Transmission by IV Drug Use

Intravenous drug users have been recognised as a vulnerable group from the early days of the epidemic. Sharing syringes used for IV injection particularly was an efficient mode of transmission in many populations. Recreational drug use is illegal in many countries and unacceptable in many cultures. Even non-injectable drug use makes people vulnerable by modifying their level of judgement and taking away inhibitions leading to unsafe sex behaviours. IVDUs have been targeted in many activities across the globe. *Supply reduction, demand reduction and harm reduction* are three major strategies in this group. Supply reduction prevents illegal trafficking, confiscation and destruction of drug supplies and supply lines. Demand reduction is practiced in many educational institutions. Proper IEC programmes on the risks of drug use are acceptable to all societies and all ages. Rehabilitation and detoxification clinics modify use pattern by scientific methods like counselling, methadone or buprenorphine substitution, etc. These will gradually reduce dependency and promote adherence to counselling and healthy lifestyles. Walk in centres with facilities for sterilisation or sterile injections are beneficial. Community-based rehabilitation packages including promotion of safer sex practices are needed for IVDUs. There is evidence from multicentric studies that these significantly reduce HIV transmission.

Reducing Transmission Among MSM

Men having sex with men (male homosexuals) have been recognised as vulnerable from the early days of the epidemic. Many of them have problems like having sex with many partners (regular and non-regular) at any point in time, having STIs, propensity for anal intercourse, habituation to injecting/other drug use, having sex with female partners. Poly-drug use, partner violence, depression and other psychosocial issues are also important. Specialised sex education packages, condom promotion, integrated STI care, context specific counselling, etc. are strategies found successful for them.

Reducing Transmission by Blood and Blood Products

All health establishments handle emergencies where blood is required. Proper screening, donor selection, storage and

delivery are vital. Quality of screening is ensured. Licensing of blood banks and avoidance of all unauthorised blood collections are needed across the globe. Recruitment of voluntary low risk donors is encouraged and all professional donors excluded. Supply of non-human blood components, component transfusion, autologous transfusion, etc. are important strategies.

Reducing Transmission in Health Care Settings

It is dealt in chapter 9 of section 17.

Targeted Intervention Approach of NACO (India)

National AIDS Control Organisation (NACO), Ministry of Health and Family Welfare, Government of India has adopted targeted intervention as a regular strategy. It envisages comprehensive and integrated approach to marginalised and vulnerable populations like CSWs, MSMs, IVDUs, migrant labourers, street children, prisoners, etc. There are around 900 projects run by Non-Governmental Organisations (NGOs) and other agencies across the country. They perform need assessment, counselling, education, peer group activities, behaviour change communication monitoring and care and support activities. They are run with financial assistance and scrutinised by the state AIDS control societies.

Voluntary Counselling and Testing (VCT)

One major activity aimed at making the above facilities available to the public at low cost includes Voluntary Counselling and Confidential Testing Centres in all states. The services of male and female counsellor for pre-/post-test counselling and laboratory technician for serological testing is available. These centres have become Integrated Counselling and Testing Centres (ICTCs). These will act as the portal of entry for people with high-risk behaviour to enter the care set-up voluntarily and confidentially.

GENERAL INTERVENTIONS AMONGST HIV INFECTED PERSONS

Lifestyle Changes

Avoidance of high-risk behaviour and change to safer sex and safer injection practices are the most important issues for PLWHAs at all stages. The usage of condoms and sterile needles must be insisted. Avoidance of both needle-sharing and dangerous sex practices (multi-partner sex, unprotected sex) do help. Even among well educated people, there is a wrong belief that if both partners are infected, there is no need for protected sex. Protected sex at any stage will help in preventing first or subsequent infection with various subtypes of HIV and more importantly other sexually transmitted pathogens. It is well known that any infection (including common infections and self-limited infections) like herpes or candida can activate immunologic cells and increase the viral load. Therefore, PLWHA must clearly avoid contact with other infectious diseases patients, pets and other animals, untreated animal products, etc.

Use of habit forming drugs like alcohol, psychedelic drugs, etc. can lead to chronic systemic ailments, hampering the health status. The person should be cautious when working or travelling to high-risk environments including endemic areas. They should take only boiled water and well washed vegetables to avoid gastrointestinal infections.

Regular exercise must be promoted. All lifestyle risk factors like smoking, sedentary lifestyle, high intake of fatty foods, etc. should be curtailed. Interventions like counselling, yoga, etc. can create a good mental make-up for the affected individuals.

Nutrition plays a major role. Improvement in nutritional status of all family members of PLWHA gets reflected in the survival. High calorie, high protein diet rich in micronutrients must be encouraged. Early screening for diabetes, metabolic syndrome and other such ailments are to be done systematically.

Specific Interventions at Certain Stages

Crisis situations can occur any time in human life. Issues related to marriage, contraception, conception, childbirth, breast feeding, death, etc. might make the services of a well trained counsellor absolutely essential.

PREVENTION OF MOTHER TO CHILD TRANSMISSION

HIV affects women of the childbearing age and hence pregnancies associated with HIV infection are bound to happen. Proper contraceptive counselling in PLWHAs can prevent a large number of avoidable pregnancies and thus help reduce the number of infected children being born. In many instances antenatal screening is the first time a woman is found to be infected. Apart from the psychological support needed for the expectant mother, proper use of antiretrovirals (ARVs) can ensure a significant reduction in vertical transmission. The use of ARV drugs before labour, reduction in the time spent in labour (by elective caesarian section), and avoidance of breastfeeding has all been shown to be effective. Exclusive formula or breast feeding is superior to mixed feeding. Routine screening of antenatal women (with informed consent and counselling) is fast becoming the standard practice. Infected persons are given full care and further counselling regarding child rearing and infection control practices in children. All vaccines must be given to the newborn as in any other child.

EMERGING AVENUES IN PREVENTIVE INTERVENTION

HIV Vaccines

Even though a vaccine is the most sought after preventive intervention in any disease, HIV vaccine development must overcome many obstacles like variations in antigen configurations, rapidity of new mutant evolution, sanctuaries of virus persistence in the body and the difficulty in immunologically active cells being part of the disease process. However under the International AIDS Vaccine Initiative (IAVI), many countries (including India) are enthusiastic about vaccines. Many candidate materials have been tried as prophylactic and therapeutic vaccines. DNA vaccines (either alone or with adjuvants), live vector based vaccines, subunit vaccines, peptide vaccines, VLP (virus like particle) vaccines, fusion competent vaccines, Tat toxoid vaccines, inactivated vaccines are all being tried. Many of them act through cytotoxic T-cell (CTL) production or by inducing neutralising antibodies. There are many ethical and psychological issues involved in any vaccine trial and hence an easy solution is not likely to evolve soon. A prophylactic vaccine is not going to prevent HIV infections in everybody and the importance of all other preventive strategies should not be underestimated. According to a model developed by IAVI, a 30% effective vaccine given to 20% of the risk population could reduce new infections by just

17%. There have been several advanced-phased HIV vaccine trials to date that have been conducted in developed and developing countries. Phase 3 trials involve thousands of high-risk volunteers to test the effectiveness of an HIV vaccine on HIV seroincidence. Phase 2B trials involve a smaller number of volunteers and can determine a preliminary assessment of efficacy. They can guide future vaccine efforts, but are not enough for licensing or release of a vaccine. Currently, there is no licensed preventive (in HIV-negative participants) or therapeutic (in HIV-positive participants) HIV vaccine. Despite the recent encouraging progress from the Thai RV144 trial, we remain a long way from an affordable, effective vaccine against HIV.

Microbicides

Microbicides are chemicals that work in the vagina by different mechanisms. They are materials that can be used by a woman without depending on the partner to protect herself. Some of them are foaming agents, acidifying gels, entry inhibitors or vaginal defense enhancers. The initial euphoria associated with the introduction of vaginal microbicides has given way to a more realistic approach that looks at the side effects and actual statistically proven effectiveness. Many agents are being discarded and newer ones are being studied. A detailed evaluation of microbicides is not within the purview of this book.

Male Circumcision

Many reports have highlighted the decreased risk of HIV transmission if the male partner is circumcised. The inner part of the foreskin has a higher number of Langerhans' cells with receptors for HIV. The skin over the penis is different in circumcised man which reduces trauma during penetrative sex. Many models have shown a possible reduction of 10% to 20% new infections in communities where at least 10% males are circumcised every year. The reduction in male infection rate will lead in future to a similar fall in female infection rate as well. However, male circumcision is to be considered alongwith proper and consistent condom use as the most important intervention.

CONCLUSION

With the current level of knowledge about HIV disease and the modalities available for countering the replication and transmission of the virus, it is now possible to do many preventive interventions at different stages of the disease and the epidemic. Even when ARV drugs are changing the scenario of survival in PLWHAs, this epidemic is still not under control. A few best practices from countries like Thailand, Uganda and Senegal could be extrapolated to other parts of the world and newer observations from other countries must be identified and disseminated. Changes in knowledge, attitudes, behaviour and practices are to be addressed in larger scale.

17.1 Basic Considerations of Infections

Subhasish Kamal Guha

The infectious diseases continue to pose a major public health challenge for the developing nations. However, the morbidity and mortality due to infectious diseases has declined among developed nations because of improvements in sanitation, overall living conditions, availability of safe drinking water, and access to many anti-microbials and vaccines.

EPIDEMIOLOGY OF INFECTIOUS DISEASES IN INDIA

A number of infectious diseases are prevalent in India. With successful implementation of immunisation of infant and children, there has been considerable decline in the incidence of diseases like measles, diphtheria, whooping cough, etc. However, certain diseases continue to be endemic in various states of India. Some of the infectious diseases are localised to certain states or districts. Kala-azar is endemic in Bihar, Jharkhand, Eastern Uttar Pradesh and West Bengal. *Penicillium marneffei* is similarly observed in Manipur and Nagaland among people living with HIV/AIDS. Kyasanur Forest disease, endemic in Shimoga, North and South Kannada and Chikamagaloor districts of Karnataka is another example of localised disease.

Certain infectious diseases, although prevalent throughout the country, seem to have increased incidence in certain states, e.g. hydatid disease in Andhra Pradesh and Tamilnadu, lymphatic filariasis in Uttar Pradesh, Bihar, Jharkhand, Andhra Pradesh, Orissa, Tamilnadu, Kerala and Gujarat. It may be mentioned here that lymphatic filariasis is distinctly uncommon in North and Northeastern states. Malaria is a major public health problem across the country. But malaria in forests, forested foothills and hills, forest fringe areas and development project sites is a matter of concern. Fifteen major cities including the four metropolitan ones contribute to the bulk of urban malaria. Dengue and dengue haemorrhagic fever (DHF) has caused epidemics during 2005-2006 in Delhi, West Bengal, Rajasthan, Kerala and Punjab. Chikungunya is reported from Maharashtra, Karnataka, Andhra Pradesh, Gujarat, Tamilnadu, Madhya Pradesh, Delhi, Kerala, and Rajasthan. Although Japanese encephalitis is endemic in the states of Bihar, Haryana, Karnataka, Kerala, Maharashtra, Manipur, Tamilnadu and West Bengal, most of the recent outbreaks have occurred in Assam and Uttar Pradesh. Leptospirosis, endemic throughout the country, caused epidemic in Orissa in 1994 following the super cyclone and outbreaks during the monsoon of 2000 in Gujarat, Kerala, Maharashtra, and Andaman & Nicobar Islands.

Outbreak of Bubonic plague occurred in Beed, Maharashtra in 1994 followed by an outbreak of pneumonic plague in Surat, Gujarat. In 2002, the last report of pneumonic plague came from Hat Koti village of Shimla district of Himachal Pradesh. Rabies is endemic all over India except Lakshadweep and Andaman and Nicobar islands. India is the highest tuberculosis burden country of the world.

The HIV epidemic is also fuelling the spread of tuberculosis. The 'high prevalent' states for HIV include Maharashtra, Tamilnadu, Andhra Pradesh, Karnataka, Manipur and Nagaland. HIV/AIDS is an emerging health and social problems of the entire country. The incidence of leprosy is on the decline. The six states/union territories that are still having high prevalence include Bihar, Chhattisgarh, Jharkhand, West Bengal, Chandigarh and Dadra & Nagar Haveli.

HOST FACTORS IN INFECTION

Age, immunisation, prior illness, nutritional status, pregnancy, immune status, co-morbid diseases—all have impact on the risk of infection following exposure to potential pathogens. Hospitalisation also increases the risk of acquiring infection through contact with pathogens, through breach of skin (intravenous devices or surgical incisions) or mucosa (catheter or endotracheal tubes), by introduction of foreign bodies, through alteration of the natural flora with antibiotics, and by immunosuppressive therapy.

Both innate and adaptive or specific immunity play important roles in determining the outcome of host-microbial interactions and have been discussed in the Immunology Section of this book.

MICROORGANISM-HOST INTERACTION

Impact of Infection on the Body

Infection has many effects on the host. These can be acute, chronic, allergic, and toxigenic.

Acute effects are fever, protein catabolism, negative nitrogen balance, acute-phase protein response, hypoalbuminaemia, low serum iron, anaemia, neutrophilia, inflammation, convulsion, confusion, shock, haemorrhage, haemolytic anaemia, intra-vascular coagulation, organ failure involving kidneys, liver, lung, heart, brain, and necrosis of skin.

Chronic effects of infection can be loss of weight, muscle wasting, malnutrition, growth retardation in children, anaemia, tissue destruction, etc. Post-infective syndromes may include lactose intolerance, malabsorption, fatigue, depression, etc.

Allergic (immune-mediated) manifestations of infection include rash, arthritis, pericarditis, encephalitis, peripheral neuropathy, haemolytic anaemia, and glomerulonephritis.

Toxin-mediated effects include erythematous rash in streptococcal infection, multisystem disturbances in staphylococcal toxic shock syndrome, diarrhoea due to toxins, organ dysfunction (e.g. diphtheria) and neurological manifestations (e.g. tetanus, botulism and diphtheria).

In addition, certain viruses (oncogenic) are implicated in the aetiology of malignancies.

PATHOLOGY OF INFECTION

Diseases due to an infectious agent are the outcome of interaction between the microorganism and the host defence mechanism. Depending on this interaction, infection may vary from sub-clinical or asymptomatic infection on one hand to severe, fulminant disease culminating in death on the other. Factors like number and virulence of the organisms, anatomical and physiological effects produced by it and the ability of the host's defence mechanism—all play important role in the outcome of host-microorganism interaction. Certain genetic factors are also significantly involved in the response to infection.

Organisms act either directly and/or indirectly through their toxins. The effects of infection may be generalised but can also be site-specific, e.g. poliomyelitis virus in anterior horn cells.

EMERGING AND RE-EMERGING INFECTIOUS DISEASES

Declaration by WHO of global eradication of smallpox on 8th May, 1980, was a landmark in the battle against infectious diseases. Guinea worm disease has also been eradicated from most of the world except for few countries in Africa. It is expected that diseases like poliomyelitis, neonatal tetanus, leprosy, onchocerciasis and Chagas' disease will soon join the list.

Some of the infectious diseases, once largely controlled by public health measures, have come back with vengeance in recent years. These re-emerging infections include malaria, dengue, chikungunya, plague, cholera, yellow fever with spread to new geographical areas.

Additionally, a number of new infectious agents have emerged in the last 2 to 3 decades causing outbreaks or epidemic in various countries with rapid spread across the globe. Some of the examples are severe acute respiratory syndrome (corona virus), diarrhoeal diseases (*Vibrio cholerae* O139, *Cryptosporidium parvum*, *Cyclospora cayetanensis*, *Escherichia coli* O157-H7, *Campylobacter jejuni/coli*, and *Shigella* spp.), Ebola and Nipah haemorrhagic fever, pulmonary Hanta virus, Monkey pox, HIV/AIDS, Avian (H5N1) and Swine (H1N1) flu, etc.

Factors responsible for spread of new, re-emerging or drug resistant infections include changes in human demographics and behaviour, impact of new technologies and industries, economic development and changes in land use, increased international travel and commerce, microbial adaptation and change, and the breakdown of public health measures.

Some of these diseases like plague, dengue, chikungunya, cholera, Nipah virus, avian and swine flu have recently caused outbreaks in India raising public health concerns.

Anti-microbial drug resistance is also a pervasive health problem. multidrug-resistant (MDR) and extensively drug-resistant tuberculosis (XDR TB), methicillin and vancomycin resistant *Staphylococcus aureus* (MRSA and VRSA), vancomycin resistant Enterococcus (VRE), multidrug resistant *Plasmodium falciparum* malaria, penicillin resistant pneumococcus and penicillin and tetracycline resistant gonococcus are all major problems of anti-microbial therapy.

FUTURE DIRECTIONS

The genetic constitution of many microorganisms allows them to undergo rapid evolution and to develop mutations that offer them survival benefit. Changes in environment and the host can predispose new populations to some infections. The deliberate release of deadly spores of *Bacillus anthracis* via the US Postal Service was an eye-opener to everyone about the reality of bioterrorism. We have also witnessed recently the scare in public minds, media, politicians and even health care delivery system when swine flu epidemic broke out in India. The battle between the emerging anti-microbial resistance and new, potent, costly anti-microbial is destined to continue. A well-coordinated team approach involving physicians, microbiologist, intensive care specialists and public health managers is the need of the hour for the war against infection.

17.2 Laboratory Diagnosis of Infections

Camilla Rodrigues

There are several advantages in making a specific diagnosis of an infectious disease. In addition to better patient care with appropriate therapy, considerable financial expense is spared and preventive measures can be initiated.

SPECIMEN COLLECTION AND TRANSPORT

This is the first vital step. It is important to protect the sample from contamination by normal flora as with stool and urine specimens. Also for isolation of anaerobes, maintenance of the redox potential with transport media as Stuart's medium along with rapid transport to the laboratory is essential. The stage of an illness determines what sample is required and whether or not the microorganisms will be isolated, e.g. *Salmonella typhi* is recovered maximally from blood cultures in the first week of typhoid fever but from stool and urine only in subsequent weeks. For tuberculosis where irregular shedding of *Mycobacterium tuberculosis* occurs, successive samples need to be tested.

IDENTIFICATION OF INFECTIOUS AGENTS

To identify microorganisms five different approaches may be adopted namely microscopy, culture, serology, antigen detection and molecular methods.

Microscopy

Direct microscopy

Examination of coverslip preparations helps in the immediate diagnosis of cholera, amoebiasis, giardiasis and helminthic infestations. Various staining procedures can be employed like Gram's stain, acid fast staining for Mycobacteria; Wright's stain to detect malarial parasites and microfilaria in blood smears and silver stains are for the identification of fungi and *Pneumocystis*. India ink is useful in negative staining to detect capsular organisms, e.g. *Cryptococcus* in CSF.

Culture

Blood culture

This is indicated in all infections where bacteraemia is the hallmark, e.g. in infective endocarditis, where ideally three blood samples should be drawn at least half an hour apart. If cultures are persistently negative, supplemental media for nutritionally dependent *Streptococci* can be used. Blood culture is also helpful in other acute febrile illnesses, such as typhoid, meningitis, bacterial pneumonia, osteomyelitis and in fever of unknown origin.

Although recovery of bacteria from blood during episodes of sepsis is not difficult, certain concepts need to be understood. Adequate skin preparation prior to venepuncture is of utmost importance. In addition, a minimum of 30 to 40 ml of blood should be cultured. Increasing the volume collected for culture is regarded as an essential component in enhancing isolation of microorganisms. The culture medium should include an anticoagulant and ideally an anti-complement and anti-phagocytic substance to reduce the intra-cellular killing of microorganisms by neutrophils following injection of the blood into the culture medium.

There is data to substantiate that two or three blood culture sets are adequate for detecting common pathogens. The recovery in the first culture is 80%, 88% in two cultures and 99% in all three cultures.

Timing

Optimally at the onset of a shaking chill but in less urgent situations spaced at intervals of ½ to 1 hour. Ratio of blood to broth ideally should be 1:5 to 1:10. Organisms as *Brucella*, *Legionella*, some fungi, mycobacteria should be incubated for longer than the traditional 5 days.

Automated blood culture systems

The continuous monitoring blood culture systems are modular with a single computer controlling the incubator units. Culture vials are incubated in individual cells and monitored at intervals of 10 to 15 minutes for evidence of microbial growth. Three such systems, the BACTEC blood culture system (BD Diagnostic Systems), the BacT/alert (Biomerieux) and the TREK-ESP culture systems (TREK Diagnostic systems) are available in India. Multiple studies have shown that the bottles need to be incubated for only 5 days.

Sputum culture

Sputum samples may contain large number of bacteria indigenous to the oral cavity. Early morning samples are advisable since they contain pooled overnight secretions likely to contain pathogenic organisms. When sputum production is not possible, induction with heated or ultrasonic nebulised saline may be effective. More invasive methods include transtracheal aspiration, bronchoscopy and bronchoalveolar lavage.

Urine culture

Collection of urine should be performed to minimise contamination by organisms from the urethra. Thus, adequate cleaning prior to the collection of mid-stream specimen of urine is vital. Urine samples should reach the laboratory within 30 minutes. Dip slides should be used if delay is anticipated in the samples reaching the laboratory. The presence of more than 100,000 colonies/ml signifies true infection.

Gastrointestinal culture

Gastric aspirates for culture is used for the diagnosis of tuberculosis in children. Endoscopic biopsies are used to detect *Helicobacter pylori*. Stool samples are cultured on special media to prevent the colonic flora from overgrowing the pathogen.

TB culture techniques

Culture of mycobacteria is a much more sensitive test than smear examination and allows for biochemical identification

of the species considerably enhancing the specificity. Agar based media allow detection of colonies in 10 to 12 days, whereas the most commonly used Lowenstein-Jensen medium (L-J) usually takes 18 to 24 days; because of the slow doubling time of *M. tuberculosis*.

Automated liquid culture methods

The mycobacterial growth indicator tube (MGIT) 960: The test employs a new state of the art fluorescent technology that enables positive results in 7 to 10 days. This dispenses with the need for radioisotope labelled substrates required for BACTEC 460 TB. It is based on oxygen quenching of mycobacteria with a fluorescent embedded dye.

Automated organism identification and anti-microbial susceptibility testing: There are fully automated instruments available today for rapid and accurate identification as well as susceptibility testing by minimum inhibitory concentration (MIC). The basis of identification system reactivity is usually based on pH or enzyme profiles but can also be carbon sourced and visual detection of growth.

Importantly, dialogue between the clinician and microbiologist is necessary if one is to tell whether organisms identified by the laboratory represent contaminants, commensals or true pathogens.

Serology

Isolation of the offending agent is the mainstay in the diagnosis of disease. If this is not possible and the organism is either fastidious or hazardous to grow or takes long to cultivate, serology is resorted to. This detects either (1) the specific or non-specific immune responses of the host, or (2) the presence of the antigen in the host.

Specific IgG and IgM antibodies can be detected using immunological techniques against an increasing range of viruses, e.g. hepatitis (A-G), HIV, rubella, measles, Epstein Barr, CMV, herpes simplex, etc. IgM antibodies are indicative of recent infection. The secondary response on re-exposure to the same antigen is predominantly IgG driven. There are various types of serological reactions, such as precipitation, agglutination, complement fixation, immunofluorescence, ELISA, Western blot, etc.

Widal test

Whilst interpreting this commonly used agglutination test certain provisos need to be kept in mind. The majority of patients develop a four-fold rise against the somatic O antigen of the typhoid bacillus; H agglutinins are more subject to non-specific variations. Early anti-microbial therapy may dampen the immunologic response and false positives can occur in an anamnestic response during an unrelated fever.

Enzyme-linked immunosorbent assay (ELISA)

ELISA assay has been used extensively to detect either antigen or antibody and has been described as specific, sensitive, simple, inexpensive and reproducible. The indicator in this technique is an enzyme which catalyses a chemical reaction in a substrate. Various enzyme-substrate combinations have been used. The end product of the enzyme reaction can be quantitatively measured spectrophotometrically, fluorometrically, or by other means. It has proven to be as sensitive as radioimmunoassay (RIA) in detecting small quantities of antigen. These techniques are being extensively utilised in diagnosis of toxoplasma, rubella, cytomegalovirus and herpes simplex infections (TORCH), hepatitis and HIV infections.

Immunofluorescence antibody (IFA)

Immunofluorescence staining has long been used in rapid viral diagnosis. The method is based on tagging an antibody with fluorescein isothiocyanate and demonstrating the antibody-virus complex or viral antigens within or on the surface of the cells by examining the preparation microscopically with UV illumination. A number of procedures have been described, including the direct and indirect or anti-complementary IFAs. As the IFA test is performed microscopically it requires approximately 10^5 infectious particles to be visualised.

DETECTION OF MICROBIAL ANTIGENS/PRODUCTS

Today assays are available for rapid detection of bacterial antigens in various body fluids. These are also useful when smear is negative, prior antibiotics have been initiated and culture is negative. Also rapid antigen methods have the advantage that since they are antigen based detection systems, they can be used in the initial stages of the illness and one does not have to wait for specific antibody production. The turn around time is faster in these assays – ranging from 10 minutes to a couple of hours. The common methods encompass latex agglutination, counter current immunoelectrophoresis (CIEP), immunochromatographic assays (ICT)/lateral flow formats, ELISA, direct immunofluorescence, etc.

A. Cerebrospinal Fluid (CSF)

i. Latex agglutination

Latex agglutination techniques are used to demonstrate the soluble polysaccharide antigens of *Neisseria meningitidis*, *Haemophilus influenzae* type B and *Streptococcus pneumoniae* in patients of acute pyogenic meningitis.

In neonatal meningitis the latex agglutination method can be used for detection of *E. coli* and Group B *Streptococci*. These tests offer good specificity more than 98% but the sensitivity varies with each bacterium tested. For *N. meningitidis* A, C, Y, W135, and *N. meningitidis* B/*E. coli* K1 it is 71% and 65% respectively. For *S. pneumoniae* it is 88% and for *Haemophilus influenzae* and Group B *Streptococci*, it is 67%. This assay can also be used for serum after appropriate treatment with EDTA.

ii. Cryptococcus neoformans

Latex agglutination and ELISA are the preferred tests for detection of cryptococcal antigen. They can be used for diagnosis as well as therapeutic monitoring. The latex agglutination methods have a sensitivity of approximately 93% and specificity from 93% to100% and are equivalent to ELISA in detecting antigen. *Trichosporon beigelii*, *Capnocytophaga* spps. and *Stomatococcus* have been shown to produce a cross reacting polysaccharide antigen. Treatment with pronase B reduces the false positive in serum tests in certain rheumatological disorders.

B. Serum

i. Plasmodium species

Rapid diagnostic tests (RDTs) for malaria have an ability to detect more than 100 parasites/mL of blood. These qualitative

tests are rapid, simple, easy to perform and interpret. The stability of the kit in high environmental temperature and humidity in tropics should be taken into account. As they cannot quantitate, they are not useful for prognostication. RDTs have decreased sensitivity at lower levels of parasitaemia yielding false negative results in non-immune patients with low levels of parasitaemia.

There are 3 types of antigens that are used in detection namely pLDH (*parasite* Lactate dehydrogenase), Hrp II (histidine rich protein) and *parasite* aldolase:

(a) pLDH : This enzyme is located in the glycolytic pathway of the malaria parasite produced by both sexual and asexual stages of the parasite.

Though microscopy is considered the 'gold standard' method for diagnosis of malaria, it requires up to 60 minutes time from specimen collection to reporting of result. Detection of parasite specific lactate dehydrogenase (pLDH) are available in a lateral flow format that have high sensitivity and specificity in high endemic regions and are a useful adjunct to microscopy.

(b) Hrp II: Water soluble protein produced by asexual stage and young gametocytes of *P. falciparum*. Hrp II is generally more sensitive than pLDH but has a disadvantage that the antigen persists at detectable levels for more than 28 days after treatment.

(c) *Plasmodium* aldolase, an enzyme of the glycolytic pathway produced by all four species, has been recently developed.

ii. Dengue

Dengue enzyme immunoassay (EIA) NS1 antigen: Detection of the NS1 antigen is valuable as it allows for detection of infection prior to seroconversion and can be detected in serum from day 1 after onset of fever up to day 9. This antigen is a marker of early acute active infection and early diagnosis of dengue allows for earlier implementation of supportive therapy and monitoring. This reduces the risk of complications, such as dengue haemorrhagic fever, or dengue shock syndrome. After day 9, once NS1 antibodies are produced this antigen is no longer detected. Cross reactivity across the flavivirus group may occur.

iii. Aspergillus

Enzyme immunoassay (EIA) for galactomannan antigen assays: Galactomannan is a heteropolysaccharide present in the cell wall of most *Aspergillus* and *Penicillium* spp. and its production is proportional to the fungal load in tissues. Though strictly not a rapid assay, the decision to offer galactomannan testing depends on resources, institutional index of invasive aspergillosis and the hospital case mix. A high unremitting level of galactomannan despite antifungal therapy is associated with an unfavourable prognosis.

This test is best performed before the initiation of antifungal therapy as otherwise sensitivity is diminished. It is also advised that twice-weekly tests be performed to enhance sensitivity. The clinical specificity is around 90% but can be lower in infants due to ingestion of dietary galactomannans. False positive results may be seen in patients on piperacillin-tazobactam. The early latex agglutination tests were specific but not very sensitive (detection limit 25 ng/ml). Sandwich ELISA techniques have enhanced the sensitivity to 1ng/ml.

β-D-glucan: 1,3-β-D-glucan antigen is present in the cell wall of most fungi including *Pneumocystis jirovecii* (except *Cryptococcus* spp. and Zygomycetes). The EIA assay utilises serum for antigen detection. False positive results are seen in haemodialysis, cardiopulmonary bypass and patients on immunoglobulin products. Environmental contamination may compromise specificity. The cut off of 60 pg/ml is under consideration.

C. Urine

In patients with community-acquired pneumonia, antigen testing is useful in patients on treatment to establish the aetiological agent.

S. pneumoniae

A rapid immunochromatographic (ICT) assay for the detection of the *S. pneumoniae* antigen in urine of patients with pneumonia, and in the CSF of patients with meningitis is available. Urinary antigens of *Pneumococci* are detected and their sensitivity surpasses that of Gram stain. The clinical sensitivity and specificity is 86% and 94% respectively. Similarly for detection of *Legionella pneumophila* serogroup I antigen in urine, an *in vitro* rapid ICT assay is available that has a clinical sensitivity and specificity of >95%.

Histoplasma antigen detection in serum, urine and CSF is a useful indicator of systemic infection. ELISA tests can be performed on urine, CSF, serum and bronchoalveolar lavage fluid. The sensitivity is approximately 92% in urine specimens and 82% in serum specimens from patients with disseminated disease. The test has low sensitivity in self limited disease and chronic pulmonary histoplasmosis. This test is not readily available in India due to low prevalence of the disease.

D. Stool

i. Clostridium difficile antigen

Clostridium difficile associated diarrhoea (CDAD) is a cause of infectious diarrhoea mostly in hospitals. By enzyme immunoassays (EIA) toxin A and B can be detected with a specificity approaching 100%. Direct testing of stool sample extracts for toxin presence using a variety of immunoassay techniques has largely replaced the culture method. As strains which only produce either toxin A or B have been reported as pathogenic, methods which detect both are preferable.

ii. Helicobacter pylori

Antigen assays are available for detection with sensitivity of 96% and specificity of 95%. The *H. pylori* Sp HpSA antigen assay (Meridian diagnostics) detects faecal excretion of *H. pylori* antigens and is a useful non-invasive test for diagnosis and follow-up to ascertain complete eradication and outcome of successful therapy.

iii. Rotavirus and adenovirus

Rotavirus and adenovirus antigens can be demonstrated by latex agglutination tests. Ready to use homogenous ICT systems are also available incorporating monoclonal antibodies to specific viral antigens. The advantage is that if these assays flag positive, needless antibiotics can be avoided.

iv. Cryptosporidial antigen

Stool samples in human disease provide for high numbers of oocysts and relatively simple preparation and processing. Non-invasive, acid-fast staining techniques are used widely in clinical laboratories.

E. Throat/Nasopharyngeal Samples/Sputum

Bronchoalveolar lavage (BAL)

Viruses can be detected directly from patient specimens and by culture isolation/confirmation. Respiratory Viral Screen DFA Kits utilises fluorescein-labelled monoclonal antibodies to detect and identify in patient specimens, and to screen for the presence of influenza A, influenza B, adenovirus, and respiratory syncytial virus (RSV) in patient specimens and culture confirmation, and to screen for parainfluenza 1, 2 and 3 following amplification in culture.

Rapid antigen detection methods also include sophisticated methods as gas liquid chromatography (GLC) and high performance liquid chromatography (HPLC). It is used today in the rapid identification of mycobacteria.

MOLECULAR METHODS

Advances in molecular medicine have provided the research and diagnostic laboratory with tools that are revolutionising its function. Molecular methods of diagnosis offer the answer to microorganisms with growth characteristics that are slow (mycobacteria), difficult (viruses, chlamydia) or fastidious (mycoplasma). Another advantage is the ability to detect low pathogen numbers as in meningitis and can be employed in monitoring response to treatment (viral load assays for Hepatitis B, Hepatitis C and HIV).

Nucleic Acid Probes

Nucleic acid hybridisation is a powerful and widely used technique which exploits the ability of complementary sequence in single-stranded (ss) DNA or RNA to pair with each other to form a duplex. The single strand nucleic acid probes used for hybridisation should be complementary to the amplified sequence or the region of interest on the gene to be identified. *In situ* hybridization is used to detect and locate specific DNA/RNA sequence(s) in tissues or chromosomes by making use of radioactive or fluorescent labelled DNA/RNA probes complementary to the required sequence. However in paucibacillary states like tuberculous meningitis and pleural effusion the number of bacilli is too low to be picked-up by this technology. This technique is commercially available for the identification of *M. tuberculosis* complex, *M. avium*, *M. intracellulare*, *M. kansasii* and *M. gordonae*. Nucleic acid probes form a useful adjunct to automated cultures for confirmatory identification.

Nucleic Acid Amplification

These tests can be divided into three groups: (a) target amplification; (b) signal amplification; (c) probe amplification

(a) Target amplification

Polymerase chain reaction (PCR): PCR is an *in vitro* method for amplifying specific DNA sequence.

Real-time PCR: This technology offers rapid PCR with simultaneous amplicon detection. A fluorescent signal is used for real-time monitoring of PCR amplicon production.

Transcription mediated amplification (TMA): TMA uses a species sequence of ribosomal RNA (rRNA) as the target for reverse transcriptase. The advantage of this technology being that the dead cells have no transcription machinery hence only viable cells are picked-up and amplified.

Nucleic acid sequence based amplification (NASBA): NASBA is also like TMA as isothermal amplification wherein RNA is transcribed into cDNA and then RNA copies are synthesised using RNA polymerase.

(b) Signal amplification

This is an alternative to enzymatic duplication of target nucleic acid to increase the signal generated from a hybridised probe molecule. Commonly used technologies include branched DNA (bDNA) and hybrid capture assays.

(c) Probe amplification

The end product of the reaction is an amplified version of the original components used to detect the target and include the ligase chain reaction (LCR), Q-beta replicase and cycling probe technology. In LCR, a phenotypic change in the organism, such as virulence or drug resistance, can be detected.

Emerging technologies: DNA micro array technology, i.e. biochip, DNA chip, gene array, etc. have the potential to assess and visualise thousands of nucleic acids simultaneously. The solid platform contains genetic material arrayed in a pre-determined fashion. When the chip is probed with cDNA (from RNA of the clinical sample) hybridisation can be detected.

Thus, significant developments have occurred in the past two decades in the diagnostic arena. The large scale global use of antibiotics with consequent anti-microbial resistance in pathogens and opportunistic microorganisms stress the importance of rapid, accurate, comprehensive and up-to-date microbiology diagnostics. Physicians must continue to apply traditional microbiology with newer molecular testing to the understanding and application of clinical medicine.

17.3 Syndromic Approach to Infectious Diseases

Rajeev Soman

Infectious diseases cut across the usual boundaries established by medical specialists and various combinations of organ involvement occur in particular infectious diseases. Combining clues from the history, physical examination and laboratory can help to establish the pattern of organ involvement. This pattern or syndrome determines the differential diagnosis. The principle of parsimony in medicine is to explain the observed signs and symptoms on the basis of a single unifying diagnosis. By combining several findings that are nonspecific when present alone, a diagnosis can be arrived at. However, this can be difficult when all the characteristics of a disease have not developed at that point in time.

FEVER AND RASH

Patients with fever and rash require immediate attention. The need for cardiorespiratory support, specific anti-microbial therapy or for isolation precautions has to be ascertained. Patients with viral and bacterial illnesses allow droplet or airborne spread of the pathogen. Hence, health care workers should use standard precautions including avoidance of intimate contact with secretions.

Causes of fever and rash can be life-threatening or trivial, and the extensive differential diagnosis tests the clinical acumen of the most experienced clinician (**Tables 1 and 2**). A thorough history is crucial; details of recent travel, exposure to an animal or human source of infection, or specific ingestion might furnish an important clue to help discover the cause. The patient with fever may receive an antibiotic or nonsteroidal anti-inflammatory drug (NSAID) and subsequently develop a rash, or the rash may be a late appearing manifestation or a unique interaction between the microbe and the antibiotic. The specifics of the rash on physical examination are also frequently helpful. It is often necessary to treat these patients empirically before the results of cultures and other investigations are available; thus, it is helpful to reduce the differential diagnosis to a few major possibilities.

It is most convenient to categorise patients with fever and rash according to the type of rash. Although there is some overlap, most of the causes of fever with rash can be grouped according to the specifics of the eruption. A petechial eruption is generally the most threatening, as several rapidly fatal diseases are associated with a petechial rash.

Common causes of acute febrile illness include upper and lower respiratory tract infections, gastroenteritis, genitourinary infections, soft tissue infections, bacteraemia, malaria, typhoid, meningitis or viral exanthems in children.

Chronic febrile states could result from infections like tuberculosis, infective endocarditis, abscesses (abdominal, liver, prostatic, renal or perinephric), cholanigitis, pyelonephritis, bacteraemia, brucellosis and toxoplasmosis. Non-infectious causes like collagen vascular diseases—systemic lupus erythematosus (SLE), rheumatoid arthritis, Still's diseases, temporal arteritis, polyarteritis nodosa (PAN) and Wegener's granulomatosis. Inflammatory bowel disease, sarcoidosis, myxoma, pulmonary thromboembolism and drug fevers are other non-infective causes.

Fever with headache, neck stiffness, mental changes and confusion: It suggests a meningo-encephalitic process and the differential diagnosis should be accordingly considered.

Fever with conjunctival suffusion and haemorrhages: Possible differential diagnosis include leptospirosis, infective endocarditis, trichinosis.

Fever with eye pain and sinus involvement. It could be attributed to orbital cellulitis (*Streptococci*, *Staphylococci*, *Moraxella*, Pseudomonas, anaerobes), Mucormycosis, *Aspergillus*, *cavernous* sinus thrombosis, Wegener's granulomatosis and lymphoma.

Table 1: Fever and Petechial Rash

Infectious (specific treatment available)	Infectious (specific treatment not available)	Non-infectious
Meningococcaemia	Enteroviral	Thrombocytopaenia
Gonococcaemia	Rubella	Allergy
Endocarditis	Dengue	Henoch-Schönlein purpura
Purpura fulminans due to Group A *Streptococci*, *Streptococcus pneumoniae*, *Meningococci*	Atypical measles	Hypersensitivity vasculitis
	EBV0	Acute rheumatic fever, SLE, hyperglobulinaemia, amyloidosis, scurvy
Acinetobacter	Yellow fever	
Rickettsiosis		
Trichinosis		
CMV, HBV		

Table 2: Different Types of Rashes Based on Their Infective Potential

Maculopapular Rash

Infectious (specific treatment available)	Infectious (specific treatment not available)	Non-infectious
Meningococcaemia	Enteroviral infection	Drugs
Mycoplasma	HHV-6	Erythema multiforme
Chlamydia	Parvovirus B19 (fifth disease)	Erythema marginatum
Typhoid		Dermatomyositis
Secondary syphilis	Rubeola	SLE
Leptospirosis	Rubella	JRA
Scarlet fever	Adenovirus	Sweet's syndrome
Lyme disease	EBV	Kawasaki disease
Rickettsiosis	HIV (primary)	Serum sickness
Trichinosis		
Toxoplasmosis		

Contd...

Contd...

Vesico-bullous Rash

Infectious (specific treatment available)	Infectious (specific treatment not available)	Non-infectious
Staphylococcaemia	Enteroviral infection	Toxic epidermal necrolysis (TEN)
Gonococcaemia	Parvovirus B19	Plant dermatitis
Rickettsial pox	HIV	Eczema vaccinatum
Varicella-Zoster		Erythema multiforme bullosum
Herpes simplex virus		Pyoderma gangrenosum
Mycoplasma		Pustular psoriasis
Folliculitis		
Staphylococcal infection		
Pseudomonas		
Candida		
Vibrio vulnificus		

Erythematous Rash

Infectious (specific treatment available)	Infectious (specific treatment not available)	Non-infectious
Streptococcal infection	Enteroviral infection	TEN
Staphylococcal infection		Kawasaki disease
Ehrlichiosis		Eczema
S. viridans		Psoriasis pityriasis rubra
C. haemolyticum		Lymphoma
Kawasaki disease		Sézary syndrome vasodilation

Annular Erythema

Infectious (specific treatment available)
Erythema multiforme, mycoplasma, HSV
Erythema marginatum of rheumatic fever
Erythema chronicum migrans of lyme disease

Urticarial Rash

Infectious (specific treatment available)	Infectious (specific treatment not available)	Non-infectious
Mycoplasma	Adenovirus	Drugs
Lyme disease	Enteroviral	Serum sickness
Trichinosis	EBV*	Vasculitis
Strongyloidosis	Hepatitis B	Malignancy
Schistosomiasis	HIV	Idiopathic
Echinococcal cyst leakage	HSV**	

Nodular Rash

Infectious (specific treatment available)	Non-infectious
Erythema nodosum leprosum (ENL)	Weber Christian disease
Candida, cryptococci, histoplasma, Sporotrichosis	Sweet's syndrome
TB, Nocardia, melioidosis, *Staphylococci, Yersinia*	

** EBV = Epstein-Barr virus; **HSV = Herpes simplex virus.*

Fever with neck pain: Possible causes could be tuberculous lymph node abscess or spinal epidural abscess, septic jugular phlebitis, thyroiditis, temporal arteritis and Kikuchi disease.

Fever with throat pain, trismus, dysphonia, stridor: This symptom complex requires immediate attention and early institution of therapy. Aetiologies could be tetanus, Ludwig's angina, botulism, retro-pharyngeal/tonsillar/peritonsillar abscess, epiglottitis and diphtheria.

Fever with acute breathlessness and cough suggests a pneumonitic process.

Fever with chest pain, murmur, rub, plop indicates pericarditis, myocarditis, endocarditis, atrial myxoma, etc.

Fever with diarrhoea or dysentery: In many cases, a specific diagnosis is neither available nor necessary to guide treatment. Information obtained from history, stool examination and the severity of dehydration can be helpful for planning treatment.

Non-inflammatory diarrhoea: The causative organisms could be enterotoxigenic *E. Coli (ETEC)*, *Vibrio*, *Bacillus cereus*, *Staphylococci*, *Salmonella*, *Clostridium perfringens*, Rotavirus, Norwalk virus, *Giardia*, *Cryptosporidium*.

Diarrhoea peristing for more than 15 days and weight loss: It could be caused by *Giardia*, *Cryptosporidium*, bacterial overgrowth syndrome, etc.

Diarrhoea could also be a manifestation of systemic infection viz. malaria, legionella, listeria, measles, viral hepatitis, toxic shock syndrome, etc.

Fever with abdominal pain and dysentery: It could be caused by *Shigella*, *Salmonella*, enteroinvasive *E. Coli (EIEC)*, *C. difficile*, *Campylobacter*, *Yersinia*, *Tuberculosis (TB)*, *E. histolytica*, *Strongyloides*.

Bloody diarrhoea, especially if without fecal leucocytes, suggests enterohemorrhagic (Shiga toxin-producing) *E. coli* 0157 or amoebiasis (where leucocytes are destroyed by the parasite).

Persistent abdominal pain and fever or an appendicitis-like syndrome suggests *Yersinia enterocolitica*.

An outbreak involving many persons suggests: *S. aureus*, *B. cereus*, (incubation period <6 hours), *C. perfringens*, *Vibrio*, *Salmonella*, *Campylobacter*, *Shigella* or EIEC, ETEC infection. Rotavirus, Norwalk virus.

Fever with jaundice: It is commonly encountered in biliary sepsis, systemic sepsis, *Salmonella*, *Leptospira*, malaria, yellow fever, disseminated herpes simplex virus (HSV), cytomegalovirus (CMV), granulomatous hepatitis, haemolytic crisis in G6PD deficiency, cirrhosis with septicaemia, *Yersinia*, pasturella infections.

Fever with flank pain, urinary symptoms or urinary abnormalities: It can be witnessed in pyelonephritis, perinephric abscess, renal TB, prostatitis or systemic conditions like infective endocarditis and leptospirosis. Non-infective conditions like renal cell carcinoma can also present in this way.

Fever with joint involvement: It is commonly seen with rheumatic fever, septic arthritis, TB, syphilis, *Brucella*, LGV, Lyme, Whipple's disease, acute RA, SLE, JRA, haemarthrosis and acute gout.

Fever with lymphadenopathy: The various causes of fever with regional lymphadenopathy are tabulated (**Table 3**).

Table 3: Causes of Fever with Lymphadenopathy

Cervical
- Throat infection with adenovirus, enterovirus, *Streptococcus, C. diphtheriae*
- Tuberculosis (TB)
- Rubella, HSV, CMV*, EBV,
- Toxoplasmosis
- Kikuchi disease

Axillary, epitrochlear
- TB, Brucella, tularemia, CSD*
- EBV
- Filaria
- Hodgkin's disease

Mediastinal, hilar, paratracheal
- TB
- EBV, CMV*
- Histoplasmosis, cryptococcosis, coccidioidomycosis
- *Pneumocystis carinii (jiroveci)* pneumonia (PCP)
- Sarcoidosis, lymphoma

Abdominal
- TB
- Lymphoma, carcinoma

Inguinal
- Chancroid, LGV, syphilis, gonorrhoea, granuloma inguinale, HSV
- Filariasis
- TB, plague, tularemia, CSD*
- Toxoplasmosis

Generalised
- TB
- HIV, viral hepatitis
- Syphilis, LGV*
- Rickettsia
- Histoplasmosis
- Lymphoma, leukaemia

**LGV = Lymphagranulama venereum; *CSD = Cat-scratch disease; *CMV = Cytamegalovirus.*

Soft Tissue Infections

An array of terms have been used leading to confusion. These are based on the pattern of tissue involved, the pathological process and the etiologic microorganisms (**Table 4**).

Undifferentiated fever syndromes (where there are no localising features): It could be seen with malaria, sepsis, bacteraemia and endovascular infections.

Fulminant infectious disease syndromes: Aggressive and often empiric treatment is needed in infections due to *P. falciparum*, *Meningococci*, *Streptococci*. Delay contributes to fatality even in intra-abdominal abscess (specially splenic), miliary tuberculosis and disseminated fungal infection.

Pattern of fever: Some points to keep in mind are:

- Intermittent fever in abscess, miliary tuberculosis, lymphoma.
- Sustained fever in typhoid, typhus.
- Fever at regular intervals in non-falciparum malaria, cyclic neutropaenia.
- Periodic fever in lymphoma (Pel-Ebstein), rat-bite fever, cholangitis, UTI.
- Sweats, chills, weight-loss are not diagnostic of any particular disease.
- Relative bradycardia in typhoid, *Legionella*, psittacosis, *Leptospira*, *Brucella*, neoplasm, factitious.

Table 4: Categories of Soft Tissue Infections and Common Organisms Involved

Name	Tissues Involve	Organisation
Meleney's synergistic gangrene	Post-surgical, slowly expanding indolent ulceration that involves superficial fascia	*S. aureus* + microaerophilic *Streptococci*
Clostridial cellulitis	Gas in tissues, but fascia and muscle spared	*Cl. perfringens*
Non-clostridial anaerobic cellulitis	Usually in diabetics, foul odour, gas in tissues	*Cl. perfringens*
Necrotising fasciitis	Progressive destruction of fascia and fat, may spare the skin initially, pain, fever, toxicity	
	Type 1 post-surgical, DM, PVD, breach in continuity of mucosa or skin, e.g. Ludwig's, Fournier's	aerobic + anaerobic
	Type 2 younger patient, after trauma, skin is portal of entry, no other co-morbid condition	Group A *Streptococci*
Myonecrosis	Bronze, black skin, haemorrhagic bullae, gas in tissues, haemolysis, severe systemic toxicity	Clostridia
	Post-traumatic, post surgical, colonic carcinoma, leukaemia, chemotherapy, radiotherapy	

FEVER IN THE IMMUNOCOMPROMISED HOST

Infections are difficult to evaluate as the usual symptoms, signs, and radiologic, serologic and haematologic alterations may not develop. The law of parsimony does not hold good and co-infections, and multiple, sequential infections occur. Non-infectious mimics can also occur. However, the current diagnostic tests are not rapid, sensitive or specific enough to identify or exclude a microbial cause. On the other hand, prompt treatment is needed.

Fever in the Elderly

The signs of infection are more general than focal and so need careful evaluation.

CONCLUSION

The syndromic approach to infectious diseases is helpful. Integrating the findings about the nature of the infection, the setting in which it has developed and the host characteristics can help to predict the likely organism and its susceptibility to anti-microbial agents. Those entities that have a specific treatment and will have grave consequences if left untreated, have to be given a greater emphasis and should not be missed.

17.4 Anti-Microbial Therapy—An Overview

Jagriti Bhatia, Dharamvir Singh Arya

INTRODUCTION

The anti-microbial agents kill or attenuate the growth of micro organisms. These include anti-bacterials, anti-fungals, anti-virals, anti-protozoal, and anthelmintic agents that may have been obtained either from a natural, semi-synthetic or a synthetic source. The modern day anti-microbial agents have made a giant leap forward from the infancy period of 1930s and 40s when sulphonamide and penicillin were the only 'miracle' anti-bacterials available. This medical achievement is shadowed in the present circumstances of 'irrational' use of anti-microbials resulting in development of antibiotic resistance and a dark possibility of non-availability of antibiotics to treat infections with multi-drug resistant organisms.

PHARMACOLOGY OF ANTI-MICROBIALS

Pharmacokinetics

The processes of absorption, distribution, metabolism, and excretion ultimately determine the drug concentration achieved in the blood and tissues after the drug administration. The knowledge of these pharmacokinetic parameters helps to ascertain the dosing as well as selection of a given anti-microbial for a particular infection. The selected drug has to be able to reach the site of infection to be effective, e.g. levofloxacin achieves high concentration in urine and is thus very effective in urinary tract infections.

The absorption of a drug and its movement across membranes is determined by its lipid solubility, size and the charge. In addition, the membrane transporters, like the P-glycoprotein, can selectively efflux some drugs out of the cell and reduce the drug absorption. The anti-microbials that are either poorly absorbed or are excreted in bile and are eliminated through gut may disturb the normal gastrointestinal flora, e.g. ampicillin causes diarrhoea more frequently than amoxicillin because it is incompletely absorbed.

The anti-microbial drug concentration in plasma and extracellular fluid (ECF) tends to be similar provided the capillaries allow free diffusion of the drug. The surface area to volume ratio of the ECF also determines the drug concentration achieved in the ECF. Thus, peritoneal fluid rapidly equilibrates with the plasma levels of the drug in contrast to a fluid-filled cyst. The capillaries supplying the central nervous system (CNS), posterior chamber of the eye and prostate are non-fenestrated. Thus, concentration of anti-bacterials in these specialised tissues cannot be predicted from the knowledge of plasma concentrations. However, when there is inflammation, as in the case of meningitis, the tight junctions in the cerebral capillaries open and allow marked penetration of even the polar drugs.

The access of anti-microbials is also physically difficult in avascular sites and in the case of cardiac vegetations as there is collection of fibrin. The penetration is also poor in the case of bacterial and fungal 'biofilm' on prosthetic devices like the artificial heart valves, artificial hip, long dwelling intravascular catheters.

The intracellular penetration of drug depends on lipid solubility. Lipid-soluble drugs like rifampicin, quinolones, and macrolides achieve high intracellular concentrations. The pH of the tissue also affects drug diffusion, e.g. prostatic tissue has a lower pH than plasma. Thus, weakly basic drugs like macrolides and quinolones accumulate in the prostatic fluid. Since, these drugs ionise at the acidic pH they fail to back diffuse into the prostatic capillaries.

It is important to have knowledge of drug kinetics in children, elderly, pregnancy, renal failure, and hepatic failure. These physiological and pathological states can profoundly affect selection of anti-microbials. For instance, aminoglycosides are eliminated by the kidneys and hence their dose should be reduced in renal failure.

Pharmacodynamics

It refers to the quantitative relationship between anti-microbial drug concentrations in serum and tissues, *in vitro* susceptibility and microbial response at the site of infection. Many factors affect the relationship between drug concentration and anti-microbial effect *in vitro*. The *in vitro* testing of bacterial susceptibility to various anti-microbials and determination of the minimal inhibitory concentration (MIC) provides good information regarding anti-microbial drug selection. MIC is a measure of the anti-microbial concentration required to inhibit the growth of the bacteria.

Anti-bacterials have relatively little bactericidal effect on bacteria in the stationary phase of growth as compared to the exponential phase of growth. The anti-microbial may be bactericidal, i.e. reduces bacterial numbers like aminoglycosides, cephalsporins, rifampin, or bacteristatic, i.e. inhibit bacterial growth like tetracyclines, erythromycin, chloramphenicol. The bactericidal agents act best on rapidly dividing bacteria. The bactericidal agents are generally preferred in an immunocompromised patient and in the treatment of serious infections like meningitis and endocarditis.

The bactericidal anti-microbials may exhibit either concentration-dependent killing (e.g. aminoglycosides and quinolones) or time-dependent killing (β-lactams and vancomycin). In the former, the rate and the extent of anti-bacterial activity is proportional to the anti-microbial concentration, whereas in the latter it is determined by the length of time the drug concentration was above the MIC. The drugs that have concentration-dependent killing also have post antibiotic effect (PAE). The PAE is the length of time for which the bacterial growth is inhibited after concentration of the anti-microbial falls below the MIC. There are several mechanisms by which the drug may exhibit PAE. Since, aminoglycosides have a

long PAE, once daily dosing produces good bactericidal effect. Also, this regimen is associated with less side-effects.

Any change in the milieu in which microbes grow will influence their growth rate and this will influence the action of anti-microbials. Important factors influencing the growth of microbes include temperature, pH, pO_2 and the type and concentration of nutrients.

In addition to their effect on microbial growths, pH and pO_2 can influence anti-microbials directly, e.g. macrolides are ineffective below the pH of 7 as in an abscess cavity. Oxygen is critical to the bactericidal effect of aminoglycosides because they enter bacteria via an oxygen-dependent transport system.

Anti-Microbial Therapy

The anti-microbials are used prophylactically either to prevent infection or to suppress the early infection from progressing further. Anti-microbials are generally administered to prevent wound infections following surgery, dental procedures, prosthetic implants and in immunocompromised patients to prevent emergence of opportunistic infections, e.g. in HIV-AIDS and neutropaenic patients or on immunosuppressive drugs. Post-exposure prophylaxis is used to prevent development of disease in a healthy person who has been exposed to specific microorganisms. The example of latter is use of rifampin to prevent meningococcal meningitis, anti-retrovirals for HIV exposure and oseltamivir for influenza.

The anti-microbial therapy is sometimes begun empirically without isolating the infecting organism. In this case, the appropriate specimens should be obtained for laboratory diagnosis of the pathogen prior to start of the anti-microbial therapy. The initial anti-microbial therapy is directed at the most likely pathogen involved and is later modified in accordance with the patient's clinical condition and the laboratory report. The selection of anti-microbials should also be guided by the various factors like the age, pregnancy, immune status, hepatic and renal function, malnutrition source of infection (e.g. hospital or community) and site of infection in the host (e.g. meningitis, endocarditis, urinary tract infection).

It is preferable to use single and specific anti-microbial agent with narrow spectrum of activity as it diminishes the alteration of normal flora and thus limits the overgrowth of resistant nosocomial organisms (e.g. *Candida albicans*, *Enterococci*, *Clostridium difficile*). However, combination anti-microbial therapy has to be used in certain conditions to prevent emergence of resistant mutants or to enhance the microbial killing, e.g. in tuberculosis, leprosy, malaria, pseudomonas infection, AIDS.

Anti-Microbial Drug Resistance

Microbial resistance is of two types: intrinsic and acquired. Intrinsic resistance means that the bacterial species is inherently resistant to the effect of the anti-bacterial drug, e.g. *Streptococci* and anaerobes, both lack the respiratory quinones required for energy-dependent uptake of aminoglycosides. Acquired resistance means that bacterial species has acquired a mechanism of resistance since the introduction of antibacterial drugs into clinical medicine, e.g. growing proportion of gonococci that produce penicillinase.

The production of drug inactivating enzymes (e.g. production of beta-lactamase by *Gonococci*) is a common mechanism of resistance in the case of aminoglycosides, β-lactams, macrolides and chloramphenicol. Another mechanism is alteration in the target site of the drug, e.g. resistance to quinolones. Alternatively, the organism can develop mechanisms to prevent access of drug to the target site, e.g. *Pseudomonas* has become resistant to aminoglycosides, β-lactams and quinolones because of reduced permeability of their outer membranes.

The acquisition of resistance can occur either by mutation or by transfer of genetic information between bacteria on plasmids. Plasmids can transfer complex mechanism of resistance including the active efflux pumps that render some bacteria resistant to tetracyclines.

The anti-microbial drugs are grouped based on their pharmacological structure but for a clinician it is worthwhile to remember them based on their clinical use as given in **Table 1**.

Table 1: Anti-Microbials Used Against Common Infections

Anti-bacterial and anti-tubercular drugs
Anti-leprotic drugs
Anti-fungal drugs
Anti-viral drugs
Anti-malarial drugs
Anti-amoebic and other anti-protozoal drugs
Anthelmintic drugs

The details of these anti-microbial, anti-protozoal, anti-fungal and anti-viral drugs are discussed in their respective chapters. Here the description is given of the commonly or routinely used antibiotics.

BETA-LACTAM ANTIBIOTICS

The antibiotics included in this group are penicillins, cephalosporins, carbapenems, and monobactams. These share a common structure as well as mechanism of action. These agents act by inhibiting the cell wall formation in the bacteria which predisposes the bacteria to lysis. The bacteria resistant to these drugs may produce β-lactamase enzyme to destroy the β-lactam antibiotics. The 'extended spectrum β-lactamases' (ESBLs) can target penicillins, cephalosporins and also carbapenems. These enzymes are usually produced by the plasmids.

Penicillins are combined with β-lactamase inhibitors like clavulanic acid, sulbactam, and tazobactam to enhance their activity by preventing their hydrolysis.

Penicillins

Penicillins are amongst the most effective and least toxic anti-microbials available. They are excreted by the kidney and hence dose should be adjusted in renal failure.

Acid-labile penicillins

They are hydrolysed by gastric acid and hence are ineffective orally. These agents are active against most Gram-positive and Gram-negative aerobic cocci that do not produce β-lactamase and against many anaerobes including anaerobic cocci, *Clostridium*, *Spirochaetes*, and *Actinomyces*.

Aqueous penicillin G (benzyl penicillin or crystalline penicillin) is given IM or IV in divided doses. Procaine penicillin G is given IM in the dose of 500,000 to 1,000,000 U/day. Benzathine penicillin G, administered IM provides detectable blood levels for 4 weeks. Its use is limited to prophylaxis of rheumatic fever and treatment of syphilis.

Hypersensitivity is the most common reaction producing fever, eosinophilia, serum sickness or anaphylaxis. Hence skin testing should be performed before penicillin is administered.

Extended spectrum penicillins

They provide coverage against many aerobic gram-negative bacilli and many anaerobes.

Ampicillin is active against many of the *Enterobacteriaceae* and against *H. influenzae* and *Neisseria* spp. It is hydrolysed by β-lactamase and is therefore inactive against most strains of *Staphylococci, Pseudomonas, Enterobacter* and *Klebsiella*.

Usual dose—0.5 g PO q 6 h for mild infections 1 to 2 g IM or IV q 4 to 6 h for moderate or severe infection.

Amoxicillin has identical spectrum as that of ampicillin. Gastrointestinal absorption is better than ampicillin, hence is associated with less diarrhoea than with ampicillin, but it is also less effective in the treatment of shigellosis.

Carboxy- and ureido-penicillins

These are also known as anti-pseudomonal penicillins. Both of these are susceptible to destruction by β-lactamases. Carboxypenicillins (carbenicillin, ticarcillin) are indicated for treatment of infection due to *Pseudomonas aeruginosa* and indole positive Proteus spp. However, not all isolates may be sensitive to carbenicillins. Carbenicillin indanyl sodium is an acid stable, orally active indanyl ester of carbenicillin. It is rapidly converted to carbenicillin by ester hydrolysis and achieves good concentration in urine. Thus, it is indicated in urinary tract infection with sensitive bacteria. The ureido-penicillins (azlocillin, mezlocillin, piperacillin) have superior activity against *Pseudomonas aeruginosa* and are also useful in the treatment of infections with *Klebsiella*. These agents are combined with a β-lactamase inhibitor and are indicated in serious gram-negative infections especially in neutropaenic and immunocompromised patients and in burns. The concurrent use of an aminoglycoside like gentamicin makes the combination synergistic.

The adverse effects include phlebitis and hypokalaemia. Prolongation of bleeding time due to inhibition of platelet aggregation has been reported with all anti-pseudomonal penicillins but is less severe with ureido-penicillins. Carbenicillin is inactive orally and is available as a sodium salt. Thus, the risk of volume overload should be remembered when using high doses of carbenicillin.

Beta-lactamase resistant or semisynthetic penicillins

They are produced by modification of 6-aminopenicillanic acid nucleus and are indicated for the treatment of infections caused by beta-lactamase producing *Staphylococci*. The drugs in this group are oxacillin, dicloxacillin and nafcillin. *Staphylococci* resistant to any one semisynthetic penicillin are also resistant to other semisynthetic penicillins and cephalosporins.

Cephalosporins

The cephalosporins are grouped into four generations. The Gram-positive activity decreases and Gram-negative activity of cephalosporin increases from 1st to 4th generation. These agents are not effective in enterococcal infections. Most of the cephalosporins are excreted by kidney; hence dose adjustment is required in renal failure.

Hypersensitivity reactions can occur and some penicillin allergic patients are also allergic to cephalosporins. Thrombophlebitis, sterile abscess (after IM injection), diarrhoea, coagulopathy (seen with cefamandole, cefoperazone, cefotetan and moxalactam) and disulfiram-like reaction (cefoperazone) are some other adverse effects associated with cephalosporins.

First-generation cephalosporins

The cephalosporins in this group are cephalothin, cephapirin, cefazolin, cefadroxil, cephalexin and cephaloridine.

The anti-bacterial spectrum includes beta-lactamase producing Gram-positive cocci (*Staphylococci, Pneumococci, Streptococci*) and Gram-negative bacilli (*E. coli, Proteus*) that cause most community-acquired infections including *Klebsiella* spp. However, *Enterobacter* spp. and *P. aeruginosa* are typically resistant as are methicillin-resistant *Staphylococci*. None of these achieve sufficient concentration in CSF. The dose for cephalexin is 250 to 500 mg PO q 6 h and for cefadroxil is 1 to 2 g/day PO in 1 to 2 doses.

These are well absorbed orally and are used primarily in treatment of community-acquired respiratory tract and urinary tract infections. However, they are not used for serious infections. Cefazolin is used in the dose of 0.5 to 2 g IM or IV q 8 h.

Second-generation cephalosporins

The drugs in this group are cefamandole, cefoxitin, cefuroxime, cefaclor.

These agents offer wider coverage against gram-negative bacilli than the first-generation cephalosporins. Their main use would appear to be in the Gram-negative infections, especially those caused by beta-lactamase producing organisms including *H. influenzae*. However, they are less active than first-generation cephalosporins against the Gram-positive cocci and are inactive against anaerobes and *Pseudomonas aeruginosa*.

Dose of cefuroxime is 0.75 to 1.5 g IV q 8 h, up to 3 g q 8 h in meningitis. Cefuroxime enters CSF in sufficient concentration. It is also used in surgical prophylaxis. The dose of cefuroxime axetil (well absorbed by mouth) is 250 to 500 mg PO q 12 h. It is effective for treatment of otitis media, urinary tract infections (UTI), respiratory tract infection, but equally effective and less expensive drugs are available for these conditions.

Cefaclor—dose is 250 to 500 mg PO q 8 h. Spectrum of activity is similar to cephalexin but with enhanced activity against *H. influenzae* including beta-lactamase producing strains.

Third-generation cephalosporins

These are cefotaxime, ceftizoxime, ceftriaxone, ceftazidime, cefoperazone, moxalactam, ceftibuten. In general these agents are more active against most Gram-negative bacilli and less active against Gram-positive cocci especially *S. aureus* than the first- and second-generation agents. The anti-pseudomonal

activity is variable but reaches its peak in ceftazidime and cefoperazone. None are effective against *Enterococci*. Most of them are capable of inducing β-lactamase production in Gram-negative bacilli. These drugs are the drugs of choice for Gram-negative bacillary meningitis. They may also be useful for treatment of other Gram-negative bacillary infections but widespread use may lead to the emergence of resistant flora and superinfection with *Enterococci*. These agents should not be used for surgical prophylaxis because of increased cost and decreased activity against Gram-positive organisms. The dosages are: cefotaxime 1 to 2 g IV q 6 to 12 h, ceftizoxime 0.5 to 2 g IV q 8 to 12 h and ceftriaxone 1 to 2 g IV q 12 to 24 h.

Ceftriaxone does not require dose adjustment in mild to moderate renal failure because of dual hepatic and renal excretion. Cefotaxime and Ceftizoxime dose should be reduced in renal failure.

Ceftazidime (1 to 2 g IV q 8 to 12 h) has the best activity against *P. aeruginosa* amongst all the cephalosporins. It is less active against Gram-positive organisms compared to other third-generation cephalosporins. Its activity against other Gram-negative rods is equivalent to Cefotaxime.

Cefoperazone (1 to 2 g IV q 8 to 12 h) is less active than other third-generation agents against most Gram-negative pathogens. Cefoperazone does not penetrate the CSF as well as other third generation cephalosporins and is not recommended for treatment of meningitis. Dose adjustment is not required in renal failure because of hepatic excretion. Dose reduction may be required in hepatic insufficiency.

Ceftibuten (400 to 800 mg PO) is recently introduced oral third-generation cephalosporin. The anti-bacterial spectrum is limited to *Streptococci, H. influenzae* and most *Enterobacteriaceae*.

Cefixime is the oral third-generation cephalosporin (200 mg bd), is active against *Enterobacteriaceae, Salmonella, Shigella, H. influenzae, S. pyogenes, S. pneumoniae, Moraxella, E. coli, Proteus* and *N. gonorrhoeae*, and is resistant to many beta-lactamases. It does not act on *S. aureus* and *Pseudomonas*.

Fourth-generation cephalosporins

Cefepime and cefpirome are resistant to hydrolysis by several β-lactamases and are more active against the Gram-negative bacteria.

Several cephalosporins, e.g. ceftibiprole with activity against MRSA are in development. These agents are able to inhibit pbp2a in *Staphylococci*.

Aztreonam

Aztreonam is a monobactam, a monocyclic beta-lactam antibiotic with activity exclusively against gram-negative bacilli, including most strains of *P. aeruginosa* and *Serratia. It is administered intravenously and eliminated by kidneys by tubular secretion.* Aztreonam may be administered to patients allergic to penicillin or cephalosporin (with the exception of ceftazidime) as it lacks cross-sensitivity with other β-lactam drugs.

Carbapenem

It includes imipenem, meropenem, doripenem and ertapenem. These drugs have a β-lactam structure but are neither penicillins nor cephalosporins. They also have a low susceptibility to β-lactamases. Imipenem is rapidly degraded by renal dehydropeptidase I. Thus, it is administered with cilastatin which inhibits this enzyme and increases the duration of action of imipenem. It is a broad spectrum antibiotic with activity against most Gram-positive cocci (except *Enterococcus faecium* and methicillin-resistant *Staphylococci*), Gram-negative bacilli (excluding *P. maltophilia* and some *P. cepacia*) and anaerobes. Some strains of *P. aeruginosa* have become resistant to imipenem. The indications for its use are infections with highly resistant organisms and as empirical therapy for serious mixed aerobic/anaerobic infections when the potential toxicity of alternative anti-microbial combination is unacceptable. In addition to hypersensitivity reactions and gastrointestinal upset like nausea and vomiting, imipenem in high doses may also cause seizures, especially in those patients who have a concomitant renal insufficiency.

The anti-microbial spectrum of meropenem is similar to that of imipenem. Since, meropenem is not inactivated by renal dehydropeptidase, it does not require to be combined with cilastatin. It is also less likely to cause seizures than imipenem. Ertapenem has a long plasma half-life and thus once-daily dosing is possible. It is also less active against *Pseudomonas* and *Acinetobacter* species.

MACROLIDES

These are bacteriostatic agents which act by inhibition of ribosomal protein synthesis. This group includes erythromycin, azithromycin, clarithromycin, roxithromycin and spiramycin.

Their anti-bacterial spectrum includes *Moraxella, H. influenzae, Legionella, Mycoplasma, Campylobacter* and *Chlamydia*. Erythromycin is also active against some Gram-positive cocci. Clarithromycin and azithromycin are effective in Mycobacterium avium complex (MAC) infection. The adverse effects are mainly due to gastrointestinal irritation. This is less with clarithromycin and azithromycin as compared to erythromycin. There is risk of hepatitis with erythromycin estolate, especially in adults. Drug interactions like rise in the plasma levels of digoxin, theophylline, anti-coagulants, and cisapride is seen with erythromycin.

The indication for use are respiratory tract infections, skin and soft tissue infections, sexually transmitted diseases and *H. pylori* infection. Azithromycin and clarithromycin are also useful in MAC infection.

TETRACYCLINES

These are bacteriostatic agents and act by inhibiting ribosomal protein synthesis. They are well absorbed orally. Doxycycline is well absorbed orally. It is preferred in renal insufficiency because it is excreted by liver. The clinical uses of tetracyclines are treatment of non-gonococcal urethritis, rocky-mountain spotted fever, chronic bronchitis, and acne. They may be used in infections caused by rickettsiae, *Chlamydia, Nocardia, Actinomyces, Plasmodium falciparum, Campylobacter jejuni*, and *H. pylori*. Resistance is widespread among *Staphylococci* and Gram-negative bacilli. Demeclocycline is used to treat syndrome of inappropriate antidiuretic hormone secretion (SIADH). The gastrointestinal upset and photosensitivity are common adverse effects. The use of outdated tetracyclines damage kidney and cause Fanconi's syndrome. They damage the growing bones and teeth and hence are contraindicated in pregnant, lactating mothers and children.

CHLORAMPHENICOL

It is a bacteriostatic agent and acts by reversibly inhibiting ribosomal protein synthesis.

It is active against wide variety of Gram-negative and Gram-positive organisms including anaerobes. It can be used orally or intravenously. Intramuscular absorption is not reliable. It penetrates into all body compartments including CSF. It is metabolised in liver, hence dose adjustment is required in hepatic insufficiency.

Its use is associated with idiosyncratic aplastic anaemia, dose-related reversible bone marrow suppression, gray baby syndrome in infants and peripheral neuritis.

Chloramphenicol was earlier the drug of choice for typhoid fever. It may be used for the treatment of meningococcal meningitis and *H. influenzae* infection and anaerobic infections, e.g. empyema, brain abscess and rickettsial infection.

FLUOROQUINOLONES

These inhibit DNA gyrase in a wide variety of bacteria and are well absorbed orally.

Older fluoroquinolones (norfloxacin, ciprofloxacin, ofloxacin) have a spectrum of activity that includes Gram-negative rods and some atypical bacteria. The newer fluoroquinolones (levofloxacin, sparfloxacin, gatifloxacin, moxifloxacin, gemifloxacin) have improved activity against *Staphylococci* and *Streptococci*. However, gatifloxacin has recently been withdrawn from the market due to toxicity. *In vitro* activity against anaerobes has been demonstrated with clinafloxacin and gatifloxacin. Ofloxacin, ciprofloxacin, levofloxacin and sparfloxacin are also effective against *Mycobacterium tuberculosis*. The older fluoroquinolones also have activity against atypical mycobacteria. Among the fluoroquinolones, ciprofloxacin has the best anti-pseudomonal activity. In the process of developing a fluoroquinolone with enhanced Gram-positive activity the newer quinolones have lost some activity against *P. aeruginosa*.

The adverse reactions seen with fluoroquinolones are hypotension, tachycardia, QTc interval prolongation, headache, dizziness, sleep disturbances, seizures, confusion, rash, photosensitivity, urticaria, transient elevation of transaminases, cholestatic jaundice, arthropathy, tendinitis, tendon rupture, azotaemia, crystalluria, haematuria, interstitial nephritis, and renal failure.

The newer fluoroquinolones with their expanded Gram-positive activity and excellent activity against the atypical pneumonia pathogens have quickly become the drugs of choice for community-acquired pneumonia.

Dose

Ciprofloxacin	–	250 to 750 mg q 12 h
Ofloxacin	–	200 to 400 mg q 12 h
Moxifloxacin	–	400 mg od
Norfloxacin	–	400 to 800 mg q 12 h
Gemifloxacin	–	320 mg od
Sparfloxacin	–	400 mg PO on day one and 200 mg PO q 24 h on subsequent days
Levofloxacin	–	500 mg orally q 24 h

VANCOMYCIN

It is a glycopeptide which acts by inhibition of cell wall synthesis.

It is bactericidal against only Gram-positive organisms. It is used to treat infections caused by methicillin-resistant *Staphylococci*, as a substitute to penicillins and cephalosporins when patient is allergic to either of them, and enterococcal endocarditis. Oral vancomycin is used to treat *C. difficile*-induced colitis.

Vancomycin may give rise to red-man syndrome characterised by tingling, flushing of face, neck and upper torso, sometimes with hypertension, deafness, and skin rash. *Nephrotoxicity* is not seen with currently available preparations (chromatographically purified).

Dose

500 mg to 1 gm IV q 12 h given in a drip form not faster than 1 gm/hr.

TEICOPLANIN

Teicoplanin is a glycopeptide with activity similar to vancomycin. The half-life is longer allowing once a day dosing. The combination of teicoplanin and rifampin is antagonistic. Teicoplanin resistance is well described in *Enterococci*. *S. aureus* isolates, resistant to teicoplanin have been described and they can be cross resistant to vancomycin.

Indications are similar to vancomycin and dose is 200 to 400 mg IV q 24 h.

Oritavancin, dalbavancin, telavancin are newer glycopeptides having activity against vancomycin-resistant *Enterococci* and being rapidly bactericidal. These are highly protein bound and have very long elimination half-life.

LIPOPEPTIDES

Daptomycin is a cyclic lipopeptide. It binds to the cell membrane and then forms complexes in a calcium-dependent manner which ultimately causes disruption of the cell membrane and cell lysis.

It is used in the treatment of complicated skin and skin structure infections involving *Staphylococci*, *Enterococci* and some *Streptococci*. It can be used in combination when infection with a gram-negative or anaerobic organism is suspected.

The adverse effect of daptomycin is myositis and myopathy leading to elevation of CPK level.

Dose

A dose of 4 mg/kg over a period of 30 mins. By IV infusion in 0.9% sodium chloride solution once a day for 7 to 14 days. If creatinine clearance is less than 30 ml/min, then give once in 48 hrs.

STREPTOGRAMINS

Quinupristin/dalfopristin is a combination of two naturally occurring compounds isolated from *Streptomyces pristinaespiralis*. They act by inhibiting protein synthesis. The anti-bacterial spectrum of activity is similar to vancomycin. It may cause venous irritation, arthralgias, myalgias and conjugated hyperbilirubinaemia. It is used for the treatment of vancomycin-resistant *E. faecium* and treatment of glycopeptide intermediate-resistant *S. aureus* (GISA). Dose (quinupristin/dalfopristin)

(30 to 70 mix) 7.5 mg/kg 8 h by IV route. No dose adjustment required for renal or hepatic insufficiency.

OXAZOLIDINONES

Linezolid, eperezolid are synthetic anti-microbials and act by inhibiting protein synthesis. Anti-microbial spectrum is similar to vancomycin. These compounds also have activity against gram-negative anaerobes and mycobacteria. Adverse reactions are skin rash and increase in transaminases.

Dose

The recommended dose is 600 mg twice daily. Indications are similar to quinupristin/dalfopristin in treatment of vancomycin-resistant *Enterococci* (VRE) and GISA.

AMINOGLYCOSIDES

They bind to the bacterial ribosomes and inhibit protein synthesis. Gentamicin, tobramycin, amikacin, netilmicin, kanamycin and streptomycin are the currently used aminoglycosides.

The aminoglycosides are active against Gram-negative organisms including *E. coli, Klebsiella, Aerobacter, Salmonella, Shigella, Vibrio, M. tuberculosis,* atypical mycobacteria, *Neisseria* and *Brucella*. They are also effective against *Staphylococci*.

Nephrotoxicity is usually reversible but acute renal failure with azotaemia may occur. Ototoxicity occurs with prolonged use (more than 14 days) of aminoglycosides and with concurrent use of other ototoxic agent. Neuromuscular blockade is a rare complication.

They are used in urinary tract infections, along with penicillin in treatment of streptococcal endocarditis, bacteraemia in immunocompromised patients and other serious infections caused by gram-negative bacilli (especially *Pseudomonas*). Streptomycin is used in plague, tularaemia, brucellosis, and tuberculosis.

Dose

Gentamicin and tobramycin (3 to 5 mg/kg/day), netilmicin (4 to 6 mg/kg/day) and amikacin and kanamycin (15 mg/kg/day).

It is advisable to give aminoglycosides as single dose because the efficacy is related to peak-levels and side-effects are also less with single dose.

SULPHONAMIDES AND TRIMETHOPRIM

The fixed dose combination of trimethoprim and sulphamethoxazole in the ratio of 1:5 is bactericidal. The use of these two drugs causes sequential block in the folinic acid synthesis by the bacteria. In *in vitro* studies it is highly effective against *S. aureus, Streptococci, C. diphtheriae, E. coli, Salmonella, Shigella, H. influenzae, K. pneumoniae, Proteus* and *V. cholerae*. It is somewhat less effective against *N. gonorrhoeae, N. meningitidis, C. welchii* and *B. pertusis*. It is useful in urinary tract infection due to *E. coli* and *Proteus, Pneumocystis carinii* infection and prophylaxis in HIV patients, acute and chronic bronchitis, chancroid, gonorrhoea, shigellosis, typhoid fever. The adverse reactions include glossitis, stomatitis, anaemia, leucopaenia, thrombocytopaenia and megaloblastic marrow changes.

METRONIDAZOLE

Metronidazole is active against most Gram-negative anaerobic bacteria including *B. fragilis* and many *Clostridium* spp. Many anaerobic *Streptococci* however are resistant to this agent. Metronidazole is also active against several protozoa (*Trichomonas vaginalis, Giardia lamblia, Entamoeba histolytica* and *Dracunculus medinensis*).

The side-effects with metronidazole are nausea, dry mouth, metallic taste, disulfiram-like effect, peripheral neuropathy, encephalopathy, ataxia, seizures and teratogenicity.

It is useful in anaerobic infections like pelvic inflammatory disease, lung abscess, intra-abdominal infection, pseudomembranous colitis, amoebiasis, and giardiasis.

Dose

400 to 800 mg q 8 h.

CLINDAMYCIN

It is semisynthetic derivative of lincomycin. It is bacteriostatic at low concentration and bactericidal at high concentration. It is well absorbed orally. It probably acts by interfering with protein synthesis.

It inhibits growth of many gram-positive organisms especially *Staphylococci* (including those producing penicillinase), pneumococci, certain *Streptococci* and *C. diphtheriae, B. anthracis* is moderately sensitive.

The adverse reactions observed are nausea, vomiting, abdominal pain, diarrhoea. Rarely may it cause pseudomembranous colitis and monilial superinfection.

It is useful in acute and chronic osteomyelitis, anaerobic infections like empyema, brain abscess and in staphylococcal, pneumococcal and streptococcal infections not responding to penicillin or erythromycin.

Dose

150 to 450 mg four times a day.

ANTI-MYCOBACTERIAL DRUGS

These include the first line anti-tubercular agents like isoniazid, rifampin, pyrazinamide, ethambutol, streptomycin; the second line agents like thiacetazone, para-aminosalicylic acid, ethionamide, cycloserine, kanamycin, amikacin, capreomycin, ciprofloxacin, ofloxacin, moxifloxacin. The drugs like clarithromycin, azithromycin, and rifabutin are more active against the nontubercular mycobacteria. The treatment of tuberculosis is complicated by the development of multi-drug resistant (MDR) and extremely drug resistant (XDR) strains.

ANTI-LEPROTIC DRUGS

These include dapsone, clofazimine, rifampin, ethionamide, ofloxacin, minocycline, and clarithromycin. The multi-drug therapy is preferred for all cases of leprosy.

ANTI-VIRAL AGENTS

These include anti-herpes agents like the idoxuridine, acyclovir, valacyclovir, famciclovir, foscarnet, trifluridine, vidarabine; anti-influenza agents like the amantadine, rimantadine, oseltamivir; and others like lamivudine for hepatitis B.

The anti-retroviral agents include the nucleoside reverse transcriptase inhibitors (NRTIs) like zidovudine, didanosine, lamivudine, stavudine; non-nucleoside reverse transcriptase inhibitors (NNRTIs) like nevirapine, efavirenz; protease

inhibitors like saquinavir, indinavir, ritonavir, nelfinavir; integrase inhibitors like raltegravir; and fusion inhibitor like enfuvirtide.

ANTI-FUNGALS

The systemic mycoses are usually treated with amphotericin B, flucytosine, ketoconazole, fluconazole, itraconazole, voriconazole and echinocandins like the caspofungin, amidulafungin, and micafungin.The superficial fungal infections may be treated with oral drugs like griseofulvin and terbinafine and also topically with nystatin, miconazole, clotrimazole, and topical terbinafine. The systemic fungal infections may be difficult to treat especially in the immunocompromised or neutropaenic patients.

CONCLUSIONS

In conclusion one has to remember to use antibiotics with a definite indication. Use antibiotics in adequate dosage and for adequate length of time so that it eradicates infection as well as precludes the occurrence of drug resistance. It is important to remember the excretion of drugs so that the dose is properly adjusted based on the clinical condition like age, i.e. childhood and old age, but associated disorders like renal impairment, cardiovascular disorders, and also always consider the possibility of drug allergy so that the anti-microbials serve purpose effectively well and to the benefit of the patient simultaneously avoiding drug resistance.

17.5 Infections in the Immunocompromised Host

Ghan Shyam Pangtey, Anupam Prakash

INTRODUCTION

The dysfunction of immune system in the body can occur due to infections, use of specific drugs and certain disease states like malignancy, diabetes, etc. Such situations are being increasingly encountered because of the spread of the HIV/AIDS epidemic, success with organ transplants and also with immunosuppressive and cancer chemotherapy medications. Infections *per se* contribute to significant morbidity and mortality; however, infections in the immunocompromised states can prove to be devastating. Three decades back, the commonest infecting organisms were bacteria (76.1%) followed by serious opportunistic viral and fungal infections (10.7%) and oppurtunistic pneumonias were the leading cause of death. Despite advent of efficacious antibiotics and improvement in health care standards, this spectrum has only changed towards a slightly greater preponderance of viral and fungal infections. Indian data is however, lacking.

This chapter discusses the basic considerations of infections in the immunocompromised patients (ICP) only as far as they differ from that in immunocompetent individuals. ICP are more susceptible to infection and disease, have a greater tendency to develop persistent infection and multiple infections, and may exhibit unusual clinical manifestations.

AETIOPATHOGENESIS

The failure of immune system may be witnessed in malnutrition (<75% of ideal body weight), alcoholism, extremes of ages, uncontrolled diabetes, uraemia, HIV infection, leukaemias/lymphomas, congenital/primary immunodeficiency disorders, hypogammaglobulinaemia, malignancies, and use of corticosteroids, monoclonal antibodies, immunosuppressive or cancer chemotherapeutic agents, post-splenectomy and post-irradiation states. Viral infections like Epstein-Barr virus, measles and varicella can also be associated with transient immunosuppression. Corticosteroids exert multiple effects on both immune response and the inflammatory response by decreasing concentration and activity of lymphocytes, monocytes and basophils in vascular circulation and redistribution to lymphoid compartment. Absolute neutrophil count, however, increases as these cells become restricted to vascular compartment and are unable to migrate to areas of inflammation. Corticosteroids also inhibit interleukins, especially IL-1 and IL-2 (IL-1 stimulates production of prostaglandins and IL-2 promotes further T-cell proliferation). Cyclosporin and tacrolimus are calcineurin inhibitors which are commonly used as immunosuppressives and interfere with cytokine transcription in response to T-cell receptor signalling. Cyclosporine decreases IL-2, while tacrolimus decreases IL-1, IL-2, interferon-gamma, IL-2 receptors and T-cell proliferation. RNA and DNA synthesis inhibitors like azathioprine and mycophenolate mofetil block proliferation of T and B cells during clonal expansion and cause leucopaenia.

The common infections associated with specific defects in immunity are given in **Table 1**. Candidiasis remains the commonest fungal infection in ICPs but *Pneumocystis jirovecii*, aspergillosis, zygomycosis, cryptococcosis, histoplasmosis, and coccidioidomycosis increasingly pose a major problem. Less common fungal pathogens include—*Sporothrix schenckii*, *Penicillium marneffei*, *Paracoccidioides brasiliensis*, *Fusarium* spp., *Trichosporon beigelii*, *Pseudallescheria boydii*.

Table 1: Diseases Resulting from Immune Deficiency or Component Defect of the Immune System

Component (deficiency/defect)	Disease	Pathogens
Phagocytes (Abnormal NADPH Oxidase Degranulation defect)	Chronic granulomatous disease	*Staphylococcus aureus*, *Pseudomonas* spp., *Escherichia coli*, *Aspergillus* spp.
Complement (C1, C2, C4 deficiency C5-9)	Deficiency of classical pathway	Encapsulated bacteria: *Streptococcus pneumoniae* Severe Neisserial infections, meningococcal meningitis
Cytokines (IL-12 deficiency)	Mutations in *B1* chain *or* IL receptors	*Salmonella* spp. *Mycobacteria* spp. Recurrent opportunistic infection with bacteria and viruses (i.e. atypical mycobacteria)
MHC I/II (Bare lymphocyte syndrome)	Defective CMI	Opportunistic infections (e.g. *Candida, Cryptococcus neoformans*)
T cells (DiGeorge syndrome, AIDS, hyper IgM syndrome)	Defective CMI: Thymic failure, CD4 deficiency	Intracellular pathogens (e.g. Mycobacteria) *Pneumocystis carinii* Invasive fungal infections (e.g. *Candida albicans*), Pyogenic bacterial infection, *Cryptosporidium parvum*
B cells (X linked agammaglo-bulinaemia)	B cell dysfunction or low antibody production	*Haemophilus influenzae* *Streptococcus pneumoniae*
T/B cells (Adenosine deaminase deficiency)	Complete dysfunction of humoral and cellular immune respone	Recurrent infections with opportunistic pathogens (e.g. *Pneumocystis jirovecii*, Mycobacteria, Herpes, pyogenic bacteria
Splenectomy patients	Loss of phagocytic activity	*Haemophilus influenzae*, *Streptococcus pneumoniae*, *Neisseria meningitidis*
Desferrioxamine therapy	Acts as sider-ophore (act like growth hormone)	*Rhizopus oryzae*

ICP infected with *Mycobacterium tuberculosis* also have increased risk of tuberculosis reactivation. These patients are also at increased risk of serious influenza-associated complications.

CLINICAL FEATURES

Fever along with system-specific signs and symptoms may or may not be observed in ICP and the signs of inflammation or infection may be absent. The infectious complications are usually insidious in onset as the inflammatory response is muted. Besides, there are greater chances that the patients develop bacteraemia, fungaemia and multi-organ dysfunction rather than system-specific signs or symptoms. This is attributable to the inability of the body's defences to localise the infection. Hypothermia, tachypnoea, tachycardia, depressed sensorium, hypotension, and evidence of vital organ dysfunction may be present. Interestingly, clinical presentations caused by the same aetiological agent can vary depending upon the underlying immunosuppressive state, viz. CMV causes retinitis in HIV and pneumonitis in transplant recipients while BK virus causes nephropathy in renal transplantation and haemorrhagic cystitis in haematopoietic stem cell transplants.

INVESTIGATIONS

A careful clinical history followed by thorough examination is the key to identification of the cause of infection. It is important to identify the portal of entry as these are the common sites of defence breach leading to infection and gives a clue to the aetiological agent. Therefore, cultures from all possible sites are important (blood, urine, sputum, stool, catheter sites, catheter tips, nail scrapings, skin lesions), since empirical antibiotics need to be started without any delay, as infections in an ICP can be rapidly fatal. Bacterial, fungal and anaerobic cultures may be warranted. Complete blood counts are essential to see for the leucocyte response to infections and to identify or monitor neutropaenic states. Blood biochemistry and oxygen saturation help identify vital organ dysfunctions. Staining of aspiration or biopsy of skin lesions may be helpful to identify meningococcal/gonococcal or fungal aetiologies. Sputum examination or tracheal aspirate/bronchoalveolar lavage fluid examination may be helpful in suspected cases of pneumonia. Imaging studies and echocardiography need to be individualised as per situation. Cerebrospinal fluid (CSF) examination is helpful in suspected meningitis. Specific antigen detection kits or polymerase chain reaction (PCR) may be utilised for CMV, *Aspergillus*, herpes and mycobacterial diseases. In the ICP, although there is a greater risk of tuberculosis reactivation, tuberculin skin testing is falsely negative and newer assays (T-cell interferon-gamma release and QuantiFERON-TB Gold) can improve diagnostic yield.

The infectious causes of fever can be confirmed microbiologically in only 30% to 50% patients. The various pathogenic organisms commonly infecting the neutropenic cancer patients are enumerated in **Table 2**. Even though the organism may not be isolated in up to two-third of patients but most of them respond to empirical antibiotic therapy suggesting the cause to be infectious only.

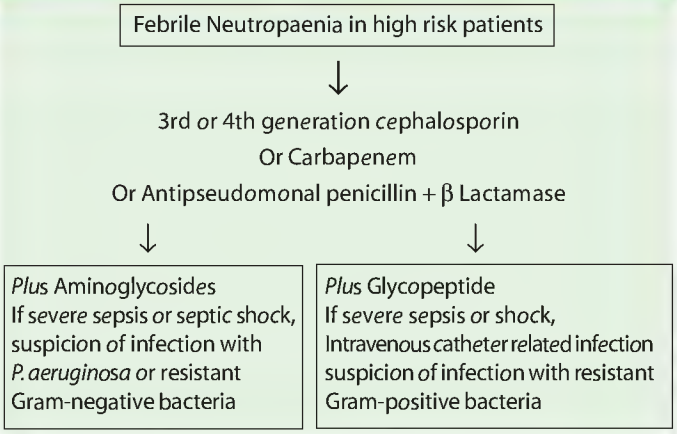
MANAGEMENT

Empirical antibiotic and anti-fungal therapy needs to be initiated at the earliest in the ICP depending upon the likely pathogen, pending culture reports. In neutropaenic patients (post-chemotherapy), broad-spectrum antibiotics covering both gram-positive and gram-negative organisms need to be administered while anti-fungal agent is required if the immunosuppression is prolonged (**Table 3**). Granulocyte-colony-stimulating factor may be needed for persistent neutropaenia. A high index of suspicion for fungal and anaerobic infections is required especially in patients with sepsis, uncontrolled diabetes, on cancer chemotherapy, having prolonged intravenous catheters or receiving broad spectrum antibiotics. Management of specific infections and underlying immunocompromised states has been dealt in respective chapters.

Table 2: Common Infections in Neutropaenic Cancer Patients

Gram-positive aerobic: Coagulase negative *Staphylococci*, *Streptococcus viridans*, *Staphylococcus aureus*, other *Streptococci*, *Enterococcus* spp., *Corynebacterium* spp., *Bacillus* spp., *Listeria monocytogenes*

Gram-negative aerobic: *Escherichia coli*, *Klebsiella* spp. *Pseudomonas* spp. Other Enterobacteriaceae (*Proteus*, *Enterobacter*, *Serratia*, *Citrobacter* spp.) *Legionella*



Anaerobic: *Bacteroides* spp., *Clostridium* spp., *Fusobacterium* spp., *Propionibacterium* spp.

Fungal: *Candida* spp., *Aspergillus* spp., Others (*Fusarium*, *Pseudallescheria boydii*, *Scedosporium*, *Rhizopus*, *Mucor*)

Viral: Herpes simplex virus, varicella-zoster virus, respiratory viruses (influenzae, RSV)

Parasitic infection: *Strongyloides stercoralis*, *Leishmania*, etc.

Table 3: Empirical Antibiotic Therapy for High Risk Febrile Neutropaenia Patients

PREVENTION

Apart from the routine measures of sticking to aseptic precautions, meticulous care of indwelling devices and intravascular catheters, personal hygiene practices; primary or secondary prophylactic antibiotic use should be employed. Primary prophylaxis is indicated in patients at high risk of infection, e.g. in severely neutropaenic patients (absolute neutrophil count <500/mm^3). Secondary prophylaxis is considered following the treatment of an infectious episode during the subsequent phase of treatment, e.g. use of co-trimoxazole in HIV patients with CD4 counts <250/mm^3. Vaccination in the ICP is also recommended, viz. vaccination for hepatitis B in uraemia and influenza vaccination in HIV-infected, solid-organ and haematopoietic stem-cell transplant recipients, haemodialysis patients; and is discussed in appropriate sections of the book.

17.6 Hospital Acquired Infections/ Nosocomial Infections

A Shobhana

DEFINITION

The term nosocomial infection has been replaced by 'hospital acquired infection' (HAI) and has been expanded to 'health care associated infections' (HCAI), which includes infections acquired in institutions other than acute-care facilities (e.g. nursing homes) during hospitalisation but not identified until after discharge and through outpatient care such as day surgery, dialysis, or those on home parenteral therapy. It is defined as a disease condition resulting from the presence of an infectious agent or its toxin which was not present or incubating at the time of admission to hospital. Usually the infection becomes evident 48 hours or more after admission.

The common sites of infection are respiratory tract, blood stream, urinary tract, and surgical site.

The Burden

The worldwide nosocomial infection rate ranges from 6% to 15%. In Asia it ranges from 4% to 48% of which 45% to 65% are lower respiratory tract infections. Highest prevalence occurs in intensive care units (ICUs), in acute surgical and orthopaedic wards. In a surveillance conducted in 12 ICUs in India, the rate of HCAI was 4.9% and 9.6 per 1000 ICU days. The commonest organisms were *Pseudomonas* spp, *Acinetobacter* spp, *S. aureus*, methicillin-resistant *S. aureus* (MRSA), *Enterobacteriaceae*, *Candida* spp, *Enterococci and Stenotrophomonas.*

Common Sources of Infection

Causative organisms may be present on the skin, nose, mouth, gastrointestinal tract, or vagina of the patient. They may be acquired from external sources like health care personnel, visitors, hospital equipments, medical devices, or the health care environment. Most infections are of bacterial aetiology, though fungal and viral infections may occur in immunosuppressed patients and those already on broad-spectrum antibiotics.

Modes of Transmission

The mode of transmission usually is either cross-infection via unclean hands of hospital personnel, auto-inoculation (e.g. aspiration), droplet infection or through contaminated materials (e.g. contaminated intravenous fluids).

HOSPITAL ACQUIRED PNEUMONIA (HAP)

Definitions

Pneumonia occurring 48 hours or more after admission and which was not incubating at the time of admission is HAP. Intubation and mechanical ventilation (MV) is associated with 20-fold increase in the risk of developing pneumonia. Ventilator associated pneumonia (VAP) is pneumonia in a person who has a device to assist respiration through an endotracheal tube or tracheostomy tube for a period of at least 48 hours before the onset of infection. VAP represents 80% of episodes of HAP. Mortality in VAP due to *Pseudomonas* and *Staphylococcus* is very high. Health care associated pneumonia (HCAP) is defined as pneumonia in any patient with at least one of the following risk factors:

1. Hospitalisation in an acute care hospital for ≥2 days within the last 90 days.
2. Residence in a nursing home or long-term care facility within the last 90 days.
3. Received outpatient intravenous antibiotics or chemotherapy or home wound care in last 30 days.
4. Attended a hospital clinic or haemodialysis clinic in the last 30 days.
5. Has a family member with known multi-drug resistant pathogens.

Causative Organisms

HCAP may be early onset, that is within 4 days of hospitalisation or late onset, beyond 4 days. The organisms causing early infections are *Moraxella catarrhalis, Haemophilus influenzae* and *S. pneumoniae;* whereas Gram-negative bacteria or *S. aureus* are associated with the late HCAP. Viruses may cause early and late infections while yeasts, fungi, *Legionella and Pneumocystis carinii* are typically late pathogens. Late onset pathogens often are multi-drug resistant (MDR). Over 80% of nosocomial pneumonias are caused by Gram-negative bacteria. Now *Acinetobacter* is the organism which is of great concern.

In India, 38% of HAP are caused by *Acinetobacter, Pseudomonas* spp (20%), *Klebsiella pneumoniae* (23%) and MRSA (5%). Forty-eight percent of VAP and 2.3% HAP are caused by MDR organisms (**Table 1**), while 7.3% are polymicrobial. In most ICUs, MRSA although present is not as big a problem as in the western world. (**Table 2**) outlines the various risk factors for HAP and VAP

Table 1: Risk Factors for Multidrug Resistant (MDR) Infections

Regular dialysis
Immunosuppression
Heart disease
Renal failure
Hepatic failure
High incidence of antibiotic resistance in the community
Presence of a family member with MDR organism

Table 2: Risk Factors for HAP and VAP

Males
Elderly age
Pre-existing diseases—pulmonary, diabetes, dialysis
Immunosuppression
Presence of intubation
Enteral feeding
Mechanical ventilation
Supine position
APACHE II score >15
Previous use of antibiotic for >2 weeks
Multi-organ failure
Reintubation due to failed weaning
Use of paralytics, sedative
Length of ICU stay

Diagnosis of HCAP or VAP is made in the presence of progressive radiographic infiltrates or pleural effusion and at least 2 of the 4 clinical signs of infection—fever >38°C, purulent secretions, leucocytosis or leucopaenia, decreasing oxygenation.

Management

1. Identification of pulmonary infection is the first step.
2. Appropriate cultures are required. Semi-quantitative or quantitative cultures of lower respiratory tract should be performed if HAP or VAP is suspected. Endotracheal aspirates, bronchoalveolar lavage (BAL), protected specimen brush (PSB) are required to isolate organisms. A quantitative endotracheal culture or non-bronchoscopic BAL is more relevant in the Indian set-up. Recent start or change of antibiotics in the preceding 24 to 72 hours may give rise to false negative reports.
3. A broad-spectrum antibiotic should be started at the earliest in all clinically unstable patients regardless of culture reports as delay is associated with increased mortality. Choice of empirical antibiotic is guided by the local data on risk factors, local prevalence of organisms, and resistance patterns. Broad spectrum antibiotics covering Gram-negative and Gram-positive organisms are usually started. A re-evaluation is done at 48 to 72 hours. Once culture-sensitivity reports are available de-escalation may be done.

A clinical pulmonary infection score (CPIS), based on temperature, total leucocyte count, chest radiographic findings, respiratory secretions, endotracheal aspirate cultures and oxygenation status has been developed to predict presence of VAP. If CPIS is less than, 6 both at baseline and at 72 hours, most clinicians would safely allow stopping antibiotics.

BLOOD STREAM INFECTION (BSI)

Epidemiology

Primary blood stream infections are identified by growth of pathogenic bacteria or fungi (that are not related to another site of infection) from one or more blood cultures. Skin contaminants like coagulase negative *Staphylococcus* or *Diphtheroids* are considered causative of BSI, if more than one blood culture is positive along with presence of systemic signs and symptoms of infection like fever, chills, and hypotension. An alternative focus of infection should be absent.

Catheter associated blood stream infections (CABSI) is said to be present if fever occurs during and up to 48 hours after removal of central venous catheter or arterial catheter but diagnosis does not require growth of same organism from the blood and the catheter.

Catheter related blood stream infection (CRBSI)

Diagnosis of CRBSI requires growth of same organism quantitative or semiquantitative from the blood as well as the catheter.

CRBSI is seen in 5% patients with indwelling vascular uncoated catheter and almost 2 to 5 infections per 1000 catheter days. All lines arterial or central venous are risky. The incidence of CRBSI increases with the duration of catheterisation, number of ports, and number of manipulations. Mortality may be almost 8% in *S. aureus* bacteraemia. Fever, hypotension, purulence at exit site, blocked lumen, all may herald CRBSI. BSI due to short peripheral intravenous catheters is very low but phlebitis is very common.

In a report from north India, incidence of CRBSI was 19.4%, organisms causing nosocomial BSIs were *Pseudomonas* (33.3% episodes), and *Acinetobacter, Escherichia coli, Candida spp, coagulase-negative Staphylococci* and *S. aureus*.

Diagnosis

BSI are identified by the growth of pathogenic bacteria or fungi (that are not related to another site of infection) from one or more blood cultures drawn from peripheral veins. Atleast two sets of blood cultures must be drawn in each instance. Three sets may be needed to establish continuous bacteraemia.

Different methods of diagnosing CRBSI have been described. Some require removal of the catheter (qualitative, semi-quantitative and quantitative cultures) while some can be done while retaining the catheter in place (qualitative or quantitative blood cultures from catheter). The best method is to obtain paired blood cultures, one from the central catheter and another from the peripheral venous blood and the differential time to culture positivity is noted. If central line sample shows positivity 2 hours earlier than the peripheral culture, it is a CRBSI.

Management

Catheter should be removed if CRBSI is suspected, if there is purulence at the insertion site or the patient is haemodynamically unstable, has organ dysfunction, fungal sepsis or MDR organisms and once the diagnosis is confirmed. Routine replacement over a guidewire is not recommended. Empirical antibiotics should be started in seriously ill patients according to the local microbiological flora and this may require a change according to the culture sensitivity reports. Duration of antibiotics is tailored according to the causative organism and by the presence or absence of any complication. Fungal sepsis should be considered in patients at risk like in those with prior antibiotic exposure, parenteral nutrition, abdominal surgeries, and immunocompromised host.

SURGICAL SITE INFECTION (SSI)

Epidemiology

In India, incidence of post-operative infections in hospitals varies from 10% to 25%. Wound infection affects nearly 20% of post-operative cases **Table 3**. These occur due to close contact of medical and paramedical staff with the patient at various stages of treatment. In a north Indian hospital, incidence of wound infection in post-operative elective surgeries ranged from 11% to 70% due to *S. aureus* and 30% due to *E. coli*.

Table 3: Factors Determining Nosocomial Wound Infection

Factors related to surgical procedures: Pre-operative shaving-1 day before operation, type of surgery, anaesthesia, wound drains, tissue damage, blood loss
Host factors: Age, immunity, diabetes, nutrition, obesity, antibiotic exposures

Diagnosis and Management

Signs of wound infection are local redness, swelling, wound discharge, fever and in severe cases shock and organ dysfunction. Appropriate cultures from wound, drain and blood should be sent and empirical antibiotics started. Prevention of SSI includes treating infections harboured by the host before surgery, good antiseptic precautions, and antibiotic prophylaxis within 1 hour of surgery, hair clipping rather

removal and optimum post-operative care including good glycaemic control.

URINARY TRACT INFECTIONS (UTI)

UTIs in hospital are mostly due to urological manipulation or the presence of indwelling catheters. Risk for UTI is high in females, diabetics, the elderly, in the peripartum period and is proportional to the duration of catheterisation.

Catheter-Associated Urinary Tract Infections (CAUTI)

A diagnosis of CAUTIs is confirmed when a patient meets one of the two criteria. The first is when a patient with a urinary catheter has one or more of the following symptoms with no other recognised cause: fever (temperature >38°C), urgency or suprapubic tenderness with a culture-positive urine showing more than 10^5 colony-forming units per ml, with no more than two microorganisms isolated. The second criterion is when a patient with a urinary catheter has at least two of the following criteria with no other recognised cause: positive dipstick analysis for leucocyte esterase or nitrate, pyuria (>10 leucocytes per mL of urine), organisms seen on gram-stain or physician diagnosis of urinary tract infection. In a report from north India, 24% of nosocomial infections were due to UTIs and all had indwelling catheters. Commonest isolated pathogen is *E. coli*, others include *Enterococci*, *Pseudomonas*, *Klebsiella*, *Enterobacter*, *S. epidermidis*, *S. aureus*, and *Serratia*.

To prevent UTIs, indwelling catheters are to be used only when necessary, sterile techniques are to be used during catheterisation, closed system of drainage is to be used, samples must be taken aseptically and irrigation is to be avoided. Asymptomatic bacteriuria in catheterised patients is not to be treated.

TRACHEOBRONCHITIS

It is a very common problem, characterised by at least 2 of the 4, namely fever, cough, new or increased sputum production, rhonchi, or wheezing and at least one of the following: positive culture obtained by deep tracheal aspirate or bronchoscopy or positive antigen on respiratory secretions but without radiographic evidence of pneumonia.

SINUSITIS

This entity is often overlooked in febrile patients especially when nasogastric or nasotracheal tubes are present. Apart from imaging, aspiration of affected sinus is necessary to diagnose the causative organism.

CLOSTRIDIUM DIFFICILE ASSOCIATED DIARRHOEA (CDAD)

In hospitalised patients *C. difficile* is one of the most important causes of diarrhoea. Illness ranges from mild watery stool to life-threatening colitis and toxic megacolon.

The identifiable risk factors for this include previous antibiotic treatment, chemotherapeutics, immunosuppressives, surgery, exposure to gastric acid suppressants, low immunity and advanced age. Metronidazole and oral vancomycin are the drugs of choice.

PREVENTION AND CONTROL OF NOSOCOMIAL INFECTIONS

A hospital infection control committee comprising of a senior microbiologist, intensivist, physician and surgeon is essential to prevent and control HAI. A central sterile supply department (CSSD) should be involved in dealing with sterile equipment and stores. Periodic surveillance of infections is important. Microorganisms, sensitivity patterns, antibiotic use, outcomes, all must be audited. Antibiotic policy should be formulated and revised regularly for effective therapy.

STRATEGIES TO BE ADOPTED TO COMBAT HCAI

1. Environmental factors:
   - Adequate bed-space ratio
   - Identifying infected zones
   - Proper disposal of biomedical wastes in protocol containers
   - Ensure food hygiene
   - Routine checking of potable, dialysis water
   - Ventilation strategies for operating theatres, isolation areas for infected or immunocompromised cases
2. Specific standard precautions for all patients in health care settings as recommended by Centers for Disease Control and Prevention:
   - Hand hygiene with alcohol based hand rubs is to be performed after examining each patient, before and after every procedure or handling patient's body fluids. In suspected *C. difficile* infection hands are to be washed with soap and water.
   - Respiratory and cough etiquettes are to be followed.
   - Mask, eye protection or face shield is to be worn for procedures which might involve splashes.
   - N95 or higher masks for diseases transmitted by respiratory aerosols like tuberculosis, some viruses.
   - Gloves are to be used where recommended. Masks and gowns are to be worn while handling patients infected with *Acinetobacter*, MRSA or MDR pathogens.
   - Appropriate handling of soiled linen and equipment and disinfection of environmental surfaces.
   - Used needles are not to be bent, broken by hand or recapped.
   - For patient resuscitation, a mouthpiece, resuscitation bag are needed to prevent contact with oral secretions.
   - For injected medications, single dose vials are preferable to multiple dose vials.

CONCLUSION

With the better availability of technology, India also faces the problems of HAI with its attendant emergence of MDR pathogens. As a consequence of these the outcome in the form of patient survival and cost of therapy is worrying. Strict infection control policies and judicious use of antibiotic will be the cornerstone of combating these problems.

17.7 Prevention of Health Care Associated Infections

BB Rewari, Usha K Baveja

INTRODUCTION

The health care personnel/professionals/workers (HCP/W) are at constant risk of acquiring infections from patients, specimens, contaminated equipment/articles and the hospital environment during routine activities. Three elements are required for transmission of infectious agents in a health care setting. These include the reservoir/source of infectious microorganism; a susceptible host with a portal of entry optimal for the agent and mode of transmission advantageous to the agent. The reservoirs of infectious agents include patients, health care workers, and visitors carrying the agent/s. The susceptibility of the host is determined by a complex interaction between the host factors on one hand and the virulence of infectious agent, and timely administration of care and appropriate prophylaxis on the other hand. The portal of entry of infectious agent has to be ideal, only then the infectious agent will be able to enter the host, colonise, establish itself and cause infection.

MODES OF TRANSMISSION OF INFECTIOUS AGENTS

Infectious agents in healthcare settings can be transmitted by various routes including contact (direct and indirect), droplet, and airborne and other less common routes.

Contact Transmission

There are two types of contact transmission: direct and indirect. *Direct contact transmission* is the most common and important mode of transmission of healthcare associated infections. Such transmission involves direct body-to-body contact with the transfer of microorganisms during routine care of patients. Examples are: percutaneous exposure due to needle sticks or cuts from other sharp instruments, etc. Muco-cutaneous exposure occurs through contact of the mucous membrane of the eyes, nose or mouth, or contact of the skin with the blood of infected patients.

Indirect contact transmission is the transmission of pathogens by contact with blood/body fluid contaminated objects such as dressings, needles, surfaces and instruments.

Droplet Transmission

Droplets are primarily generated by patients during coughing, sneezing and talking, and during the performance of certain procedures such as suctioning and bronchoscopy. Here, the pathogen (bacteria, viruses, fungi and parasites) in the droplet travel directly from mucosal surface of patient to the mucosal surface of HCW. The area of defined risk for such transmission is approximately ≤3 feet around the patient based on epidemiological and simulated studies.

Airborne Transmission

Aerosolisation means the formation of aerosols and droplets when blood or another body fluid is mechanically disturbed. Small particles (<5 µm) can remain suspended in air and can be dispersed widely by air currents. *Mycobacterium tuberculosis* is an example of a typical microorganism transmitted by this airborne route. Many viral infections like severe acute respiratory syndrome (SARS), avian influenza, H1N1 influenza are also transmitted through this route in addition to the direct contact route.

Oral-Faecal Transmission

Enteric pathogens spread in various ways, including through the ingestion of contaminated food; through direct person-to-person contact; and through contact with infectious waste, usually faeces.

Other Sources of Infections

Transmission of infection from other sources like contaminated water, contaminated fluids, fomites, etc., can also occur. In addition, the vector borne infection can also be transmitted in a healthcare facility like anywhere else through different vectors.

TRANSMISSIBLE INFECTIONS

HCW are at occupational risk for a number of infections that include air-borne infections such as tuberculosis, varicella, measles, influenza; blood-borne infections such as HIV, hepatitis B virus, hepatitis C virus, Ebola, Lhasa viruses; faeco-oral transmission such as *Salmonella*, hepatitis A virus, and through direct contact (herpes simplex virus, *Sarcoptes scabiei*).

RISK OF OCCUPATIONALLY ACQUIRED INFECTIONS IN HCWs

Rate of infection following needle stick/percutaneous exposure/cuts from other sharps with blood or body fluids and other potentially infectious materials (OPIM):

- HIV – 0.3%
- HBV – 6% to 30%
- HCV – 2% to 9%

Factors affecting transmission of blood borne viruses:

- Amount of blood in the exposure;
- Amount of virus in patient's blood;
- Duration of contact;
- Stage of disease (e.g. HIV-infection stage) of the patient;
- Type of exposure (abrasion, penetration, injection);
- Whether post-exposure prophylaxis (PEP) taken in time (within 2 hrs) or not; and
- In case of HBV whether the HCW is immunised or not and whether the source material is positive for HBsAg/HBe antigen.

FACTORS DETERMINING THE RATE OF TRANSMISSION OF INFECTIONS TO HCWs

Blood Borne Viruses

- Frequency of occupational exposure (contact with blood or body fluids, accidental needle stick/sharp instrument injuries).

- Occupational area in the hospital: Such as gynaecology, obstetrics departments, haemodialysis unit, pathology/microbiology, surgery, surgical intensive care, emergency room, blood bank, clinical laboratory, intravenous teams, dentistry; oral surgery, etc.
- Working with 'at risk' populations [injecting drug users (IDUs), multiply transfused, commercial sex workers (CSWs), dialysis patients].
- Practice of standard work precautions.
- HBV immunisation status.
- Source of infectivity (HBeAg-positive, HIV-positive, HCV positive).

Respiratory emerging pathogens have a higher transmission potential compared to those pathogens transmitted through faeco-oral route.

PREVENTION OF HEALTH CARE ASSOCIATED INFECTIONS IN HCWs

HCWs need to protect themselves from highly transmissible airborne/droplet infections including emerging viral respiratory infections and tuberculosis; blood borne viral and bacterial infections acquired through accidental mucocutaneous exposure; food and water borne infections; infections acquired from the environment and vector borne diseases in the health care setting.

Immunisation of HCWs

Centers for Disease Control (CDC) strongly recommends that all the HCWs must be immunised against vaccine preventable diseases as per the National Immunisation Schedules of the countries. Briefly, these include HBV, MMR, BCG (TB), varicella, influenza, DPT, polio and enteric fever. Vaccines for diseases like HAV, meningococcal, pneumococcal disease outbreaks and so many emerging infections like H1N1, etc. are given under defined special circumstances, e.g. outbreak of a disease which may adversely affect HCWs providing care (high morbidity and mortality). In certain situations hyperimmune gamma globulins are administered to provide instant protection as in cases of tetanus, diphtheria, pneumococcal disease and following needle stick injury in a non-vaccinated HCW with HBV-positive blood.

Prevention of Air Borne Infections

Engineering controls

To minimise exposure to air borne biological agents, health care facilities should use isolation rooms, negative pressure ventilation, air filtration and disinfection.

The routine practices and droplet/contact precautions required to prevent transmission of airborne/droplet infections like wearing mask (1/N95 respirator as the case warrants), eye and face protection, hand hygiene, respiratory hygiene, proper cleaning and disinfection of equipment need to be followed.

Hand hygiene

All persons entering the facility should practice good hand hygiene; alcohol-based hand rub should be available at the entrances and exits of the facility, residential units and at point-of-care in the resident's room.

Respiratory hygiene (respiratory cough etiquette)

Patients should be taught how to perform respiratory hygiene practices (coughing into sleeve, using tissues, wearing a mask).

Contact precautions

HCW should wear gloves when entering the room of a patient suspected to have H1N1 or similar infection. Gowns should be worn as per routine practices. HCW should use alcohol-based hand rubs or soap and water after removing gown and gloves, and after leaving the patient's room.

Droplet precautions/respiratory protection

HCW should wear a mask1 (droplet precautions) or N95 respirator (respiratory protection) when within 2 metres of a case with H1N1. The choice between a mask1 and N95 respirator should be based on the following:

A mask1 should be worn: If within 2 metres of a patient. An N95 respirator should be worn: If conducting an aerosol-generating medical procedure. HCW should also wear eye or face protection (i.e. goggles, safety glasses, or face shield).

Cleaning and disinfection of equipment

Equipment and environmental surfaces should be cleaned and disinfected daily.

Prevention of Blood Borne Infections

Risk reduction by prevention of exposure to infected blood/OPIM remains the mainstay to prevent occupational exposure and subsequent infection. All HCWs must follow standard work precautions at all the times while providing healthcare services; follow the correct protocols for sterilisation and disinfection; safe disposal of waste; educate themselves about post-exposure management and prophylaxis and take immunisation against HBV, etc. All the patients and all specimens should be considered potentially infectious and blood and body fluid precautions must be practiced at all times while giving care to patients.

Standard work precautions include:

- Hand washing;
- Use of personal protective equipment (barrier precautions) as indicated. Barrier precautions include use of latex or vinyl gloves, gown/apron, protective eyewear or mask and protective foot cover;
- Safe handling of sharps;
- Careful handling of hollow bore needle to prevent deep injuries;
- No recapping, bending of the needles. Dispose needles immediately. Do not leave used needles on trolley or bed. Use safe autodestruct-retract needles;
- Never pass used sharps from one person to another directly, place the sharp on the trolley to be picked up by the surgeon;
- Use forceps instead of fingers for guiding sutures; and
- Follow correct protocols of biomedical waste management/disposal and sharps disposal (plastic sharps container with 1% fresh bleach).

However, the success of standard work precautions is limited.

Management of Occupational Exposure to HIV

Most exposures do not result in infection. Every exposure is assessed (mild, moderate, severe) taking into account factors as given below and a prudent decision on PEP is made.

- Amount of blood in the exposure;
- Amount of virus in patient's blood;
- Duration of contact;
- Stage of disease (HIV-infection stage) of the patient; and
- Type of exposure (abrasion, penetration, injection).

The need for HIV PEP has to be evaluated based on types of exposure and status of source material as described in **Table 1**.

Determination of HIV, HBV and HCV status of source material; evaluation of source

- If the HIV/HBV status of the source patient is known, and confirmed negative for HIV and HBV, there is no need for prophylaxis for HIV and/or HBV.
- If the status of the patient is unknown, and neither the patient nor his/her blood is available for testing, then the choice of whether to use PEP and what regimen will depend on the severity of the wound, and how much is known about the individual's (source patient's) risk history.
- If the status of the patient is unknown, and the patient is available to be counselled and gives consent for testing, this should be done.
- If the patient is known to be HIV positive, and evaluation of risk is in order, the two key factors to consider are whether the patient is anti-retroviral (ARV) drug naïve, or whether s/he has been exposed to ARV medications; and whether the patient is likely to have a high viral load—as determined by testing if available, or by clinical signs and symptoms.
- In the case of a high risk exposure from a source patient who has been exposed to or is taking ARV medications, consult an expert to choose PEP regimen taking into consideration the possibility of drug resistance.

A decision to administer PEP for HIV and prophylaxis against HBV is taken after ascertaining the above facts and appropriate prophylaxis is given.

Management of exposure

The situation is treated as an emergency.

Immediate steps after exposure:

- Do not panic, allow site to bleed under running tap water, do not squeeze the area;
- Do not use bleach, alcohol, betadine, or iodine on the cut/needle stick, etc., which may be caustic and may cause inflammation;
- Wash cuts with plenty of soap and running tap water;
- Flush splashes into nose, mouth, skin with water. Irrigate eyes with clean water or saline;
- Report the incident to the designated officer in-charge (EMO);
- Counselling and medical management;
- Administer PEP as required (depending upon the infection status of source blood) and
- Collect 3 to 5 ml blood specimen from HCW immediately and test for HIV, HBV and HCV to ensure that the HCW is not already infected.

Take first dose of PEP within 2 hours if status of blood/body fluid is known to be positive or unknown. The various regimens for PEP and drugs to be used are given in **Table 2**.

HIV, HBV and HCV testing of the exposed HCW

The blood is collected at zero hour and tested for the above markers. This is done to know the pre-exposure status of the HCP as far as these infections are concerned. If the HCP is already positive for HIV, then PEP is not recommended. In such a case the HCP should access the ART services like any other HIV infected individual. In case the HCW is positive for HBV and negative for HIV, then PEP should be given after evaluation of the severity of exposure. The guidelines for HBV prophylaxis are given in **Table 3**.

Irrespective of whether the HCW decides to take PEP or not, the testing for HIV has to be undertaken at zero hour, 6 weeks, 12 weeks, and 6 months after exposure to ensure that HIV transmission has been prevented.

In case the source blood is found to be positive for HBV and HCW is found to be negative for the same, appropriate prophylaxis for HBV should be administered.

Table 1: Evaluation of Need for PEP Based on Exposure and Status of Source

Exposure	Status of Source Material			HIV Status Negative
	HIV+ and low risk	HIV+ and high risk	HIV status unknown	
Mucous membrane/non-intact skin; small volume (drops)	Consider 2-drug PEP	2-drug PEP	Consider 2-drug PEP	No PEP is required if the source blood is confirmed HIV and HBV negative
Mucous membrane/non-intact skin; large volume (major blood splash)	2-drug PEP	3-drug PEP	Consider 2-drug PEP	
Percutaneous exposure: not severe solid needle, superficial	2-drug PEP	3-drug PEP	Consider 2-drug PEP	
Percutaneous exposure: severe large bore hollow needle, deep injury, visible blood in device, needle in patient artery/vein/blood injected	3-drug PEP	3-drug PEP	2-drug PEP Consider	

Table 2: PEP Regimen (Basic and Advanced)

Medication	Dosage of drugs for PEP	
	Basic regimen (2-drug)	**Advanced Regimen (3-drug regimen)**
Zidovudine (AZT) (or Stavudine (d4T) + Lamivudine (3TC)	300 mg twice a day 150 mg twice a day	300 mg twice a day + (150 mg twice a day) **+ Protease Inhibitors** **1st choice** Lopinavir/ritonavir (LPV/r) 800/200 mg once daily with meals **2nd choice** Nelfinavir (NLF) 1250 mg twice a day or **3rd choice** EFV 600 mg at Bed time

Table 3: HBV Post-Exposure Prophylaxis

Exposed person	Treatment according to the status of source material		
	HBsAg-positive	**HBsAg-negative**	**Source not tested or unknown**
Unvaccinated	HBIG x 1*, initiate HBV vaccine	Initiate HBV vaccine	Initiate HBV vaccine
Previously vaccinated, known responder	Test exposed for HBsAb. If adequate no treatment. If inadequate, HB vaccine booster	No treatment	No treatment
Previously vaccinated, known non-responder	HBIG x 2 or HBIG x 1 plus 1 dose HB vaccine	No treatment	If source high risk for Hep B, treat as if source is positive
Response unknown	Test exposed for HBsAb. If adequate no treatment. If inadequate HBIG x 1*, initiate HBV vaccine	No treatment	Test exposed for HBsAb. If adequate, no treatment. If adequate, HBV vaccine booster

** HBIG dose 0.06 mL/kg IM.*

If the source is found to be positive for HCV and HCW is found to be negative for HCV, then refer the HCP to the designated hospital team for further care.

Management of Exposure to Hepatitis C Virus

There is no vaccination at this time, and no recommended chemoprophylaxis. For HCW exposed to Hepatitis C virus, follow-up care by the designated team is recommended.

CONCLUSION

The risk of health care associated infections is an unavoidable part of care-giving activities. However, the risk can be minimised by taking required immunisations; diligently following infection control practices and following standard work precautions while rendering service to patients.

17.8 Hospital Infection Control

Rohini Kelkar

DEFINITION AND EPIDEMIOLOGY

Hospital acquired infection can be defined as 'An infection occurring in a patient in a hospital in whom the infection was not present or incubating at the time of admission'. Hospital acquired infections (HAIs) or nosocomial infections are a significant cause of mortality and morbidity amongst hospitalised patients and compromise patient safety. Early studies in the 1980s from the US have reported that HAIs account for 14% of all adverse events. A World Health Organisation prevalence study showed an average of 8.7% of hospital patients had nosocomial infections with 10% prevalence in the South-East Asian region.

Despite progress in medical care, infections continue to develop in hospitalised patients due to factors, like increasing numbers of immunocompromised patients, invasive medical procedures, overcrowding leading to transmission of drug-resistant bacteria coupled with poor infection control procedures.

HAIs may be endemic or epidemic. Epidemic infections occur during outbreaks. Definitions have been developed for site-specific infections, e.g. urinary tract infection (UTI), surgical site infection (SSI), bloodstream infection (BSI), catheter related BSI and nosocomial pneumonia. These definitions can be utilised to identify the risk factors and take corrective measures in each organisation so as to reduce HAIs to acceptable limits.

AETIOPATHOGENESIS

HAIs are caused by many different microorganisms ranging from pathogenic bacteria like methicillin resistant *Staphylococcus aureus* to commensals like coagulase negative *Staphylococci* causing line associated infections. *Legionella* species found in water can cause nosocomial outbreaks of pneumonia through inhalation of contaminated aerosols. Viruses like hepatitis B and C can be transmitted through contaminated injections, transfusions, etc. Many parasites and fungi are opportunistic organisms and can cause infections during severe immunosuppression and extended antibiotic treatment. *Aspergillus* spores present in dust can cause nosocomial infections during hospital renovation and construction activities.

The reservoirs of infection may be endogenous, for example, Gram-negative bacteria present in the gut can cause surgical site infections after abdominal surgery. Exogenous infections are due to cross-transmission through direct contact as in the case of hands or body fluids; air-borne as in the case of droplets or dust; through carriers or through contaminated objects, like equipment, hands of health care workers or environmental sources like water, fluids and food.

DIAGNOSIS

By definition, HAIs are infections that occur more than 48 hours after admission. There are two important components to the diagnosis: (a) a simple timely and effective surveillance system that can monitor HAIs, and (b) standardised microbiology services to provide timely diagnosis of infections, monitor data and provide management guidelines through the performance of anti-microbial susceptibility testing using internationally recognised methods, reports of resistance patterns and accurate identification of aetiologic agents.

PREVENTION AND CONTROL

Hospital Infection Control Programme

Prevention of HAIs is the responsibility of every health care provider. Important components of the programme include:

1. Infection Control Committee which recommends the policies and practices.
2. Infection Control Team which includes an infection control nurse and a doctor.

The infection control committee should have representation from all relevant specialities and should perform the following:

1. Compile an infection control manual of recommended instructions and practices for patient care in hospital settings.
2. Review the activities for prevention of HAIs.
3. Review epidemiological surveillance data and plan appropriate interventions.
4. Ensure health care worker training on infection control.
5. Review investigation of outbreaks.

Important inputs are required from the hospital management, physicians, the nursing department, microbiologist, sterilisation services, food services and laundry, housekeeping and engineering departments.

Standards of Hygiene

In dealing with patients it is of utmost importance to maintain high standards of hygiene for all procedures.

Hand hygiene

Hand washing is the single most important measure for preventing the spread of infection. Hands should be washed before significant contact with any patient and after all activities likely to cause contamination.

Hand antisepsis is with antiseptics like chlorhexidine gluconate 2% w/v, povidone iodine or triclosan, if the hands are soiled or with 4% w/v chlorhexidine gluconate before surgery or any invasive procedures.

The hand wash procedure, duration and agent used are all critical.

Hand-rubs are useful for lowering the microbial counts on the skin, but cannot be used in the presence of organic soil.

Universal precautions

These are devised by the Centers for Disease Control and Prevention to protect health care workers from transmissible blood borne pathogens. These apply to blood, body fluids and any body fluid visibly contaminated with blood. These do not apply to secretions and excretions unless they contain visible blood.

These precautions include good hygienic practices particularly hand washing, the use of protective barriers like gloves, gowns, masks and eye shields, appropriate handling and disposal of sharps and other infectious wastes and the use of aseptic techniques.

These are recommended during the handling of blood, e.g. during blood collection and in laboratories, while handling body fluids and while handling non-intact skin and mucous membranes. Any spillage of blood and or body fluids should also be treated immediately with a solution of sodium hypochlorite (10,000 ppm available chlorine).

Isolation

Isolation of patients in a separate room or an isolated area is required only for patients with epidemiologically significant and highly contagious infections like pneumonia due to methicillin resistant *Staphylococcus aureus* or multiple drug resistant-tuberculosis and during outbreaks with viruses like acute respiratory syndrome.

Physical Environment

The physical environment of the hospital has to be designed taking into account the physical requirements that are fundamental to infection control.

Patient care areas should be adequately ventilated. Operating rooms are designed to minimise the risk of infection. Ideally, these have air handling systems that provide filtered air. The temperature, humidity and air changes per hour are all controlled as to minimise bacteria multiplication. Special environmental control measures are required during construction activities. This also includes control and monitoring of hospital water, food hygiene, laundry services, especially care of contaminated linen and biomedical waste.

Sterility of Instruments and Equipment

All instruments used for patient procedures must be thoroughly cleaned and decontaminated/sterilised depending on the use, e.g. surgical instruments must be sterilised to make them free from all forms of microbial life including bacterial spores.

Heat labile instruments like fibreoptics used for endoscopy or bronchoscopy should be decontaminated with an approved high level chemical disinfectant.

Adequate quality controls are essential for sterilisation and disinfection procedures.

In general single use items should not be reprocessed except in situations of non-availability, high cost or if the item has crossed the expiry date. Injection needles should not be reused/reprocessed.

Surveillance of Nosocomial/Health Care Associated Infection

This includes monitoring of hospital-acquired infections. Surveillance helps to track infection trends, i.e. the prevalent microorganisms, anti-microbial susceptibility patterns and multi-drug resistant organisms.

Outbreak Investigation

An unusual increase of cases of HAI indicates an outbreak, which requires prompt identification followed by investigation and the institution of appropriate control measures.

Occupational Health and Safety

Health care workers are at risk of acquiring infections through occupational exposures or may transmit infections to patients or other employees. Immunisation and specific post exposure policies for blood borne pathogens must be implemented.

Antibiotic Policy

In countries like India, where anti-microbials are sold across the counter, it is essential to control and rationalise the use of anti-microbials. Moreover, it is this 'misuse' that is responsible for the high levels of drug resistant microorganisms. Each facility should have a policy that outlines the rational use of anti-microbials in different clinical situations. Emphasis must be placed on preventive measures rather than concentrating on only therapeutics.

Biomedical Wastes

Disposal of hospital wastes has become an important component of infection control. The process involves several steps as given below:

1. Identification of different categories of hospital wastes
2. Segregation of wastes at the point of generation
3. Collection in appropriate containers, e.g. all sharp (needles etc.) must be collected in puncture-proof containers
4. Transportation
5. Storage
6. Treatment
7. Disposal

This is the 'cradle to grave' concept of waste management. Presently, there is a legal requirement to manage hospital wastes in India. The Biomedical Waste Management and Handling Rules Act came into force on 1998. In exercise of the powers conferred by section 6, 8 and 25 of EP Act, 1986. The central government notified these rules. For violating the rules the board can provide imprisonment which may extend up to 5 years with fine.

17.9 Staphylococcal Infections

Rita Sood

Association between cluster-forming cocci and abscesses was first observed by a Scottish surgeon, Alexander Ogston. He coined the name *'Staphylococcus'* for the organism (*Staphyle*, bunch of grapes; *kokkos*, berry) to distinguish it from chain-forming *Streptococci*. More than 30 species of *Staphylococci* can infect humans. However, most infections are caused by *Staphylococcus aureus*, the most virulent species and an important cause of morbidity and mortality in humans. It is distinguishable from other *Staphylococci* by its ability to produce coagulase, an enzyme that converts fibrinogen to fibrin. The other less virulent species of *Staphylococci* are grouped together as *coagulase negative Staphylococci* (CoNS).

STAPHYLOCOCCUS AUREUS INFECTIONS

S. aureus forms part of normal human flora, colonising the anterior nares, axilla, perineum, oropharynx, vagina and toe-webs. 25% to 50% of healthy persons may be carriers and this is relevant to the epidemiology, as source of most infections is endogeneous. Factors predisposing to *S. aureus* colonisation are shown in **Table 1**.

Table 1: Factors Predisposing to *S. aureus* Colonisation

Insulin-dependent diabetes
HIV-infection
IV drug abuse
Chronic haemodialysis
Skin diseases, e.g. eczema

S. aureus may also be acquired from other people or from environment as from hands of hospital personnel or through aerosols contaminated by respiratory or nasal secretions.

Pathogenesis

S. aureus has a capacity to induce abscess formation. A breach in the skin or mucosal barrier is necessary for initiation of a staphylococcal infection. After colonisation, the organisms replicate at the initial site of infection, elaborating enzymes which facilitate their survival and local spread across tissue surfaces. *S. aureus* also has a capacity for intracellular survival and to induce cellular changes which contribute to systemic manifestations of the disease. The predisposing factors for occurrence of staphylococcal diseases are shown in **Table 2**.

The primary host response to *S. aureus* infection is the recruitment of neutrophils. The staphylococcal cell wall as well as staphylococcal toxin can initiate an inflammatory response that can lead to sepsis.

Clinical Manifestations

S. aureus usually causes localised infections resulting in abscess formation. However, bacteraemia and haematogenous spread may occur, the severity of which is determined by the host response. Constitutional symptoms may result from both, localised or systemic infections (**Table 3**).

Table 2: Factors Predisposing to Staphylococcal Infections

Breach in Skin	**Impaired Leucocyte Function**
Wounds—traumatic, surgical	Quantitative
Burns	Neutropaenia
Skin diseases, e.g. eczema	Qualitative
Minor abrasions	Chronic granulomatous disease
Injections, e.g. insulin	Job's syndrome
Intravenous access, e.g. catheters	Chediak-Higashi syndrome
Breach in Mucous Membrane	
Viral infections, e.g. influenza	
Presence of Foreign Materials	
Intravenous catheters	
Arterio-venous shunts	
Prosthetic cardiac valves	
Orthopaedic prostheses	

Table 3: Common Illnesses Caused by *S. aureus*

Localised Infections

Skin and Soft-tissue Infections	**Pleuro-pulmonary Infections**
Folliculitis	Nosocomial pneumonia
Furuncle	Aspiration pneumonia
Carbuncle	Post viral (e.g. influenza) pneumonia
Cellulitis	Septic pulmonary emboli
Impetigo	Empyema
Surgical wound infections	Pyopneumothorax
Acute paronychia	**Musculoskeletal Infections**
Mastitis, breast abscess	Osteomyelitis
Umbilical infections in new born	Septic arthritis
Stye or hordeolum externa	Pyomyositis
Urinary Tract Infections (rare)	Psoas abscess
Post-surgery	**Toxin-mediated Illness**
Renal cortical abscess	Food poisoning
Peri-nephric abscess	Toxic shock syndrome
Bacteraemia and Septicaemia	Staphylococcal scalded skin syndrome
Sepsis, septic shock	
Metastatic foci of infections (kidney, bones, joints, lungs)	
Infective endocarditis	
Device-related infections	
Injection drug use related infections	

Localised Infections

Skin, appendages and soft tissue infections

Most infections arise in relation to hair follicles and result in localised pus collection. The affected area may be red,

swollen and painful. Common predisposing factors are minor trauma, insect bites, injections and poor personal hygiene. *Folliculitis* is a superficial infection of hair follicle. When this infection becomes more extensive and deep seated, it presents as a boil or *furuncle*. When several adjacent hair follicles are involved, they coalesce and may involve deeper layer of subcutaneous tissue and result in large indurated mass with multiple draining sinuses called *carbuncle*. These may occur in poorly controlled diabetics. *Staphylococcus* can result in mastitis or breast abscesses in 1% to 3% of breast-feeding women.

Pleuropulmonary infections

Staphylococcal pneumonia can occur as a result of aspiration of oro-pharyngeal flora, commonly in a patient with pre-existing lung disease, e.g. bronchiectasis, or due to metastatic seeding of a previously healthy lung. *S. aureus* is a cause of serious pulmonary infections in newborns and infants. In adults, nosocomial *S. aureus* pneumonia is often a complication of intubation and ventilation. Patients with right-sided endocarditis can present with septic pulmonary emboli. Staphylococcal pneumonias can be complicated by pneumatoceles, empyema and pyopneumothorax.

Musculoskeletal infections

S. aureus is the most common cause of bone and joint infections, both haematogenous and due to contiguous spread from adjacent soft tissue infections. Commonly involved joints include knees, shoulders, hips and phalanges. Pre-existing joint diseases, like osteoarthritis and rheumatoid arthritis are the predisposing factors. Increasing use of joint aspirations is contributing to higher incidence of septic arthritis.

Haematogenous osteomyelitis involves long bones more commonly in children whereas in adults, vertebrae are the commoner site. These infections are more common in patients with endocarditis, intravenous drug users, diabetics and those undergoing haemodialysis.

Pyomyositis is an acute inflammation of skeletal muscles seen only in tropics and sub-tropics. It presents as fever, swelling and pain overlying the involved muscle. The infection is almost always caused by *S. aureus* and gluteal and quadriceps are the common muscles involved.

Bacteremia, Septicaemia and Infective Endocarditis

S. aureus bacteraemia may be complicated by sepsis, endocarditis, vasculitis or metastatic seeding of infection. Commonly seeded tissue sites are bones, kidneys, joints and lungs. Immunocompromised states particularly diabetes, HIV infection and renal insufficiency increase the risk of bacteraemia and its complications. The presence of *S. aureus* in the urine suggests haematogenous dissemination. In patients with severe burns, staphylococcal sepsis is a leading cause of shock and death.

The overall incidence of *S. aureus* endocarditis has increased over the last few years. Intravenous drug abuse, diabetes mellitus, chronic haemodialysis and immunosuppression are predisposing factors and increase mortality. Acute right-sided endocarditis is most often seen in intravenous drug users. Prosthetic device infections are usually caused by *Staphylococcus aureus*.

Toxin-Mediated Illness

Staphylococcal food poisoning

Food poisoning due to *S. aureus* is caused by the ingestion of staphylococcal enterotoxin, preformed in the contaminated food. It is characterised by severe vomiting, nausea, abdominal cramps and diarrhoea and occurs within 1 to 6 hours of ingestion of food. Symptoms generally resolve within few hours and treatment is supportive.

Toxic shock syndrome (TSS)

It is characterised by high fever, erythematous rash, desquamation, diarrhoea, mental confusion, hypotension and multi-organ failure. It is caused by toxins secreted by *S. aureus* bacteria growing under conditions in which there is little or no oxygen. TSS was originally described in menstruating women using tampons. TSS is caused by enterotoxin or TSS toxin-1 (TSST-1). As the syndrome is caused by toxin, the mainstay of treatment is supportive measures along with antibiotics.

Staphylococcal scalded skin syndrome (SSSS)

SSSS mostly affects newborns and children. It is characterised by sudden onset of extensive erythema followed by bullous desquamation of large areas of skin. It is caused by epidermolytic toxins of *S. aureus*.

COAGULASE-NEGATIVE INFECTIONS

The coagulase-negative *Staphylococci* (CoNS) form large part of skin flora and are among the most common causes of prosthetic-device infections. *S. epidermidis* is the commonest, others being *S. hominis, S. haemolyticus* and *S. saprophyticus*.

Pathogenesis

S. epidermidis has a capacity to produce an exopolysaccharide (a bioflim, slime) which facilitates the adherence of this organism to plastic material and also their resistance to phagocytosis, other host-defences and to anti-microbial action. Majority of these infections are acquired in the hospital. Generally, the signs of localised infection are subtle, the rate of disease progression is slow, and systemic findings are limited. In the community, *S. saprophyticus* is an important pathogen causing urinary tract infections in sexually active young women whereas *S. epidermidis* is the organism associated with hospital-acquired infections.

Diagnosis

In cases of minor skin infections, staphylococcal infections are commonly diagnosed by their appearance without the need for laboratory testing. More serious infections require culture of samples of blood or infected fluids.

Laboratory diagnosis

S. aureus can be easily identified in the laboratory by Gram's stain and microscopic examination of the infected tissue. The organism can be seen as clumps of Gram-positive cocci. The diagnosis can be confirmed by cultures of infected material and blood. The isolation of *S. aureus* from blood culture is almost always indicative of bacteraemia. The laboratory diagnosis of CoNS is more difficult than *S. aureus* infections because of difficulty in interpretation. Only about 10% to 25% of blood cultures positive for CoNS reflect true bacteraemia. Multiple positive cultures of the same strain from separate

cultures, growth of the strain within 48 hours and bacterial growth in both aerobic and anaerobic cultures is likely to suggest true bacteraemia. Repeated cultures should always be taken.

Serology is not useful for the diagnosis of staphylococcal infections.

TREATMENT

General Principles

Localised skin infections can be treated with an antibiotic ointment or oral antibiotics. Serious infections warrant intravenous antibiotics supplemented by drainage with or without surgical excision. In almost all cases of infections with *S. aureus*, the prosthetic device removal is needed. In infections due to CoNS, sometimes an initial attempt at medical therapy without removal of device may be warranted.

Choice of Anti-microbials

The choice of antibiotic depends on prevailing susceptibility patterns and the severity of infection. Almost all *Staphylococci* produce beta-lactamase, and hence, penicillin use is not recommended. Semisynthetic penicillinase-resistant penicillins (SPRPs) like flucloxacillin or cloxacillin are important agents for community-acquired infections. Alternatively, first generation cephalosporins, macrolides and related agents like clindamycin can be used.

Multi-drug resistant strains of both *S. aureus* and CoNS are now prevalent. These methicillin-resistant strains of *Staphylococci* (MRSA) are usually resistant to other antibiotics and are associated with nosocomial infections. MRSA prevalence is increasing in the community setting and is associated with recent antibiotic use, sharing contaminated items, having active skin diseases, poor hygiene and living in crowded settings. HIV positive patients have been found to be at increased risk of infections with community acquired MRSA. The transmission of MRSA is largely from people with active MRSA skin infections. MRSA almost always spreads by physical contact and not through the air. Vancomycin and teicoplanin are the only agents with reliable activity against MRSA. New agents include linezolid and quinupristin/dalfopristin. Although, imipenem has excellent activity against methicillin sensitive *Staphylococci* but not against MRSA. Recently, vancomycin-resistant strains of *S. aureus* have been identified—vancomycin-intermediate resistance *S. aureus* and vancomycin resistant *S. aureus*. For minor skin and soft tissue infections in adults, tetracyclines could be useful. Parenteral vancomycin or teicoplanin are recommended in infections where risk of bacteraemia is high. Linezolid though bacteriostatic has an added benefit of being available and efficacious as an oral agent and can be useful in infections which are not deep-seated. Daptomycin is a new parenteral bactericidal agent with anti-staphylococcal activity and has been approved in USA for treatment of bactaeremias. Combinations of anti-staphylococcal antibiotics are sometimes used to enhance bactericidal activity (e.g. endocarditis). The agents used include rifampicin, gentamicin and fusidic acid, in combination with vancomycin. Therapy for toxin-mediated illnesses is entirely supportive with some role of antibiotics in TSS and SSSS.

Duration of Treatment

A 10 to 14 day treatment with antibiotics is recommended for uncomplicated infections and 4 to 8 weeks for complicated infections. Untreated *S. aureus* sepsis carries 80% mortality. Factors associated with increased risk of complications include persistently positive blood cultures 3 to 4 days after institution of therapy, community acquired infection, a removable focus of infection which is not removed and embolic manifestations.

PREVENTION

Simple measures like hand washing and appropriate isolation procedures can prevent spread of *S. aureus* infections. Regular hospital associated infection monitoring, antibiotic sensitivity surveillance and formulation of an antibiotic policy is helpful to reduce MRSA prevalence. Use of topical anti-microbial agents like mupirocin to eliminate nasal colonisation with *S. aureus* helps prevent infections in dialysis patients, but is not recommended routinely. A capsular polysaccharide-protein conjugate vaccine is under investigation.

17.10 Streptococcal Infections

Abhay Narain Rai

INTRODUCTION

Streptococcus is a genus of coccus, or sphere-like, Gram-positive, chained (the cells divide along a single plane, so *Streptococci* occur in pairs or in chains) bacteria. The name has been derived from Greek 'στεπτος' streptos, meaning easily bent or twisted, like a chain (twisted chain).

CLASSIFICATION

Streptococcus bacteria are divided into eighteen alphabetwise groups, called Lancefield groups. American bacteriologist Ms Rebecca Craighill Lancefield developed this method of classifying *Streptococci* in 1933 based on the antigens, found in the cell wall of the *Streptococcus* bacteria. Several types of *Streptococcus* do not react to Lancefield grouping, and must be classified using haemolysis.

The type of haemolytic reaction displayed on blood agar has long been used to classify the *Streptococci*. Beta-haemolysis is associated with complete lysis of red cells surrounding the colony, whereas alpha-haemolysis is a partial or 'green' haemolysis associated with reduction of red cell haemoglobin. Non-haemolytic colonies have been termed gamma-haemolytic. Group A *Streptococci* are nearly always beta-haemolytic; related Group B can manifest alpha, beta or gamma haemolysis. Most strains of *S. pneumoniae* are alpha-haemolytic but can cause ß-haemolysis during anaerobic incubation. Most of the oral *Streptococci* and *Enterococci* are non-haemolytic. The group viridans *Streptococcus* is either non-haemolytic or breaks down only partially, causing the green stain responsible for the name 'viridans'.

Group A *Streptococcus*, Group B *Streptococcus*, viridans *Streptococcus* and *S. pneumoniae* are the types most commonly of medical concern. Group A *Streptococcus* (GAS), or *S. pyogenes*, is one of the most common pathogens in humans.

Epidemiological data from developing countries for streptococcal infections is poor. On a global scale, GAS is an important cause of morbidity and mortality. In India, beta-haemolytic *Streptococci* causes up to 20% of acute respiratory tract infections and invasive streptococcal infection among hospital inmates has been reported as 2.4 per thousand (culture positive).

DISEASES

Acute *Streptococcus pyogenes* infections may present as pharyngitis (strep. throat), scarlet fever (rash), impetigo (infection of the superficial layers of the skin) or cellulitis (infection of the deep layers of the skin). Invasive, toxic infections can result in necrotizing fasciitis, myositis and streptococcal toxic shock syndrome (TSS). Patients may also develop immune-mediated post-streptococcal sequelae, such as acute rheumatic fever and acute glomerulonephritis, following acute infections caused by *Streptococcus pyogenes*. GAS infections may also cause pneumonia, meningitis, tonsillitis, septic arthritis.

Pharyngitis

Streptococcal pharyngitis presents as sore throat, pain on swallowing, fever, swollen and tender lymph nodes in the neck, and fatigue. The tonsils are swollen and often covered with pus. Cough, hoarseness, and running nose are not the symptoms of streptococcal pharyngitis, but indicate viral upper respiratory infections. When a red rash and fever accompany streptococcal sore throat, it is called scarlet fever. The two major complications of streptococcal pharyngitis are rheumatic fever and post-streptococcal glomerulonephritis.

Diagnosis

Streptococcal rapid antigen test—used to distinguish intermediate probability of *Streptococcus*.

Throat culture—used to confirm a negative rapid antigen test.

Antistreptolysin O titre (ASO titre)—confirms diagnosis, but not helpful in acute disease.

Meningitis

Bacterial meningitis is a serious infection of the CSF. It is most commonly caused by one of three types of bacteria: *Haemophilus influenzae* type b, *Neisseria meningitidis*, and *Streptococcus pneumoniae*. Meningitis caused by *Streptococcus pneumoniae* is called pneumococcal meningitis. The bacteria are spread by direct close contact with the discharges from the nose or throat of an infected person. Common symptoms are high fever, headache, and stiff neck. Other symptoms can include nausea, vomiting, photophobia, confusion, and drowsiness. Advanced bacterial meningitis can lead to brain damage, coma, and death. Survivors can suffer long-term complications, including hearing loss, mental retardation, paralysis and seizures.

Impetigo

Impetigo is a skin infection caused by bacteria. Usually the cause is staphylococcal but sometimes *Streptococcus* can cause it—the non-bullous type. It is most common in children between the ages of two and six. It usually starts when bacteria get into a break in the skin, such as a cut, scratch or insect bite. Impetigo generally appears as honey-coloured scabs formed from dried serum, and is often found on the arms, legs, or face. It could be bullous (mostly by *Staphylococcus*) or non-bullous (caused by both of them). One potential complication of impetigo is glomerulonephritis. Impetigo is contagious, mostly from direct contact but sometimes from fornites, towels, toys, clothing or household items. Once it starts, impetigo often spreads to other parts of the body.

Cellulitis (Figure 1)

Unlike impetigo, which is a very superficial skin infection, cellulitis refers to an infection also involving the skin's deeper

Figure 1: Upper limb cellulitis.

layers: the dermis and subcutaneous tissue. The main bacteria involved in cellulitis are *Streptococcus* and *Staphylococcus*. Cellulitis may occur anywhere on the body, but the leg is the most common site of the infection. Diabetics are more susceptible to cellulitis than the general population because of impairment of the immune system.

Necrotising Fasciitis

It is a rare infection of the deeper layers of skin and subcutaneous tissues (**Figure 2**), easily spreading across the fascial plane within the subcutaneous tissue. The infection begins locally, at a site of trauma, which may be severe (such as the result of surgery), minor, or even non-apparent. Patients usually complain of intense pain that may seem in excess given the external appearance of the skin. With progression of the disease, tissue becomes swollen, often within hours. Diarrhoea and vomiting are also common symptoms. In the early stages, signs of inflammation may not be apparent if the bacteria are deep within the tissue. If they are *not* deep, signs of inflammation, such as redness and swollen or hot skin, show very quickly. Skin colour may progress to violet, and blisters may form, with subsequent necrosis (death) of the subcutaneous tissues. Patients with necrotising fasciitis typically have a fever and appear very ill. Mortality rates have been noted as high as 73% if left untreated.

Figure 2: Necrotising fasciitis.

TREATMENT

GAS infections can be treated with many different antibiotics. Penicillin G (2 to 4 mU IV q4h) and clindamycin (600 to 900 mg g8h) are recommended. Supportive care in an intensive care unit may also be needed for severely ill. For persons with necrotising fasciitis, early and aggressive surgery is often needed to remove damaged tissue and stop disease spread. Early treatment reduces risk of death from invasive group A streptococcal disease. However, even the best medical care does not prevent death in every case.

Group B Streptococcus (GBS), or *S. agalactiae*, is frequently found in the urogenital tracts and rectums of women of childbearing age. Complications may arise in women with compromised immune systems, but it is more commonly significant when transmitted to babies during childbirth. A GBS infection of a newborn can cause life-threatening infections like meningitis or sepsis. Group B *Streptococcus* can also cause serious diseases in pregnant women, the elderly, and adults with other illnesses.

Streptococcus viridans is often responsible for dental infections and the formation of plaque. This type of bacteria, along with Group C, F, G and particularly D, can cause endocarditis, especially when the valves of the heart are previously damaged.

Streptococcus pneumoniae, or *Pneumococcus*, is the most common cause of invasive bacterial infection of children and the elderly. It is a normal inhabitant of the human upper respiratory tract. The bacterium can cause pneumonia, usually of the lobar type, paranasal sinusitis and otitis media, or meningitis, which is usually secondary to one of the former infections. It also causes osteomyelitis, septic arthritis, endocarditis, peritonitis, cellulitis and brain abscesses.

PREVENTION

Infections caused by streptococcal bacteria can be prevented or reduced in most cases by ensuring high standards of personal hygiene. The most helpful practice to prevent the likelihood of acquiring streptococcal diseases and reducing their spread to others is by good handwashing and prevent generation of aerosols from infected persons.

17.11 Pneumococcal Infections

DP Bhadoria, Koushik Dutta

Streptococcus pneumoniae (nicknamed pneumococcus) is the most common cause of community-acquired pneumonia and acute otitis media worldwide. Its growth in liquid media resembles *Streptococci*. Hence, it used to be called '*Diplococci*' which is no longer used now.

MICROBIOLOGY

Pneumococci are catalase negative, Gram-positive, round-shaped (coccus) capsulated bacteria growing in chains. They produce α-haemolytic toxin called pneumolysin that breaks down haemoglobin and is related to disease manifestations. The colonies are uniformly dissolved by bile salts. More than 98% isolates are susceptible to optochin.

A polysaccharide capsule is present in all but a few conjunctivitis causing strains, prevents phagocytosis and is an important virulence factor. Capsule swelling following antibody binding produces the fascinating 'quellung reaction'. Ninety serotypes have been identified based on capsule antigen. Serotyping is important since vaccines are used to produce antibodies to specific capsular polysaccharides.

β-lactam antibiotics inhibit the peptidoglycan to teichoic acid cross-linking by transpeptidase and carboxypeptidase enzymes in bacterial cell wall. A unique cell-wall polysaccharide consisting of teichoic acid with a phosphorylcholine residue is present in all strains. The exposed choline residues provide attachment to virulence factors like pneumococcal surface protein A (PspA) and pneumococcal surface adhesin A (PsaA).

EPIDEMIOLOGY

Pneumococci colonise the nasopharynx in 5% to 10% of healthy adults and 20% to 40% of children where they persist ordinarily for 4 to 6 weeks, sometimes up to 6 months. The *Pneumococci* are transmitted mainly through droplets, the transmission is increased in closed communities (school children, recruits in army, nursing homes, etc.), and in close contacts (crowding and poor ventilation). Individuals with complement deficiency, HIV infection, agammaglobulinaemia and splenectomy tend to have severe infection. Bacteraemia, usually secondary to pneumonia, is common in extremes of ages below 2 years and above 65 years.

PATHOGENESIS: HOST-PATHOGEN INTERACTIONS

Bacterial surface adhesins help in nasopharyngeal colonisation. Mucociliary clearance, glottal and cough reflexes prevent further spread. Viral infections, smoking, alcoholism, chronic lung diseases and heart failure compromise the defence resulting in easy spread to anatomically contiguous structures (Eustachian tube, nasal sinuses or the airways). Pneumococcal cell-wall constituents and antibody-antigen reactions activate complements and release cytokines [interleukin (IL)-1β, tumour necrosis factor (TNF)-α and IL-6] resulting in influx of polymorphonuclear (PMN) leucocytes. The capsule prevents phagocytosis and promotes invasion. Uncapsulated *Pneuomococci* seldom cause invasive disease. Pneumolysin damages membranes. An IgA1 protease dampens mucosal immunity.

Specific anticapsular antibody formed a few weeks after colonisation offers best protection. Compromised IgG synthesis, defective phagocytosis and absence of spleen predispose to overwhelming infection.

SPECIFIC INFECTIONS CAUSED BY *S. PNEUMONIAE*

Apart from pneumonia, *Pneumococci* commonly cause acute otitis media, sinusitis, acute tracheobronchitis, empyema and meningitis. Pneumococcal infections are listed in **Table 1**. Airway infections are caused by direct spread from primary site of colonisation whereas remote sites can be invaded via the haematogenous route.

Table 1: Adult Infections Caused by *S. pneumoniae*

Site of Infection	Disease Caused
Common infections	
Upper respiratory tract	Acute suppurative otitis media, acute sinusitis, tracheobronchitis
Lungs	Pneumonia (usually lobar)
Pleura	Empyema (often with pneumonia)
Central nervous system	Acute pyogenic meningitis, brain abscess
Heart and pericardium	Endocarditis (acute/subacute), pericarditis
Unidentified focus	Bacteraemia (primary)/sepsis
Less common infections	
Bone and soft tissue	Septic arthritis, osteomyelitis, cellulitis
Uterus	Endometritis
Abdomen	Peritonitis (spontaneous)

Acute Otitis Media and Sinusitis

Diagnosis

Acute suppurative otitis media (ASOM), manifesting as ear ache, aural pressure and fever is commonest in infants and children. Erythema, decreased mobility, even bulging of the tympanic membrane may be seen. If untreated, the tympanic membrane may rupture leading to otorrhoea.

Maxillary sinusitis presents with unilateral pain over the sinus which may refer to the upper incisor and canine teeth. Purulent nasal discharge, local pain, tenderness, and rarely, erythema are observed. Acute pain and pressure over the high lateral wall of the nose radiating to the orbit suggests acute ethmoiditis. Pain of frontal and sphenoid sinusitis is felt in the forehead and vertex regions, respectively. The hallmark of acute sinusitis radiologically is soft-tissue density without bone destruction. Although more sensitive than clinical examination routine radiographs are not cost-effective and are not usually recommended.

Pneumonia

Diagnosis

The symptom-triad of pneumococcal pneumonia is fever, cough with purulent rusty sputum/haemoptysis and dyspnoea. Pleuritic chest pain indicates pleural inflammation and if persistent suggests empyema. Elderly patients may present with insidious and vague symptoms like fever, fatigue, confusion with minimal cough. Lobar pneumonia causes diminished chest excursion and impaired percussion note, bronchial breath sounds and/or crackles on the affected side. Pleural effusion causes dull percussion note with loss of breath sounds and vocal fremitus (**Figure 1**).

Figure 1: Chest radiograph shows right upper and middle-lobe consolidation and non-homogeneous opacities in the left lower zone, in a case of pneumonia caused by *Streptococcus pneumoniae*. The patient also had empyema which necessitated tube thoracostomy.

Chest radiograph confirms pneumonia. Gram staining of properly obtained sputum sample (<10 epithelial cells and >25 neutrophils/high-power field) shows Gram-positive *Diplococci* in 80% to 90% of cases. Sputum and blood cultures are positive in 50% to 60% and 15% to 25% of cases, respectively. Rational antibiotic therapy mandates prior attempt to isolate the organism. Pneumococcal urinary antigen assay is a rapid method to augment the diagnostic yield.

Empyema, the most common complication, occurs in almost 2% to 3% of cases. The appearance of confusion should also raise concern about meningitis. Meningitis and pneumonia in the same patient is often associated with infective endocarditis (Austrian triad). Pneumococcal endocarditis causes rapid destruction of the heart valves.

Patients with severe pneumonia (**Table 2**) often require intensive care unit (ICU) admission.

Meningitis

Diagnosis

S. pneumoniae is the most common cause of pyogenic meningitis in adults. Rapid onset of fever, headache, meningismus (neck stiffness and positive Kernig's sign) and altered mental status is typical. Lumbar puncture should be done early after ruling out optic-disk oedema, stroke and coagulopathy. Typical cerebrospinal fluid (CSF) findings include pleocytosis (500 to 5,000 cells/μL) with predominant polymorphs, an elevated protein level (0.100 0.5 g/dL), and a decrease in glucose content (< 50% of the corresponding blood glucose) with Gram-positive cocci in 80% to 90% of cases. Empiric therapy may be started immediately after drawing two blood cultures (positive in 50%), if lumbar puncture is delayed.

Table 2: Criteria for Severe Pneumococcal Pneumonia

Patients who fulfil two of the following criteria at admission
Respiratory rate ≥30/min
Partial pressure of oxygen (PaO_2/FiO_2) ≤250
Bilateral pneumonia or multilobar pneumonia
Systolic blood pressure (BP) <90 mm Hg and/or diastolic BP <60 mm Hg
Patients who develop one of the following features during admission
Need for mechanical ventilation
Increase in the size of infiltrates by ≥50% within 48 hours
Septic shock or the need for vasopressors for ≥4 hours
Urine output < 80 mL in 4 hours or serum creatinine >2 mg/dL in the absence of chronic renal failure

Seizures, cerebral oedema or hydrocephalus develop in 64% to 75% of patients. Systemic complications like septic shock or disseminated intravascular coagulation are seen in 38% to 45% patients.

TREATMENT

Beta-lactams are the mainstay of anti-pneumococcal therapy. They prevent cell-wall synthesis by blocking endo-, trans- and carboxypeptidases. Oral amoxycillin (20 to 40 mg/kg/day) for 10 days (with/without clavulanate), newer macrolides, newer fluoroquinolones, or first generation cephalosporins are commonly used antibiotics for ASOM and pneumonia. Intravenous penicillin G 4 million units q4h, amoxycillin 1g q4h or an injectable cephalosporin may be used for serious or resistant infections. Penicillins still fare better than macrolides, at least in pneumococcal pneumonia, despite some *in vitro* resistance. Failure of treatment with β-lactams, macrolides and trimethoprim/sulphamethoxazole has been reported in meningitis and otitis media caused by drug-resistant *Pneumococci;* but not for drug-resistant pneumococcal pneumonia. Susceptibility testing is essential in cases of meningitis. Antibiotics for sinusitis are reserved for patients not responding to decongestants in two weeks. Patients with severe pneumococcal pneumonia are usually treated with a combination of penicillins with macrolides (e.g. azithromycin) or newer fluoroquinolones (e.g. levofloxacin or moxifloxacin) or clindamycin. If high antibiotic resistance is suspected, empiric therapy may be started with a third generation cephalosporin combined with a newer quinolone or vancomycin (to which pneumococci are invariably sensitive *in vitro*). In case of severe penicillin/cephalosporin allergy a carbapenem may be used.

If acute pyogenic meningitis is suspected, intravenous antibiotics should be started as soon as possible with ceftriaxone 2 g twice daily plus vancomycin 15 mg/kg twice daily and dexamethasone. The treatment is modified when culture reports are available (**Table 3**). Treatment is continued for a minimum of 10 to 14 days. If a patient with a penicillin-resistant organism is slow to respond

clinically, repeat lumbar puncture may be indicated to assess bacteriologic response. Treatment failures have been reported with ceftriaxone or cefotaxime for some strains with higher penicillin resistance (MICs ≥2 µg/dL).

Table 3: Choice of Antibiotics in Pneumococcal Meningitis According to the Susceptibility Reports

Minimum Inhibitory Concentrations (MIC)	Antibiotic Therapy
Penicillin <0.1 µg/ml	Penicillin G, 4 million units intravenously daily every 4 hourly, or ceftriaxone, 2 gm intra-venously every 12 hourly
Ceftriaxone or cefotaxime ≤0.5 µg/ml	Ceftriaxone 2 g intravenously every 12 hourly, or, Cefotaxime 2 g intravenously every 6 to 8 hourly
Ceftriaxone ≥1 µg/ml	Ceftriaxone, 2 g intravenously every 12 hourly plus vancomycin, 30 mg/kg/day intravenously in two divided doses

In pneumococcal endocarditis, urgent empirical therapy should start with intravenous β-lactams (usually ceftriaxone or cefotaxime), combined with vancomycin if antibiotic resistance is prevalent in the community, which should be continued for 4 weeks.

Adjunctive Management

For ASOM and sinusitis nasal decongestants may be used. Myringotomy may relieve severe otalgia and prevent complications like mastoiditis. Recurrent infections require long-term antibiotic prophylaxis. Failure of oral therapy may require hospitalisation for intravenous antibiotics, insertion of ventilating tubes or surgical drainage of sinus.

Patients with complicated pneumococcal parapneumonic pleural effusion (pleural fluid glucose less than 50 mg/dL, Gram-stain or culture positivity or turbid/purulent pleural fluid) require tube thoracostomy.

Patients with sepsis and multi-organ dysfunction are managed according to the Surviving Sepsis Campaign Guidelines with early intensive therapy, low-dose glucocorticoids, low tidal volume ventilation, intensive glycaemic control and drotrecogin-alpha [recombinant human activated protein C (rhAPC)]. The landmark PROWESS study showed a better survival benefit of rhAPC infusion in community-acquired pneumonia related sepsis than abdominal sepsis.

The administration of dexamethasone along with antibiotic in adults with bacterial meningitis reduces mortality by 60% and all unfavourable outcomes by 50%. Adults with acute pyogenic meningitis should receive 10 mg of dexamethasone intravenously immediately before the first dose of appropriate antibiotic and then every 6 hourly for 4 days. The use of high-dose steroids in patients with severe sepsis and septic shock, however, worsens the outcome. Its role in meningitis caused by penicillin-resistant organisms is unclear as its anti-inflammatory activity may reduce penetration of some drugs into the CSF. Such patients should be carefully monitored for treatment failure. Almost two-thirds of the patients with pneumococcal meningitis required mechanical ventilation.

Prevention

The commonly used pneumococcal polysaccharide vaccine includes 25 µg each of 23 purified capsular polysaccharide antigens from serotypes causing 85% to 90% of invasive disease. This adjuvant-free, phenol/thiomersal preserved vaccine has been shown to have an overall efficacy of 50% to 70% in adults. Vaccination protects against invasive disease including meningitis but does not prevent local infections including pneumonia. Antibody level gradually declines and there is no anamnestic response. So it is prudent to offer revaccination to people more than 65 years old and splenectomised patients, more than 5 years after the previous vaccination. Unfortunately, some of the high risk groups for whom the vaccine is recommended benefit poorly from the vaccine. These include debilitated elderly or people with chronic lung disease or people with lymphoma or HIV/AIDS.

For children less than 2 years, an alterantive seven-valent pneumococcal conjugate vaccine is recommended. Widespread use of the vaccine resulted in reduced disease in unvaccinated children and adults and also due to herd immunity. The overall incidence of antibiotic resistance has also decreased. However, infections by other (replacement) serotypes are on the rise along with the prevalence of antibiotic resistance among those strains.

Conjugate vaccines with more than 8 serotypes are showing promising results in trials. Current indications of pneumococcal vaccination are summarised in **Table 4.**

Table 4: Current Indications for Pneumococcal Vaccination

Immunocompetent adults ≥65 years of age

Immunocompetent adults aged 19 to 64 years with:
- Cerebrospinal fluid leaks
- Chronic cardiovascular disease
- Chronic pulmonary disease
- Alcoholism
- Cochlear implants
- Residence in chronic care facilities

Groups of adults aged >19 years and <65 years with impaired immunity
- Those with immunocompromising diseases like HIV infection, lymphoma, multiple myeloma
- Those on immunosuppressive chemotherapy (including corticosteroids) and post-organ or bone-marrow transplantation
- Those with splenectomy or asplenia
- Patients of chronic renal disease, chronic liver disease, diabetes mellitus

17.12 Meningococcal Infections

RK Singal, Vivek Pal Singh

INTRODUCTION

Neisseria meningitidis has been recognised as a cause of serious disease for centuries. Description of an illness resembling meningococcal disease dates back to the 16th century. Vieusseux first described meningococcal disease in 1805. However, Anton Weichselaum first isolated *N. meningitidis* as the causative agent of meningococcal disease in 1887.

Approximately 10% of the general population are carriers of *N. meningitidis*. In rare instances, *Meningococci* can overcome the body's natural defence mechanisms and cause life-threatening infections—meningococcal meningitis and fulminant meningococcaemia, which can often coexist.

AETIOPATHOGENESIS

N.meningitidis is Gram-negative, aerobic, bean-shaped *Diplococci*, best isolated on chocolate agar and exclusively found in humans. Based on antigenicity of capsular polysa-ccharides *Meningococci* are divided into 13 subtypes: A, B, C, D, E, H, I, K, L, W-135, X, Y, Z. Of these five, serogroups (A, B, C, Y, and W-135) are known to cause epidemics and outbreaks accounting for more than 90% of cases.

Meningococci have the ability to exchange genetic material responsible for the capsular production and thereby can switch from serogroup B to C and *vice versa*. This switch mechanism may become an important part of meningococcal virulence with the widespread use of serogroup specific vaccines.

Humans are the only natural reservoirs of *N. meningitidis*. Spread is by direct contact or droplet infection. The incubation period averages 3 to 4 days (range 1 to 10 days), during which the person is infective. Asymptomatic nasopharyngeal carriage of *N. meningitidis* is seen in 5% to 10% of adults. Most of these strains are nonpathogenic. Colonisation of the nasopharynx by *N. meningitidis* may be transient, intermittent or long-term and the prevalence may increase in the presence of concomitant respiratory tract infection, overcrowded living conditions and smoking. Colonisation induces an immunological response to *N. meningitidis*, so that by young adulthood majority of people have measurable antibodies to the pathogenic serogroups of *N. meningitidis* (A, B, C, Y and W-135). In some people, meningococci penetrate the mucosa and gain access to the blood stream, where they may be killed by bactericidal antibodies, complement or phagocytic cells or may multiply and initiate bacteremic phase. The bacteria may seed the meninges, joints or pericardium or may multiply in the bloodstream causing meningococcaemia. Disease occurs most commonly in persons who are sero-negative and have newly acquired *N. meningitidis*. Meningococcal cell wall lipoligosaccharide (LOS) is responsible for the inflammatory cascade in meningococcaemia. In addition, *Meningococci* can invade the vascular endothelium, which produces molecules with procoagulant and adhesive properties for leucocytes. Both platelets and leucocytes contribute to the formation of microthrombi and vascular injury. Thrombosis of small to mid-sized arteries produces peripheral necrosis and gangrene necessitating digit or limb amputation.

EPIDEMIOLOGY

Meningococcal disease occurs globally and is a major cause of epidemics in sub-Saharan Africa (the meningitic belt – a region extending from Ethiopia in the east to Senegal in the west). The disease is endemic in temperate climate, but the majority of cases occur during winter and early spring. The incidence is highest amongst infants in whom protective antibodies have not yet developed. It drops after infancy and then increases during adolescence and early adulthood.

Serogroups A, B and C account for most cases of meningococcal disease worldwide, with serogroups B and C causing the majority of cases in Europe and America and serogroups A and C in Asia and Africa. The Islamic Haj pilgrimage to Mecca has historically been associated with outbreaks of *N. meningitidis* serogroup A. In India, meningococcal disease is endemic in Delhi and sporadic cases occur in Haryana, Uttar Pradesh, Rajasthan, Sikkim, Gujarat, West Bengal and Orissa. Serogroups A and C account for most cases in India. However, sporadic group B meningococcal infection has been reported in Delhi.

Those who lack or have a deficiency of antibody-dependent, complement-mediated immune lysis are most susceptible to invasive meningococcal disease. Various risk factors for invasive meningococcal disease are summarised in **Table 1**.

Table 1: Risk Factors for Invasive Meningococcal Infections

Children 6 months to 4 years
Complement deficiency
Functional/anatomic asplenia
Concurrent upper respiratory tract infection
Tobacco smoking
Immunodeficiency states (HIV, drugs)
Chronic diseases (SLE, cirrhosis, multiple myeloma)

CLINICAL FEATURES

The clinical spectrum of invasive meningococcal disease includes pyogenic meningitis, meningitis with or without meningococcaemia. Meningeal infection occurs in about 50% of patients and is similar to other forms of acute purulent meningitis. Patients present with sudden onset of fever, vomiting, photophobia, headache, neck stiffness and altered mental status. Infants usually have a slower onset of the disease with non-specific signs and without neck stiffness. *N. meningitidis* can be isolated from the bloodstream in approximately 75% of the patients, but meningococcal sepsis, also known as meningococcaemia, occurs in only 5% to 20% of patients. Meningococcaemia is characterised by the abrupt onset of fever and a petechial, purpuric or ecchymotic rash (**Figure 1**), which may progress to purpura fulminans. Meningococcaemia is often

associated with hypotension and acute adrenal haemorrhage (Waterhouse-Friedrichsen syndrome) and multi-organ failure. Up to one-third of patients present with meningitis without signs of sepsis. However, absence of meningeal signs in a patient with meningococcaemia is a poor prognostic sign. It suggests that the bacteria have multiplied so rapidly in the blood that meningeal seeding and inflammation could not occur. Neurological complications include generalised and focal seizures in up to 40% of cases. The complications of invasive meningococcal infection are summarised in **Table 2**.

Figure 1: Characteristic skin rash in a patient with meningococcaemia.

Table 2: Complications of Meningococcal Meningitis and Fulminant Meningococcaemia

Seizures
Cerebral venous thrombosis
Subdural empyema
Hydrocephalus
Hemiparesis
Deafness
Cranial nerve palsies
Mental retardation
Loss of digits/limb
Shock
Disseminated intravascular coagulation (DIC)
Multi-organ failure

Chronic meningococcaemia is a rare syndrome of prolonged, intermittent fever, rash, arthralgias, headache and splenomegaly that lasts for weeks to months. Untreated or when treated with steroids, chronic meningococcaemia may evolve into meningitis, fulminant meningococcaemia or endocarditis.

Meningococcal disease may have varied systemic manifestations. Apart from meningitis and meningococcaemia, arthritis occurs in 10% of patients. Early onset arthritis reflects a direct invasion of the joint by Meningococci, whereas late onset arthritis reflects immune complex deposition. Primary meningococcal pneumonia occurs in 5% to 15% of patients and is often due to serogroup Y. Systemic or extra-meningeal manifestations are uncommon during the course of both meningococcal meningitis and sepsis and usually occur within the first seven days of the disease.

DIFFERENTIAL DIAGNOSIS

Cutaneous differential diagnosis of acute meningococcaemia includes acute viral syndromes particularly dengue haemorrhagic fever, leptospirosis, acute hypersensitive vasculitides, septic vasculitis due to acute bacteraemia or endocarditis, toxic shock syndrome, purpura fulminans or rocky mountain spotted fever.

Chronic meningococcaemia may resemble chronic gonococcaemia, Henoch-Schönlein purpura, rat-bite fever, sweet syndrome, erythema multiforme and subacute bacterial endocarditis.

DIAGNOSIS

The gold standard for the laboratory diagnosis of meningococcal disease is bacteriologic culture, but its sensitivity may be low in patients pre-treated with antibiotics. Gram staining of cerebrospinal fluid (CSF) is still an important method of rapid and accurate diagnosis of *N. meningitidis*. Gram staining of peripheral blood buffy coat may reveal Gram-negative *Diplococci* in fulminant meningococcaemia. Non-culture methods such as direct antigen detection using latex agglutination in serum or urine can provide a rapid, group specific diagnosis but false negative results are common, especially in cases of serogroups B disease.

Since *Meningococci* are fastidious and fragile, isolation rates can be increased, if the clinical specimen is examined as soon as possible after collection. In case delay is anticipated, the sample may be incubated at 35°C in a 5% carbondioxide atmosphere or may be inoculated aseptically into a recently developed biphasic medium (trans-isolate medium) to enhance the recovery of the causative organism.

Needle aspirates or skin biopsy specimens from patients with meningococcal sepsis tested using gram stain and culture yielded a 56% to 80% sensitivity based on few studies. A study comprising of adult cases with fulminant meningococcaemia observed four variables at the time of admission indicating a fatal outcome.

1. Plasma fibrinogen levels less than 1.5g/L (sole adverse prognostic factor)
2. Factor V concentration of 0.2 or less
3. Platelet count less than 80×10^9/L
4. CSF leucocyte count 20×10^6/L or less

TREATMENT

Meningococcal disease can kill more rapidly than any other infection. Patients with either meningococcaemia or meningococcal meningitis should be hospitalised immediately. Many a times meningitis due to *N. meningitidis* may be impossible to differentiate from other causes of pyogenic meningitis, prompt antibiotic therapy with a third generation cephalosporin-ceftriaxone (2 g IV every 12 hourly) or cefotaxime (2 g IV every 4 hourly) should be initiated. Due to high prevalence of penicillin-resistant *Streptococcus pneumoniae*, empirical treatment of meningitis in infants or elderly should be a combination of vancomycin plus ceftriaxone or cefotaxime. In established cases of meningococcal meningitis penicillin G in a dose of 18 to 24 million units (4 million units IV 4 hourly) per day is the first line of therapy. Antibiotic therapy is essential for at least one week.

N. meningitidis has been relatively slow to acquire resistance to penicillin. However, invasive Meningococcal disease strains with

decreased susceptibility to penicillin have been reported worldwide including from India. Invasive meningococcal disease with decreased susceptibility to penicillin has been found to be strongly associated with serogroup Y and W-135 strains. In a study, resistance to quinolones was reported at 100% for levofloxacin, 84.6% for ofloxacin and 65.4% for ciprofloxacin. However, all isolates were susceptible to third-generation cephalosporins, azithromycin and rifampicin. Meropenem (1 g IV 8 hourly) and chloramphenicol (75 to 100 mg/kg dL) are alternatives in penicillin allergic individuals. Dexamethasone 10 mg IV 20 minutes before the first antibiotic dose and then every 6 hourly for 4 days, is recommended in every case of purulent meningitis. Activated protein C in a dose of 24 mg/kg per hour (2 g every 4 hour) as a continuous intravenous infusion for 96 hours is approved for use in patients with early severe sepsis with multi-organ failure (APACHE II score <25).

Early microsurgical arteriolysis is a reliable method to reduce the devastating amputations found in patients with meningococcal sepsis. This approach significantly improves the functional outcome in severely ischaemic limbs in meningococcal-induced sepsis in children.

PROGNOSIS

Timely treatment with appropriate antibiotics results in a good outcome in patients with meningococcal disease.

Extremes of age, shock, coma or focal neurological deficits, absence of meningeal signs, confluent rash and leucopaenia are associated with a poor prognosis.

The fatality rate in untreated cases is up to 90%. The sequelae such as deafness, seizures or mental retardation are seen in 3% to 4% of survivors, mostly children.

PREVENTION

Chemoprophylaxis

Once a case of meningococcal disease is identified, the patient's close contacts should be treated with an effective anti-microbial agent so as to eradicate potential colonisation by *N. meningitidis*. Close contacts who have previously received meningococcal vaccine should still be given chemoprophylaxis as vaccines do not confer 100% protection and immunity wanes with time.

Chemoprophylaxis is advocated for close contacts who have been directly exposed to the patient's oral secretions within one week before the onset of patient's symptoms until 24 hours after appropriate anti-microbial therapy has been initiated. Rifampicin 600 mg bid for 2 days, ciprofloxacin 500 mg orally once or ceftriaxone 250 mg once IM are recommended for chemoprophylaxis.

Meningococcal Vaccine

Routine immunisation with meningococcal conjugate vaccine continues to be recommended, despite ongoing concern about a possible association between vaccination and Guillain-Barré syndrome. Vaccination is recommended to provide pre-exposure immunity to persons who are at high risk for meningococcal disease.

Two types of vaccines are licensed. Meningococcal polysaccharide vaccine [bivalent (for serogroup A and C) and quadrivalent (for serogroup A, C, Y, and W-135)] and meningococcal conjugated polysaccharide vaccine. Both vaccines elicit protective antibodies in more than 97% of recipients (as measured at 28 days).

Both vaccines can be given with other vaccines, but at a different anatomical site. Mild-to-moderate local reactions and minor systemic symptoms may occur with either vaccine. A major limitation of these two vaccines is that neither provides immunity against serogroup B, which is responsible for approximately one-third of meningococcal disease worldwide. The meningococcal conjugate polysaccharide vaccine induces a T-cell dependent response, resulting in an improved immune response in infants, priming immunological memory and leading to a booster response to subsequent doses. Nasopharyngeal carrier rates also decreases by use of conjugate vaccine, thereby interrupting the transmission of *N. meningitidis* and establishing herd immunity. The recommendations for the use of meningococcal vaccines in previously unvaccinated persons are summarised in **Table 3**.

Table 3: Recommendations for the Use of Meningococcal Vaccines in Previously Unvaccinated Persons*

General Population	Persons at Increased Risk
A single dose of conjugate vaccine for persons 11 to 12 years of age or on entry into high school (~ 15 years of age)	A single dose of conjugate vaccine in persons 11 to 55 years of age A single dose of polysaccharide vaccine for persons 2 to 10 years of age or ≥ 55 years and is an acceptable alternative to the conjugate vaccine in 11 to 55 years age group. Vaccination of persons younger than 2 years is not recommended**

Dato from Centres for Diseose Control and Prevention, Atlonto, USA

***Meningococcol polysoccharide voccine may be used to elicit short-term protection agoinst serogroup A in trovellers to endemic areos. For children 3 to 18 months of oge, the voccine is given in two doses 3 months aport, ond in o single dose in children 19 to 23 months of oge.*

Newer approach to meningococcal vaccine

The development of quadrivalent glycoconjugate meningococcal ACWY vaccine has broadened protection against meningococcal disease. A novel meningococcal MenACWY-CRM (Menveo) glycocongugate vaccine, formulated by selective conjugation chemistry of intermediate-chain-length meningococcal saccharides was found to be immunogenic in individuals aged 2 months to 65 years of age, a need that remains unmet.

17.13 Gonococcal Infections

Chander Grover

INTRODUCTION

Gonococcal infections are a spectrum of clinical disorders which are an important public health problem. The causative organism is *Neisseria gonorrhoeae*, a Gram-negative, non-spore forming diplococcus, closely related to *N. meningitidis*, *N. lactamica* and *N. catarrhalis*.

The infection is transmitted almost exclusively through sexual contact or perinatally with occasional reports of fomite borne transmission. The organism is an obligate human parasite. It causes gonorrhoea (also known as strangury or clap) apart from causing rectal, pharyngeal, conjunctival or disseminated infections.

EPIDEMIOLOGY

Worldwide, gonorrhoea is an important bacterial sexually transmitted infection (STI). It is the second most commonly reported notifiable disease in USA with 600,000 new infections occurring annually. No such comprehensive data are available from India. However, the prevalence is reported to be 9.7% in females attending STI clinics and could be as high as 16.9% in female sex workers. Along with other bacterial STIs, the incidence of gonorrhoea has reduced over the years but has remained static for the past decade. The risk factors include unprotected sexual contact, multiple sex partners, use of intra-uterine devices, and child abuse or child birth in an infected mother.

AETIOPATHOGENESIS

N. gonorrhoeae is capable of infecting columnar epithelia where it attaches with its long pili. From here, it penetrates the epithelial cells, multiplies within them, releasing lipo-oligosaccharides and peptidoglycans and causing release of tumour necrosis factor-alpha (TNF-α). Resulting neutrophilic infiltration leads to tissue damage and purulent discharge. The organism is exocytosed from the basal side, may invade the blood stream and disseminate. Bactericidal humoral immunity is also activated. However, cell mediated immune response is generally poor. Haematogenous dissemination is produced by strains resistant to antibody and complement-mediated damage.

CLINICAL FEATURES

The manifestations of gonococcal infections are summarised in **Table 1**. *N. gonorrhoeae* infects the non-cornified epithelium of the urogenital tract, rectum, pharynx or conjunctiva. The incubation period is 1 to 14 days. However, symptoms appear earlier in males (2 to 5 days) and later in females (10 days). The risk of transmission through a single vaginal penetrative contact is 20% for males and 50% to 90% for females. The clinical features vary according to the site and severity of the infection.

1. Males

Onset is with a mild discharge which rapidly becomes profuse, purulent, associated with marked discomfort, pain, burning sensation, frequency and urgency (**Figure 1**). In 15% cases the infection may be mild or asymptomatic.

Figure 1: Thick pus extruding from the urethral meatus in a male with gonorrhoea.

2. Females

Only 50% of those infected are symptomatic and may present with increased vaginal discharge or mild urethral discharge. On examination, the cervix is inflamed, with mucopurulent or purulent discharge (**Figure 2**). Intermittent bleeding or menorrhagia may occur.

Figure 2: Inflamed cervix with purulent discharge extruding from the cervical os. The discharge is less profuse than a male urethral discharge.

3. Ano-Rectal Infection

This is seen more commonly in females and homosexuals. It may present with minimal anal pruritus and discharge to frank proctitis.

4. Pharyngeal Infection

More than 90% of these infections remain asymptomatic. Fellatio transmits the infection more efficiently than cunnilingus.

5. Conjunctivitis

This is encountered in a neonate born to an infected mother or rarely through accidental inoculation.

DIAGNOSIS

The diagnostic tests for gonococcal infections include the following:

1. Microscopy

A highly sensitive (>95%) and specific (>99%) test for symptomatic males where demonstration of more than 5 neutrophils per oil immersion field with Gram-negative, intra-cellular *Diplococci* is diagnostic (**Figure 3**). The test is not very sensitive for females, asymptomatic males or for sites other than urethra.

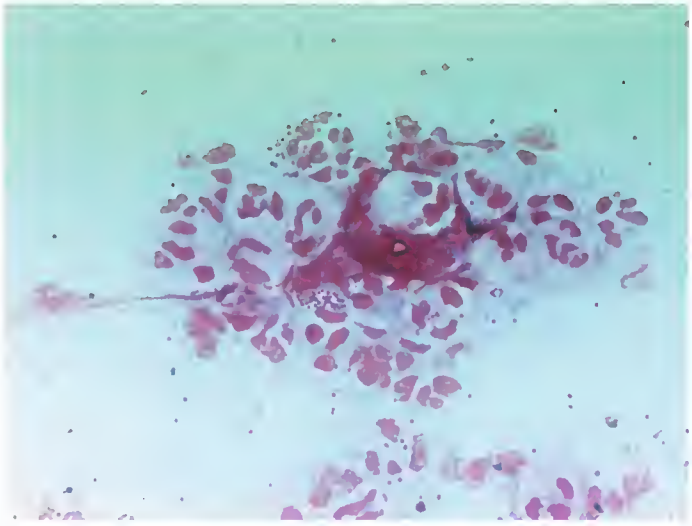

Figure 3: Multiple neutrophils in a Gram-stained smear of urethral discharge. Multiple Gram-negative intracellular *Diplococci* can be visualised.

2. Culture

This is the gold standard for diagnosis and is carried out on selective media, like modified Thayer-Martin, New York City medium. The plate is incubated under 5% carbondioxide at 37°C. This can be used to diagnose the infection from sites like endocervix, pharynx and rectum. Culture also provides the opportunity for antibiotic susceptibility testing.

3. Serology

Various tests available to detect serum antibodies against *N. gonorrhoeae* include complement fixation, latex agglutination, immunoflorescence or radio-immunoassay.

4. Nucleic Acid Amplification Tests

These are highly sensitive tests, currently approved by the FDA for the diagnosis of gonorrhoea. Widest range of specimens can be conveniently tested. However, some tests may cross-react with other *Neisseria* species.

COMPLICATIONS

These have been summarised in **Table 1**. Many complications of gonorrhoea cause long-term morbidity and are of profound public health importance. Apart from reflecting the load of reproductive tract infections (RTIs) in the society, gonococcal infections indicate high-risk behaviour and also facilitate the transmission of HIV. Hence, National STI/RTI control programmes place substantial emphasis on them.

Table 1: Clinical Manifestations of Gonococcal Infections

Primary Gonococcal Infections
Anterior urethritis
Endocervicitis
Proctitis
Pharyngitis
Conjunctivitis
Complicated Gonococcal Infection
Males
Posterior urethritis, periurethral abscess
Infection of Cowper's/Tyson's glands
Urethral stricture
Prostatitis, epididymo-orchitis
Females
Bartholin's gland abscess
Pelvic inflammatory disease (PID)
Tubo-ovarian abscess
Infertility
Spontaneous abortion, premature delivery, chorio-amnionitis
Both
Corneal perforation, blindness
DGI (arthritis-dermatitis syndrome)
Medical emergencies
Scrotal swelling, epididymo-orchitis
Severe PID
DGI

The risk factors for developing disseminated gonococcal infection (DGI) include pregnancy, pharyngeal carriage, female sex, complement deficiency and specific gonococcal serotypes. After an incubation period of 7 to 30 days, the patient develops arthralgias and synovitis of wrist, ankle and metacarpo-phalangeal joints. By this time, the primary genital infection may have regressed. Subsequently, tender, necrotic pustules on an erythematous base develop on acral areas. Few patients may develop meningitis or endocarditis. If blood, joint fluid or pustules grow the organism, the patient is said to have *proven* DGI. If cultures are positive from the primary mucosal site or from sexual partner, then the diagnosis is *probable* DGI. In the absence of any culture positivity but response to therapy, the patient is said to have *possible* DGI.

TREATMENT

The treatment of gonorrhoea is challenging because of the rapidity with which antibiotic resistance develops. From time to time, guidelines for its treatment are issued by national and international authorities. Indian National Guidelines for Syndromic Management of STIs recommend the use of Cefixime (400 mg) + Azithromycin (1 gm) orally as single dose treatment for urethral or cervical discharge. Treatment for scrotal swelling or PID (both may be medical emergencies) involves 7 days administration of Cefixime and Doxycycline tablets. High levels of quinolone resistance preclude their use as of now. *Chlamydial* co-infection needs to be treated simultaneously. Abstinence, partner notification and

treatment also need to be ensured. The WHO/IUSTI guidelines 2009 for the treatment of gonorrhoea are detailed in **Table 2**.

Table 2: WHO/IUSTI Guidelines for the Treatment of Gonorrhoea (2009)

Uncomplicated Infection – all single dose treatments
- Ceftriaxone 250 mg intramuscularly (preferred for pharyngeal infections)
- Cefixime 400 mg orally
- Spectinomycin 2 g intramuscularly (preferred for beta-lactam allergy
- Azithromycin 2 g orally

Complicated/Disseminated Infection
- Initial therapy
  - Ceftriaxone 1 g intramuscularly or intravenously 24 hourly
  - Cefotaxime 1 g intravenously 8 hourly
  - Spectinomycin 2 g intramuscularly 12 hourly.
- Continue for 7 days, may switch 24 to 48 hours after symptoms improve to
  - Cefixime 400 mg twice daily

Ophthalmia neonatorum
- Ceftriaxone 25-50 mg/kg intravenously or intramuscularly as a single dose
- Cefotaxime 100 mg/kg intramuscularly as a single dose
- Frequent conjunctival irrigation with saline

PREVENTION

Partner management and abstinence during the course of treatment are important measures which help bring down the incidence of gonococcal infections. Proper use of barrier contraception in the form of condoms, diaphragms or cervical caps reduces the risk of transmission of gonococcus. Similar effect is seen with spermicidal and bactericidal agents. Oral contraceptives increase the risk of infection. Prophylactic administration soon after exposure is likely to decrease the risk of developing gonorrhoea.

17.14 Typhoid Fever (Enteric Fever)

Swapan Kumar Niyogi

INTRODUCTION

Typhoid fever is a systemic infection caused by the bacterium *Salmonella enterica* serotype typhi (*S. typhi*). *Salmonella enterica* serotype paratyphi (*S. paratyphi*) A, B and C cause the clinically similar condition, paratyphoid fever. Typhoid and paratyphoid fever are collectively referred to as enteric fever.

In 1873, William Budd described the contagious nature of the disease and incriminated faecally contaminated water sources in transmission. The causative organism was visualised in tissue sections from Peyer's patches and spleen of infected patients by Eberth in 1880 and was grown in pure culture by Gaffky in 1884. In 1911, Elie Metchnikoff fulfilled one of Koch's postulates reproducing disease in chimpanzees after throat inoculation with *S. typhi*.

EPIDEMIOLOGY

Typhoid fever was a major cause of morbidity and mortality in the US and Europe in the 19th century. However, with the provision of clean water and good sewage systems, there has been a marked decline in the incidence of typhoid in developed countries, but the disease still remains a major public health problem in developing countries, the true burden of typhoid fever in developing countries is difficult to estimate.

Age Group

Typhoid fever is considered to be a disease mainly of children and young adults. In endemic areas, the highest attack rate occurs in children aged 5-13 years. Paratyphoid fever has the highest incidence in teenagers and young adults.

Gender

Typhoid fever is more commonly seen in males. Female have a special predilection to become chronic carriers.

Socioeconomic Factors

It is a disease of poverty and associated with inadequate sanitation facilities and unsafe water supplies.

Incubation Period

Usually 10 to 14 days but it may be as short as 3 days or as long as 21 days depending on the size of the initial inoculum. For paratyphoid fever the range is 1 to 10 days.

MODE OF TRANSMISSION

The disease is transmitted by the faecal-oral route, via contaminated food and water. Usually, water-borne transmission involves the ingestion of fewer organisms and as a result, has a longer incubation period and lower attack rate than food-borne transmission. Occasionally, health care workers can acquire the disease from infected patients, while laboratory workers can acquire the disease after accidents. *S. paratyphi* is mainly transmitted by contaminated food from street vendors.

Environmental Factors

Typhoid fever is usually observed throughout the year.

Reservoir of Infection

Humans are the natural host and reservoir for both typhoid and paratyphoid fevers.

AETIOPATHOGENESIS

The *Salmonella* are a heterogenous group of bacteria in the genus *Salmonella* of the family enterobacteriaceae. The *Salmonella* genus contains two species, which are divided into seven subspecies: *S. enterica* (six subspecies, i.e. *enterica, salamae, arizonae, diarizonae, houtenae* and *indica*) and *S. bongori* (one subspecies). The subspecies are divided into over 50 serogroups based on somatic (O) antigens present. The serogroups are further divided into over 2300 serotypes based on flagellar (H) antigens in one or both of two phases. Some have capsular (K) antigens, referred to as Vi, which may interfere with agglutination by O antisera and are associated with invasiveness. Agglutination tests with absorbed antisera form the basis for serologic classification.

The agents that cause enteric fever are, therefore, *Salmonella enterica* subspecies *enterica* serovar typhi (commonly referred to as *S. enterica* serovar typhi) and serovars paratyphi A, B and C. From a clinical perspective, the serogroups of *Salmonella* are usually considered as two broad groups. Firstly, those which are human-host restricted and responsible for the systemic invasive disease known as enteric fever, which include *S. typhi and S. paratyphi* A, B and C. The remaining serotypes (non-typhoidal *Salmonella*) often cause gastroenteritis and can be associated with localised infections and/or bacteraemia.

S. typhi is ingested with food and water. It passes through the stomach and invades the gut epithelium (distal ileum). In the small intestine, the bacteria adhere to mucosal cells and then invade, translocate to the intestinal lymphoid follicles and the draining mesenteric lymph nodes and some pass on to reticulo-endothelial cells of the liver and spleen. Salmonella are able to survive and multiply within the mononuclear phagocytic cells of the lymphoid follicles, liver and spleen. After a 7 to 14 day incubation period, the onset of a sustained secondary bacteraemia results in clinical disease.

The bacteraemia of typhoid fever persists for several weeks if antibiotic therapy is not given. In this phase the organism disseminates widely to the liver, spleen, bone marrow, gall-bladder and the Peyer's patches of terminal ileum. The symptoms and signs of typhoid fever are not thought to be entirely due to circulating endotoxin. Increased levels of circulating pro- and anti-inflammatory cytokines have been demonstrated in typhoid fever as well as a reduced capacity of whole blood to produce pro-inflammatory cytokines in severe

diseases. Ulceration of Peyer's patches is seen where the inflammatory process has resulted in ischaemia and necrosis. These ulcers are ovoid in shape with irregular undermined edges; they lie along the long axis of the gut and if extensive may lead to erosion of blood vessels or perforation of gut wall. Relapse probably occurs because of persisting organisms within the reticulo-endothelial system. Gall bladder infection may become chronic in individuals with gall bladder pathology. Typhoid fever induces systemic and local humoral and cellular immune responses but these confer incomplete protection against relapse and re-infection.

CLINICAL FEATURES

The most important symptom is prolonged fever, initially low-grade, rises progressively, and by the second week is often high and sustained (38.8 to 40.50°C or 101.8 to 104.9°F). Characteristically, continuous fever rising in a step-ladder fashion is observed. A prodorme of non-specific symptoms often precedes fever and includes chills, headache, anorexia, cough, weakness, sore throat, dizziness and muscle pain. In general, the symptoms associated with *S. typhi* are more severe than those associated with *S. paratyphi.*

Physical signs are few, but a coated tongue, tender abdomen, hepatomegaly and/or splenomegaly may be found. Relative bradycardia and dicrotic pulse may develop. Approximately, in 30% of patients, at the end of the first week, small maculo-papular, blanching and erythematous rash ('rose spot') typically on the trunk and chest may be seen particularly in fair-skinned patients. The rash resolves after 2 to 5 days without leaving a trace. Constipation is generally more common in adults, but in young children and adults with HIV infection, diarrhoea predominates.

A rapid drop in temperature, rising pulse, falling blood pressure and worsening of abdominal pain during the later period of the illness suggests intestinal bleeding or perforation. This drop is usually followed by a rise in temperature after a few hours as peritonitis develops. These complications result from necrosis at the initial site of *Salmonella* infiltration at the Peyer's patches. Both these life-threatening complications require immediate medical and surgical interventions. In typhoid state of 'coma vigil' patients become profoundly toxic, lie prostrated, semiconscious and tremulous, muttering continuously, picking at bed clothes or imaginary objects (carphology). Typhoid encephalopathy, often accompanied by shock is associated with a high mortality.

In the past, paratyphoid fever was believed to cause a milder disease than typhoid fever, but recent reports showed indistinguishable clinical features in both. *S. paratyphi* A or S. *paratyphi* B can manifest with jaundice, thrombosis, and systemic infections. *S. paratyphi* B might occasionally have an onset similar to non-specific *Salmonella* gastroenteritis. Relapse has been reported with *S. paratyphi* A. *S. paratyphi* C has a limited distribution (common in Guyana and Eastern Europe). It causes mainly bacteraemia and occasionally abscesses, arthritis, and cholecystitis.

DIAGNOSIS

Typhoid should be considered in any patient with prolonged unexplained fever (sustained or remittent temperature) around 39.5°C (103°F) and appearance of rose spot in such a case would be diagnostic.

Definitive diagnosis of typhoid fever depends on isolation of *S. typhi* or *S. paratyphi* from blood, bone marrow, stool, urine or other body fluids. Blood culture followed by microbiological identification is the mainstay diagnosis of typhoid fever. The yield of blood culture is quite variable; it can be as high as 90% during the first week of infection and decrease to 50% by the third week. A low yield is related to low numbers of *Salmonella* in infected patients and/or to recent antibiotic treatment. Bone marrow culture is more sensitive and gives positive results in up to 80% to 95% of patients even after antibiotics have already been given. Blood culture facilities are often not available in many regions, and *the method is laborious and long.* However, in the absence of a culturable organism, patient's antibodies may provide evidence of infection with the serovars of *Salmonella.* The Widal test has long been used as a serological aid in diagnosis of typhoid fever. The high number of false-positive and false-negative test result limit its clinical usefulness. To make a diagnosis, results from a single acute sample should be interpreted against the appropriate local cut-off value or there should be a four-fold rise in the antibody titres between convalescent and acute sera.

Other new-generation, rapid, serological diagnostic tools have limitation because of their low sensitivity and/or specificity. The most promising recently published results are from PCR-based amplification of DNA from the blood of enteric fever patients but again this technique is not available in resource poor countries.

Haematological investigations are non-specific, leucopaenia and neutropaenia are common. However, leucocytosis can develop (especially, in children) during the first 10 days of the illness, or later if the disease course is complicated by intestinal perforation or secondary infection.

A chronic carrier state can be distinguished by the serological response to the Vi polysaccharide, since carriers often have very high antibody titres to this antigen.

TREATMENT

General Management

Supportive measures such as adequate rest, tepid bath and sponging, appropriate nutrition and diet, all are important in the management of typhoid fever. Anti-pyretics (such as paracetamol 250-750 mg orally every 4 to 6 hours) may be given to control fever.

Anti-Microbial Therapy

In the pre-antibiotic era, the mortality rate of typhoid fever was as high as up to 15%. The introduction of treatment with chloramphenicol in 1948 greatly altered the disease course, decreasing mortality to less than 1% and duration of fever from 14 to 28 days to 3 to 5 days. Chloramphenicol (2 to 4 gm/day for adults or 50 mg/kg for children, in divided doses) remained the standard treatment for enteric fever until the emergence of plasmid-mediated resistance to this drug in 1970s. Due to global spread of chloramphenicol resistant *S. typhi* by the 1980s, ampicillin (1gm orally every 6 hour) and trimethoprim-sulphamethoxazole (TMP-SMX; one double strength tablet

twice daily) became the mainstay of the treatment. Multi-drug resistance *S. typhi*, defined as resistance to all first-line anti-microbials (ampicillin, co-trimoxazole, and chloramphenicol), were first described in India in 1990. With the emergence of multi-drug resistance, either quinolones or third-generation cephalosporins are currently recommended for empirical antibiotic treatment of typhoid fever. The greatest experience has been gained for ciprofloxacin (500mg orally twice a day for 10 days). Ciprofloxacin is also the drug of choice for patients with *S. paratyphi* infection. Ofloxacin (10 to 15 mg/kg in two divided doses) has also been successful. More recently, the emergence of high-level ciprofloxacin resistance in *S. typhi* and *S. paratyphi* A, third-generation cephalosporins, i.e. ceftriaxone (1 to 2 gm intravenous or intramuscular for 10 to 14 days) and azithromycin (1 gm orally once a day for 5 days or 1 gm orally on day 1 followed by 500 mg orally for 6 days) are the drugs of choice.

Treatment with dexamethasone (3 mg/kg for the initial dose, followed by 1 mg/kg every 6 hours for 48 hours) has been recommended among severely ill patients with shock, obtundation, stupor or coma.

Patients who develop chronic carriage of *Salmonella* can be treated with oral amoxicillin, TMP-SMX, ciprofloxacin, or norfloxacin for 6 weeks.

COMPLICATIONS

The commonest complications, occurring in the 3rd and 4th weeks of infection, include intestinal perforation and/or gastrointestinal haemorrhage and typhoid encephalopathy. Gastrointestinal bleeding occurs in 10% to 20 % of cases due to erosion of a necrotic Peyer's patch into an intestinal vessel and is usually restricted to either occult blood in stool or melaena. In 1% to 2% of cases, bleeding is significant, and can be rapidly fatal if a large vessel is involved. Intestinal (usually ileal) perforation is the most serious complication occurring in 1% to 3% of cases. Some patients manifest neuropsychiatric symptoms. Severe complications, such as disseminated intravascular coagulation and haemorrhages can lead to rapid death. Rare complications whose incidences are reduced by prompt antibiotic treatment include pancreatitis, hepatic and splenic abscesses, endocarditis, pericarditis, orchitis, hepatitis, meningitis, nephritis, myocarditis, pneumonia, arthritis, osteomyelitis and parotitis. There is no difference between complication rates between *S. paratyphi* and *S. typhi*.

Approximately 1% to 5% of patients with enteric fever become asymptomatic carriers. Carriers of *S. typhi* are either convalescent carriers who excrete the organism for a limited period of time after apparent clinical cure, or chronic carriers in whom persistent excretion of *S. typhi* in stool or urine can be detected a year after clinical illness. The incidence of chronic carriage is higher among persons with biliary abnormalities and gastrointestinal malignancies. Asymptomatic intestinal carriers are common in endemic areas and are important sources of infection.

PROGNOSIS

Despite prompt antibiotic treatment, relapse occurs in 5% to 10% of patients, usually 2 to 3 weeks after defervescence. When untreated, the fever persists for 2 weeks or more and defervescence occurs slowly over the following 2 to 3 weeks. Convalescence may last for 3 to 4 months. Death occurs in between 10% and 30% of untreated patients following complications.

If an appropriate antibiotic is given the fever gradually falls over 3 to 4 days. Morbidity and mortality are increased in those individuals infected with multi-drug resistance isolates of *S. typhi*.

PREVENTION

At present enteric fever prevention focuses on improving sanitation, ensuring the safety of food and water supplies, identification and treatment of chronic carriers of *S. typhi*, and use of typhoid vaccines to reduce the susceptibility of hosts to infection. Vaccination is recommended for use in travellers to endemic areas, for household contacts of typhoid carriers, and laboratory workers likely to handle *S. typhi* in preventing and controlling epidemics, as well as for children in endemic settings aged 2 to 20 years.

The old parenteral killed whole-cell typhoid-paratyphoid A and B vaccine has been largely discontinued because of its high reactogenecity. Two safe and efficacious vaccines, the injectable Vi polysaccharide and the oral Ty21a, have been licensed.

The parenteral Vi polysaccharide vaccine is composed of purified Vi polysaccharide from *S. typhi*. It is suitable for adults and children over the age of 2 years and is without serious side effects. A single subcutaneous or intra-muscular dose of 0.5 ml (25 µg) confers protection within 7 to 10 days of inoculation and requires a booster every 2 years.

The *S. typhi* strain Ty21a is a live attenuated oral vaccine. Enteric coated capsules are given on alternate days for four doses. It is safe for adult and children over 6 years of age. The vaccine confers protection within 10 to 14 days after the last dose and a booster dose is recommended every 5 years. The vaccine is well tolerated but as it is a live attenuated vaccine should not be given to immunocompromised patients or patients taking anti-microbials.

A new *S. typhi* Vi conjugate vaccine has been developed, conjugating Vi to a carrier protein to enhance immunogenecity, and is highly effective in children younger than 5 years but it has not been tested in infants.

Since there is no licensed vaccine for paratyphoid fever, it is important that travellers are additionally encouraged to exercise basic food and water hygiene measures while visiting endemic areas.

17.15 Bacillary Dysentery

Pankaj Tyagi, Jyotsana

Dysentery is an acute inflammatory condition of the large intestine characterised by diarrhoea with blood and mucous in the stool. Bacillary dysentery is an acute bacterial disease involving the large and small intestine manifested by the presence of loose stool mixed with blood and mucous, accompanied by fever, abdominal cramps and tenesmus (a symptom characterised by incomplete sense of evacuation with rectal pain). It is caused by bacteria of the genus *Shigella*, of which *S. dysenteriae* type 1 causes the most severe disease and the largest outbreaks (other species include *S. flexneri, S. sonnei* and *S. boydii)*. It is the most important cause of acute bloody diarrhoea.

EPIDEMIOLOGY

Shigellosis occurs worldwide, and it tends to occur whenever war, natural calamities (e.g. earthquakes, floods), or unhygienic living conditions result in overcrowding (refugees in camp, soldiers in campaigning armies and groups in pilgrims) and poor sanitation. *S. boydii* and *S. dysenteriae* are more common internationally. Disease from *Shigella* species cause an estimated 1 million deaths and 165 million cases of diarrhoea annually worldwide. In India, infectious diseases kill about 11 million children each year while acute diarrhoeal diseases account for 3.1 million deaths in children under 5 years of age, of which 6,00,000 deaths annually are contributed by shigellosis alone. In India, epidemics were mainly encountered in Southern India (Vellore—1972-73, 1997-2001), Eastern India (1984) and Andaman and Nicobar Islands (1986). Recent outbreaks (2002-03) of multi-drugresistant *S. dysenteriae* type 1 have been reported from Siliguri, Diamond Harbour, Kolkata, and Aizwal and Bangladesh. *S. flexneri* is the most common serogroup isolated in India.

Shigellosis is a highly contagious disease. Humans are the principal reservoir of infection. The organism is acid resistant and can easily pass the gastric acid barrier. The infective dose is as low as 10 to 100 organisms. The disease is transmitted faeco-orally, the commonest modes being person-to-person contact and contaminated food and water. Infected food handlers can spread the disease. Sometimes consumption of raw vegetables harvested in fields where sewage is used as fertiliser can cause contamination. Flies can breed in infected faeces and contaminated food, which further spread the infection. **Table 1** enlists the groups which are particularly at high-risk of dysentery.

Table 1: High-risk Groups for Developing Bacillary Dysentery

1. Children under 5 years of age, infants, severely malnourished and history of measles in past 6 weeks
2. Older children and adults who are obviously malnourished
3. Patients who are severely dehydrated, have had a convulsion, or are seriously ill when first seen
4. Adults 50 years of age or older
5. International travellers
6. Homosexual men
7. People with human immunodeficiency virus (HIV) infection

CLINICAL FEATURES

After an incubation period of 1 to 7 days (average 3 days), *Shigella* organisms invade the intestinal mucosa and cause inflammation. The hallmark of clinical shigellosis is an acute rectocolitis manifesting as fever and bloody diarrhoea, with tenesmus. Initially patient presents with history of sudden onset severe abdominal cramping, high-grade fever, emesis, anorexia, and large-volume watery diarrhoea and this is followed by abdominal pain, tenesmus, urgency, faecal incontinence, and small-volume mucoid diarrhoea with frank blood. As such shigellosis is often self-limiting and mild but occasionally it can be serious.

Complications of shigellosis, such as electrolyte imbalance (especially, hypokalaemia), metabolic acidosis and shock, are not common but may be fatal in children and patients who are debilitated. Seizures, the most common neurologic complication, are always associated with fever and are generalised. They are typically non-recurring and uncomplicated. Seizures are least common with *S. dysenteriae*. The prevalence of seizures is approximately 10% across all ages. Encephalopathy with lethargy, confusion, and headache has been noted in up to 40% of children hospitalised with *Shigella* infections.

Less common complications include conjunctivitis, iritis, arthritis, rectal prolapse, secondary bacterial infection, acute blood loss from mucosal ulcers, and toxic neuritis.

DIAGNOSIS

1. Acute diarrhoea often with blood and mucous.
2. Crampy abdominal pain and systemic toxicity.
3. White blood cells in stool; organism isolated on stool culture.

The diagnosis of acute bacillary dysentery should be suspected by the acute onset of the triad of lower abdominal pain, rectal burning and diarrhoea. Stool examination plays a very important role in diagnosis and differentiating it from other aetiologies. Faecal specimens are the best source of a positive culture; blood and urine are only rarely positive in acute cases. Collection and transport of faecal sample should be handled carefully as *Shigella* spp. may not survive the pH changes that occur in faeces specimens which are not properly delivered to the laboratory even if refrigerated. Cary and Blair transport medium which is available at most of the intermediate laboratories, is a satisfactory transport medium.

Blood tests are indicated for severely dehydrated patients and/or those who will undergo intravenous rehydration. These should include a complete blood count, acid-base status, glucose, electrolytes, creatinine and blood urea nitrogen. The urine output should be monitored in all patients with severe dehydration and impaired renal function.

Most of the PCR methods established for the identification of *Shigella* in stool and blood are targeted towards either invasive-

associated locus (*ial*) gene or invasive plasmid antigen (*ipa*) H locus. In most of these studies, PCR was found to be more sensitive and specific technique than the conventional culture methods and has the potential to be employed in routine diagnosis.

DIFFERENTIAL DIAGNOSIS

Various infectious and non-infectious conditions come in the differential diagnosis of dysentery and are enumerated in **Table 2**.

Table 2: Differential Diagnosis of Dysentery

Infectious	Non-infectious
Shigella	Diverticular disease
Campylobacter	Rectal or colonic malignancy
Non-typhoidal *Salmonella*	Inflammatory bowel disease
Entero-invasive *E. coli*	Anal fissure
Enterohaemorrhagic *E. coli*	Ischaemic colitis
Clostridium difficile	Intussusception
Vibrio parahaemolyticus	Haemorrhoids
Entamoeba histolytica	

Among infectious causes, clinically, it is very important to differentiate between bacillary and amoebic dysentery as management differs in both the cases. Bacillary dysentery usually occurs in the form of outbreaks while amoebic dysentery presents as sporadic cases. The diagnosis is based upon microscopic examination and isolation of the organism in stool in most cases, but blood culture positivity is less than 5% in bacillary dysentery. **Table 3** outlined the microscopically differentiating features for bacillary and amoebic dysentery.

Table 3: Differentiating Features between Bacillary and Amoebic Dysentery

Microscopic Features	Bacillary Dysentery	Amoebic Dysentery
Pus cells	Numerous	Scanty
Red blood cells (RBCs)	Discrete	In clumps
Macrophages	Present and show ingested RBC	Absent
Eosinophils	Absent or rare	Present
Charcot Leyden crystals	Absent	Present
E. histolytica	Absent	Trophozoites present
Growth on MacConkey agar	Positive for *Shigella*	Negative

Another clinical condition to be differentiated from dysentery is acute episode of ulcerative colitis. Differentiating features between the two are: self-limiting episode without relapse and positive culture of pathogen in case of bacillary dysentery, sigmoidoscopy reveals an inflamed, engorged mucosa with punctuate and sometime large area of ulceration.

TREATMENT

General principles of treatment include:

1. Fluid therapy
2. Correction of electrolyte imbalance
3. Supportive treatment for fever
4. Antibiotic therapy

Shigella infection generally is a self-limited diarrhoeal illness that lasts 5 to 7 days and may not require antibiotics in individuals who are otherwise healthy. Antibiotic treatment is recommended for infants or older patients, malnourished children, patients infected with HIV, food handlers, health care workers and children in day care centres.

Ampicillin was previously the preferred antibiotic with trimethoprim-sulphamethoxazole (TMP-SMX) as an alternative choice. With development of resistance against these drugs, quinolones, such as ciprofloxacin, ofloxacin, and norfloxacin, are the drugs of choice. Single-dose therapy with 1 g of ciprofloxacin is as effective as two doses or a 5-day standard regimen in patients with *Shigella* infection; however, single-dose therapy proved less effective than multiple-dose regimens for patients with *S. dysenteriae* 1.

Broad spectrum third-generation cephalosporins with Gram-negative activity have higher efficacy against resistant organisms. Even azithromycin can also be used to treat mild-to-moderate infection. Drug dosages are mentioned in **Table 4**.

Table 4: Drug Dosages for Dysentery

Drug	Adult Dose
TMP-SMX	SMX 800 mg/160 mg TMP PO bid for 5 d
Ciprofloxacin	500 mg PO bid for 5 d
Ceftriaxone	Uncomplicated infections 250 mg IM once; not to exceed 4 g Severe infections 1-2 g IV qd, or divided bid; not to exceed 4 g/d
Azithromycin	Day 1: 500 mg PO Days 2-5: 250 mg PO qd

Anti-diarrhoeals that slow the intestinal motility are contraindicated in shigellosis because they delay faecal excretion of *Shigella* and prolong fever and diarrhoea. Vaccination offers the greatest hope as an effective and sustainable strategy against enteric illness. The greatest barrier to the use of vaccine against shigellosis in developing areas is the poor immune responses to oral vaccines in children, who have minimal maternal antibodies, and are therefore, susceptible to infection. An investigational vaccine containing attenuated strains of *Shigella* appears promising in preventing the shigellosis.

17.16 Cholera

SK Bhattacharya, Dipika Sur

HISTORICAL PERSPECTIVE

Cholera is prevalent since ancient times and is of immense public health importance. Severe cholera is characterised by passage of profuse watery diarrhoea; vomiting and life-threatening dehydration. Occasionally, the disease is mild or asymptomatic.

Pacini, an Italian scholar was the first scientist to find *Vibrio cholerae* in the intestinal contents of patients who had died from cholera in 1854. Robert Koch a German bacteriologist first isolated and cultured *Vibrio cholerae* in Kolkata Medical College in 1884. In 1959, Dr SN De, pathologist in Kolkata, first discovered the enterotoxin of *V. cholerae* in animal experiments.

EPIDEMIOLOGY

Cholera is caused by toxigenic *Vibrio cholerae*. There are two serogroups of *Vibrio cholerae* namely O1 and O139. *Vibrio cholerae* O1 is divided into two biotypes: Eltor and Classical. Each of them can further be classified into serotypes: Ogawa and Inaba. Cholera can occur as sporadic cases, as epidemics and even pandemics. In 1992, a new strain of *Vibrio cholerae* non-O1 designated as Cholera O139 Bengal, originated in South India and spread through the Gangetic delta of India and Bangladesh and to neighbouring countries. Clinically the disease is indistinguishable from cholera O1 and WHO has recommended it as a notifiable disease.

Cholera is reported every year from one or the other part of India. Of India's 35 states and union territories, 21 reported cholera cases during at least one year between 1997 and 2006. The state of West Bengal reported cases during all 10 years, while the state of Maharashtra and the union territory of Delhi reported cases during nine, and Orissa during seven. There were 68 outbreaks in 18 states, and 222,038 cases were detected overall. This figure is about six times higher than the number reported to WHO (37,783) over the same period. The states of Odisha, West Bengal, Andaman and Nicobar Islands, Assam and Chhattisgarh accounted for 91% of all outbreak-related cases.

Cholera is spread by oro-faecal route, and rarely, from person to person contact. The incubation period is 2 to 5 days. For each symptomatic case, there are about five asymptomatic cases of classical cholera and 25 of El Tor cholera. It has a seasonal predilection occurring during summer and monsoon months. A person who has recovered from cholera may have long lasting immunity and is protected from subsequent infection for at least three years. Immunity is correlated with vibriocidal antibody titre in blood. Persons with blood Group O are more susceptible to cholera.

PATHOGENESIS

After ingestion of water or food contaminated with *Vibrio cholerae* O1 or O139 (at least 10^9 live organisms), the organisms pass the acid barrier of the stomach (achlorhydria facilitates the passage of the bacteria from the stomach to small intestine) and settle down in the small intestine. The bacteria then colonise the small intestine with the help of toxin-coregulated pillus (Tcp) and produces cholera toxin (CT). The CT has two subunits—A (active) and B (binding). The B subunit attaches to the GM1 ganglioside present in the gut mucosal surface. Subunit A consists of A1 and A2. The A1 subunit enters the mucosal cell and A2 helps to stabilise the toxin. The A1 subunit stimulates the adenylate cyclase and cyclic AMP and produces loss of fluid and electrolytes from the cell to the gut lumen. This occurs in the small intestine. The colon is also in a secretory phase. When the intestinal secretion exceeds the capacity of colonic absorption, it results in watery diarrhoea with flecks of mucous suspended in it (known as 'rice-watery stools'). However, there is no evidence of structural change in the gut mucosa in cholera.

In the inter-epidemic period, *V. cholerae* has been shown to reside in riverine, estuarine, and coastal waters along with its host, the copepod, a significant member of the zooplankton community. They remain in a viable but non-culturable form. With change of temperature, salinity, rainfall and bloom of the planktons, the organisms multiply which is an important factor in the ecology of *V. cholerae*, influencing the transmission of the disease in those regions of the world where the human population relies on untreated water as a source of drinking water.

CLINICAL FEATURES

In cholera, there is loss of large amount of fluid rich in electrolytes in the stool and this loss results in 'dehydration'. It can be classified into mild, moderate and severe. WHO manual on treatment of acute diarrhoea, however, classifies dehydration as 'diarrhoea with no dehydration' and 'diarrhoea with dehydration' (sub-classified as 'some' and 'severe'). In mild dehydration, the patient is thirsty and may not have other signs of dehydration. In moderate to severe dehydration, the patient has reduced skin turgor, sunken eyes, dry mouth with loss of tear, tachycardia, hypotension and may even become comatose. Hypotension can result in acute tubular necrosis and acute renal failure.

Cholera can affect all ages including children below two years. Pregnant women are believed to be more susceptible and the disease commonly results in abortion. Cholera occurring in the third trimester of pregnancy is associated with 50% risk of foetal mortality, even when the mother receives prompt and adequate therapy. Such women also suffer a great degree of fluid deficit than do non-pregnant women.

Haemoconcentration, neutrophilic leucocytosis, pre-renal azotaemia, acidosis and elevated anion gap are discernible on investigations in severe cases.

DIAGNOSIS

The diagnosis of cholera in endemic countries and in a field/emergency situation is on the basis of a hanging drop preparation wherein the characteristic darting motility can be identified. Serotype identification is by immobilisation using specific sera. For laboratory isolation, selective media need to be employed (TCBS- thiosulphate-citrate-bile salt-sucrose agar). PCR and monoclonal-antibody-based kits are also available for identification of *V. cholerae*.

TREATMENT

Treatment of cholera is essentially prevention and correction of dehydration. Prevention of dehydration in cholera can be done by giving extra fluid [like oral rehydration salt solution (ORS) or home-available fluid like salt-sugar solution, weak tea, coconut water, etc.], extra food to prevent undernutrition and watching for symptoms of severe dehydration like passage of many watery stools, fever, sleepiness, sunken eyes, not recovering in three days and for blood in stool (shigellosis). Mild-to-moderate (some) dehydration is treated with ORS (sodium chloride 3.5 g, potassium chloride 1.5 g, sodium bicarbonate 2.5 g or tri-sodium citrate dehydrate 2.9 g and glucose 20 g dissolved in 1 litre of clean water, osmolarity 311). It should be given as 75 ml/kg body weight within 4 hours. Cholera with 'severe' dehydration must be treated with intravenous Ringer's Lactate (30 ml/kg in 30 minutes and then 70 ml/kg in 2-1/2 hours to correct initial fluid deficit and then maintenance can be done with ORS. Sometimes during the maintenance phase, severe dehydration may recur which may again require IV fluid. With the low osmolarity ORS recommended by WHO, unscheduled IV requirement is cut down by 33%. The composition of hypo-osmolar ORS is sodium chloride 2.6 g, potassium chloride 1.5 g, trisodium citrate dehydrate 2.4 g, and glucose 16.2 g in 1 litre of water, osmolarity 224.

Antibiotic should be given orally in case of severe cholera as an adjunct to rehydration therapy. The antibiotic of choice is oral tetracycline 500 mg 4 times daily for 3 days or doxicycline 300 mg single dose. Such use of antibiotic helps in reduction of stool volume, minimize IV fluid requirement and shortens the duration of hospitalisation and excretion of vibrios in stool. Quinolones in standard doses can also be used. Anti-secretory and anti-motility drugs are not recommended.

Zinc supplementation during an episode of diarrhoea, reduces duration and severity of the episode. Additionally, supplements given daily for 10 to 14 days following the episode, reduces the occurrence of diarrhoea for the next 3 to 4 months. Recommended daily dose is 10mg zinc for infants under 6 months of age and 20 mg for older children for 10 to 14 days.

Probiotics may have a beneficial effect on the health and well being of the host and can offer a safe intervention in acute diarrhoea. However, role in cholera treatment has not been established.

PREVENTION AND CONTROL

While cholera no longer poses a threat to countries with minimum standards of hygiene, it remains a challenge to countries where access to safe water and proper sanitation are not guaranteed and especially in areas where overcrowding and poor sanitation are common, such as slums and refugee camps. Health education and social mobilisation for behaviour change with regard to personal hygienic measures are helpful for control of not only cholera but all water borne diseases. Hand washing with soap especially before eating, after defaecation and before cooking reduces the incidence of diarrhoeal cases in the community by interruption of transmission of the pathogens.

CHOLERA VACCINES

Vaccination against cholera can be used for prevention. Oral cholera vaccine (Shanchol®), which is effective (68% protection at the end of 2 years), cheap and safe, is now available in India. Heat or formalin killed whole-cell *V.cholerae* O1 vaccine with a recombinant B subunit of cholera toxin, (Dukoral®) is licensed in several industrialised countries and used mostly for travellers' diarrhoea but is prohibitively expensive. A live attenuated (CVD 103-HgR) oral cholera vaccine (Orochol®, Mutacol®) was licensed internationally but presently manufacture has been withdrawn.

17.17 Diseases Caused by Gram-Negative Enteric Bacilli

Richa Dewan, Vivek Kumar

Gram-negative bacilli (GNB) are responsible for numerous diseases. Some are commensal organisms present among normal intestinal flora. These commensal organisms plus others from animal or environmental reservoirs may cause disease. Every year an estimated 21.25 lakh deaths are reported worldwide and around 60 million DALYs are lost. GNB are responsible for around 20% to 30% episodes of intestinal infections. Besides, various extra-intestinal infections like urinary tract infections (UTIs), peritonitis, and bloodstream infections are commonly caused by GNB. Gram-negative enteric bacilli include *Escherichia coli, Klebsiella, Proteus, Enterobacter, Serratia, Citrobacter, Morganella, Providencia, Edwardsiella, and Acinetobacter* spp.

ESCHERICHIA COLI INFECTIONS

Gram-negative enteric bacilli are associated with intestinal and various extra-intestinal diseases. Depending on both the host and the pathogen, nearly every organ or body cavity can be infected with GNB.

Extra-Intestinal *E. Coli* Infections

E. coli is responsible for several extra-intestinal syndromes which include: (a) UTIs, (b) septicaemia, (c) neonatal meningitis, and (d) other infections.

Urinary tract infections

E. coli is the most common bacterium responsible for causing more than 80% community-acquired UTI. *E. coli* can cause wide range of manifestations including uncomplicated urethritis or cystitis, symptomatic cystitis, pyelonephritis, acute prostatitis, prostatic abscess, or urosepsis. Uncomplicated cystitis occurs primarily in sexually active females due to faecal contamination of the periurethral region by uropathogenic strains of *E. coli*. The bacteria reach the urinary bladder during sexual intercourse. Most of the strains of *E. coli* are capable of causing UTI, but the disease is more common with certain specific *E. coli* serogroups. These serogroups are known as nephritogenic strains which include *E. coli* serotypes O1, O2, O4, O6, O7, O18, etc.

The most frequent symptom of UTI is dysuria, often associated with urgency and increased frequency of micturition. Associated symptoms are fever, chills, backache, suprapubic pain, and nausea and vomiting. The incidence of UTI is much higher in females during adolescence and child-bearing years. After 60 years of age incidence is similar in men and women.

Septicaemia

E. coli causes septicaemia which is usually associated with UTI, especially in cases of urinary obstruction. The endotoxin or lactamase producing strains (LPSs) of the bacteria cause a systemic reaction which can lead to disseminated intravascular coagulation and even death. The mortality and morbidity associated with *E. coli* septicaemia is similar to other aerobic Gram-negative bacilli.

Neonatal meningitis

E. coli are an important cause of meningitis in neonates. In adults, it occurs following neurosurgical procedures, central nervous system (CNS) trauma, or complicating *Strongyloides stercoralis* hyper-infection involving the CNS. Neonatal meningitis has a mortality rate of 8%.

Other infections

These include intra-abdominal infections due to *E. coli*, often resulting from a perforated appendix, diverticulum, or due to intra-abdominal abscess, cholecystitis, and ascending cholangitis. Septic arthritis, endophthalmitis, sinusitis, osteomyelitis, endocarditis, or skin and soft tissue infections are the other pyogenic infections caused by *E. coli*.

Diagnosis

The strains grow both aerobically and anaerobically within 24 hours on standard diagnostic media. Most strains ferment lactose rapidly and are indole positive.

Treatment

Currently isolated strains are resistant to quinolones, cephalosporins, monobactams, and aminoglycosides except amikacin. Till recently, carbapenems and amikacin were considered the most predictable active agents. But with the evolution of superbugs carrying New Delhi beta-metallo lactamase (NDML) gene for beta-metallo lactamase, no available broad-spectrum antibiotic can be relied upon. In practice the sensitivity results should guide the choice of anti-microbial therapy.

Antibiotic Resistance

Antibiotic sensitivities of different strains of *E. coli* vary widely. Antibiotics which may be used to treat *E. coli* infection include amoxicillin as well as other semi-synthetic penicillins, cephalosporins, carbapenems, aztreonam, trimethoprim-sulphamethoxazole, ciprofloxacin, nitrofurantoin and the aminoglycosides.

Antibiotic resistance is a growing problem. This is attributed to overuse of antibiotics in humans, and as growth promoters in food of animals. Once acquired, the antibiotic-resistant *E. coli* pass on the genes responsible for antibiotic resistance to other species of bacteria, such as *Staphylococcus aureus*. *E. coli* carry multidrug resistant plasmids and under stress readily transfer these plasmids to other species. *E. coli* is frequently present over biofilms with many other species of bacteria. This mixing of species allows *E. coli* strains to accept and transfer plasmids to other bacteria. Thus, *E. coli* and the other enterobacteria are important reservoirs of transferable antibiotic resistance. The most important mechanism of drug resistance is by enzymatic destruction of drugs with the aid of beta-lactamase enzymes. These beta-lactamase enzymes make many penicillins and cephalosporins ineffective. Extended-spectrum

beta-lactamase-producing *E. coli* are highly resistant to an array of antibiotics and infections by these strains are difficult to treat. Recently concern has been raised about the prevalence of a form of 'superbug' in the United Kingdom. This name is given due to presence of carbapenemases, which destroy most of the broad-spectrum antibiotics including carbapenems. Gene encoding these enzymes has been termed as New Delhi beta-metallo lactamase, because it was first identified in patient treated in New Delhi. Preliminary reports of *in vitro* sensitivity to only 2 available antibiotics (colistin and tigecycline) are available.

Gastroenteritis

Gastroenteritis is caused by exogenous infections acquired from water, food, or vegetables contaminated with faecal *E. coli*. The strains of *E. coli* that cause gastroenteritis are classified into the following six groups: (1) enteropathogenic (EPEC), (2) enterotoxigenic (ETEC), (3) enteroinvasive (EIEC), (4) enterohaemorrhagic (EHEC), (5) enteroaggregative (EAEC), (6) diffusely adherent *E. coli* (DAEC) (**Table 1**).

EPEC, EAEC, and DAEC cause watery diarrhoea and dysentery. EPEC primarily affects infants and children in developing countries. It can lead to dehydration, if acute and failure to thrive when chronic. Specific serogroups commonly associated with outbreaks of EPEC include O26, O55, O86, O111, O114, O119, O125, O126, O128, and O142.

ETEC is distributed widely in areas with poor sanitation with contaminated food and water. Person-to-person transmission does not occur. ETEC is the primary cause of traveller's diarrhoea in the developed countries. In developing countries, ETEC causes diarrhoea among all ages but infants and children suffer more severe disease because of lack of immunity to ETEC surface antigens. Incubation period is short, varies from 1 to 3 days. The condition manifests by the sudden onset of watery diarrhoea without blood, mucous, or faecal leucocytes. Vomiting may be present. Fever is typically absent. This is a self-limiting condition and persists for less than 5 days.

EIEC produce diarrhoea and dysentery, similar to that caused by *Shigella* species. These strains cause watery diarrhoea, dysentery, fever, vomiting, painful abdominal cramps, and tenesmus. Stools often contain blood and leucocytes.

EHEC is an important cause of food-borne illness, particularly in developed countries. EHEC is a common microbiological flora of the intestine of cattle. Thus, cattle are the primary reservoir of EHEC. The infection is acquired by ingestion of beef products or foods contaminated with cattle faeces containing EHEC strains. EHEC is responsible for causing two distinct syndromes: haemorrhagic colitis and haemolytic uraemic syndrome (HUS) by producing two shiga toxins (Stx). The Stx is responsible for the systemic complication and manifestations of the infection.

Haemorrhagic Colitis

Incubation period varies from 1 to 5 days. The condition manifests as watery diarrhoea to severe haemorrhagic colitis. Watery diarrhoea is often accompanied by abdominal cramping and vomiting. In most patients, diarrhoea becomes bloody in 1 to 2 days, but usually is not associated with faecal leucocytes. Fever is present in about a third of cases. The infection typically lasts for 10 days. *E. coli* O157:H7, the most common strain causing EHEC diarrhoea has a small infective dose (around 100 bacilli) and spreads easily from child-to-child by the faecal-oral route.

Haemolytic Uraemic Syndrome (HUS)

It is a serious life-threatening complication seen in around 10% to 20% of children suffering from EHEC diarrhoea. The three important manifestations of HUS include: microangiopathic haemolytic anaemia, thrombocytopaenia, and renal insufficiency. This condition usually develops in the second week of illness, after the child has recovered from diarrhoea. The condition presents with anaemia, weakness, irritability, and oliguria or anuria. Chronic renal failure may develop in 10% of patients with HUS. Nearly 3% to 5% of patients with HUS die of the disease. Stool culture for EHEC is always negative in patients with HUS.

Epidemiology

Geographical distribution: E. coli diarrhoea primarily affects population in the developing countries. There is a worldwide variation in the prevalence of the strains.

Table 1: Diarrhoeal Illness Caused by *Escherichia Coli*

Pathogroup	Subgroup	Toxin/Phenotype	Epidemiology	Clinical Syndrome	Virulence Gene
Enterotoxigenic *E. coli* (ETEC)		Heat-labile toxin (LT) and/or heat-stable toxin (ST)	Food, water; young children and in travellers from developed countries	Traveller's diarrhoea	*elt/est* or both
Enteropathogenic *E. coli* (EPEC)	Typical EPEC Atypical EPEC	Actin accumulation Actin accumulation	Person-to-person; young children and neonates in developing countries	Watery diarrhoea	*eae, bfpAeae*
Shiga toxin-producing *E. coli* (STEC)	Typical STEC Atypical STEC	Verocytotoxin and enterohaemolysin Verocytotoxin	Food, water, person-to-person; all ages, industrialised countries	Haemorrhagic colitis, haemolytic-uraemic syndrome	*eae, stx* and *ehxAstx* with or without *eae*
Enteroaggregative *E. coli* (EAEC)	Typical EAEC Atypical EAEC	Aggregative adherence Aggregative adherence	Food, water; children and travellers from developed countries; all ages, industrialised countries	Traveller's diarrhoea, acute diarrhoea, persistent diarrhoea	*aggR* regulon *(aai)* *(aat)*
Enteroinvasive *E. coli* (EIEC)		Invasion	Food, water; children and travellers from developed countries	Dysentery	Multiple genes

ETEC is the primary cause of traveller's diarrhoea and is the major cause of infantile diarrhoea in poor and developing countries. ETEC cause nearly more than 600 million cases of diarrhoea every year and 700,000 deaths in children below 5 years of age. EHEC are an emerging cause of food-borne disease, particularly in developed countries. EPEC, EAEC, and DAEC have been reported to occur in the developing countries.

Habitat: Most strains of *E. coli* causing diseases in humans are present in intestine. Few strains such as EHEC also inhabit the cattle intestine.

Reservoir, source and transmission of infection: Most extra-intestinal infections are caused by endogenous *E.coli* as a result of direct faecal contamination of the urinary tract. Diarrhoea caused by *E. coli* is exogenous via intake of food and water contaminated with human or cattle faeces. Beef, apple juice, and alfalfa sprouts contaminated with cattle faeces are important source of infection caused by EHEC (O157:H7).

Diagnosis

The diagnosis requires specialised assays, that are not routinely available. Definite diagnosis is generally not necessary. *E. coli* diarrhoea is generally self-limited. The evaluation for STEC/EHEC infection, particularly when associated with bloody diarrhoea is appropriate if resources are available. For screening, serotyping of non-sorbitol fermenting *E.coli* is done for O157. Testing for shiga toxins or shiga genes is more sensitive, specific and rapid.

Treatment

Rehydration and replacement of salt is the mainstay of treatment for all diarrhoeal diseases. Treatment with quinolones shortens duration of illness and hastens recovery. Antibiotic therapy for STEC/EHEC (suggested by the presence of bloody diarrhoea in the absence of fever) should be avoided, because antibiotics may increase the incidence of HUS possibly via increased production and/or release of Stx toxin. For prophylaxis, rifaximin is indicated in patients, who are susceptible to serious infections or cannot afford even minor illness.

KLEBSIELLA

Klebsiella organisms cause a variety of clinical syndromes in humans. These are: (a) community-acquired pneumonia, (b) UTI, (c) nosocomial infection, and (d) bacteraemia and sepsis.

Community-acquired pneumonia is most frequently caused by *Klebsiella pneumoniae* serotypes 1, 2 and 3. It has a rapid onset and often fatal outcome if not diagnosed early. Lobar pneumonia is associated with massive mucoid inflammatory exudates, involving one or more lobes of the lung. Necrosis and abscess formation is more common than pneumococcal pneumonia.

Patients present with an acute onset of high fever with chills, flu-like symptoms, and productive cough with an abundant, thick, tenacious, and blood tinged sputum. Blood culture is positive in about 25% of the cases.

UTI caused by *K. pneumoniae* is a common problem in patients with indwelling catheters. It cannot be distinguished clinically from UTI due to *E. coli* and other common bacteria.

K. pneumoniae are emerging as important agents of nosocomial infections in hospitals. The presence of invasive devices, contamination of respiratory support equipments, use of urinary catheters, and use of antibiotics greatly increases the likelihood of nosocomial infections. In addition, poor health status and treatment in an intensive care unit (ICU) or nursing home are other factors. UTI, pneumonia, bacteraemia, wound infection, cholecystitis, and catheter-associated bacteriuria are the common nosocomial infections associated with *K. pneumoniae.* Other rare nosocomial infections include cholangitis, meningitis, endocarditis, and bacterial endophthalmitis.

Klebsiella bacteraemia and sepsis produce clinical manifestations similar to those caused by *E. coli* and other gram-negative enteric organisms. In neonatal units, outbreaks of infection caused by extended-spectrum beta-lactamase (ESBL) producing *Klebsiella* strains present a more serious problem and may be associated with high mortality. *Klebsiella* has been isolated from hepatic abscesses in diabetic patients. Associated bacteraemia with metastatic complications are common.

Members of *Klebsiella* are found as normal flora in many parts of gastrointestinal tract and biliary tract in humans. They may also colonise the skin and pharynx. Oropharyngeal carriage is usually associated with endotracheal intubation, impaired host immunity and anti-microbial use. The gut of the patient and the hands of hospital personnel are the principal reservoirs of *K. pneumoniae.* Bacteria usually spread rapidly, often leading to nosocomial outbreaks in hospitals.

K. pneumonia typically affects middle-aged and older persons with chronic debilitating diseases such as alcoholism, diabetes, or chronic bronchopulmonary disease. Extensive use of broad-spectrum antibiotics in hospitals has contributed to an increase carriage of *Klebsiella* and, subsequently, the development of multi-drug resistant strains.

K. rhinoscleromatis and K. ozaenae

Rhinoscleroma caused by *K. rhinoscleromatis* is a chronic granulomatous inflammatory disease involving the naso-pharynx. Patients present with a purulent nasal discharge with formation of crusts and nodules that may lead to respiratory obstruction. Ozena is a chronic atrophic rhinitis occurring mostly in elderly persons.

Klebsiella oxytoca

K. oxytoca is responsible for sepsis in neonates admitted in ICU, especially in premature infants.

Diagnosis

Klebsiellae are readily isolated and identified in laboratory. They are usually lactose fermenters except for rhinoscleromatis and ozaenae.

Treatment

Due to the resistance to aminoglycosides, quinolones, cephalosporins, penicillins, empirical treatment of serious *Klebsiellae* infection should include amikacin, carbapenems or tigecycline. Polymyxin B is the agent of last resort because of potential toxicity.

PROTEUS

The genus *Proteus* comprises of four species: *Proteus mirabilis*, *Proteus vulgaris*, *Proteus penneri* and *Proteus myxofaciens*. *P. mirabilis* is the most important species responsible for 90% *Proteus* infections and is associated with community-acquired UTI, bacteraemia, intra-abdominal abscesses, surgical wound infection and the infection of decubitus ulcers. Presence of urease is responsible for the generation of ammonium ions in urine which imparts alkaline pH to the urine. *P. vulgaris* and *P. penneri* are usually associated with hospital-acquired infections.

Diagnosis

Most strains are lactose negative, produce hydrogen sulphide, and demonstrate swarming motility on agar plates.

Treatment

P. mirabilis is usually susceptible to most antibiotics except tetracycline, polymyxin B, and tigecycline. 90% to 100% isolates demonstrate excellent susceptibility to imipenem, cefepime, amikacin and cotrimoxazole.

MORGANELLA, PROVIDENCIA AND ERWINIA

Morganella is an opportunistic pathogen in hospitalised patients. It causes UTI, sepsis, pneumonia, wound infection, pericarditis and spontaneous bacterial peritonitis. *Providencia* is associated with catheter-related UTI and septicaemia in the elderly patients. Some species can also lead to invasive and traveller's diarrhoea. *Erwinia* has occasionally been isolated from respiratory and urinary infections in chronic debilitated and hospitalised patients.

Treatment

These are extensively resistant to antibiotics. Imipenem, amikacin and cefepime are the most active agents.

ACINETOBACTER INFECTIONS

Acinetobacter is being isolated from immunocompromised patients in ICUs. The respiratory tract and intravascular devices are the favoured sites.

Diagnosis

These are GNB or coccobacilli seen on Gram's stain. They are strictly aerobic, non-fermenting, and oxidase negative.

Treatment

These are extensively drug resistant. Empirical therapy using ampicillin/sulbactam, rifampin, tetracyclines, imipenem/cilastatin, tigecycline, and amikacin are often effective though resistance has been reported to all of them.

CAMPYLOBACTER

Campylobacter organisms are microaerophilic, motile Gram-negative rods. Two species infect humans: *Campylobacter jejuni*, causing diarrhoea and *C. fetus*, associated with systemic infection. Dairy cattle and poultry are principal reservoir. Outbreak of enteritis is associated with consumption of raw milk. *Campylobacter enteritis* presents with fever, abdominal pain, and loose, watery, or bloody stools. The disease is self limited.

C. fetus causes fatal systemic infections including primary bacteraemia, endocarditis, meningitis and focal abscesses. Patients are usually old, debilitated or immunocompromised. Closely related species collectively termed 'campylobacter-like organisms' cause bacteraemia in HIV patients. Reactive arthritis and other rheumatological complaints may develop after weeks of primary infection mostly in HLA-B27 phenotype. *C. jejuni* particularly O19 serotype can also trigger Guillain-Barre syndrome or its Miller Fisher or cranial polyneuropathy variant.

Treatment

Fluid and electrolyte replacement is central to the treatment of diarrhoeal illnesses. Antibiotics are indicated for patients with high fever, bloody diarrhoea, severe diarrhoea or persistence for more thant 1 week. Erythromycin in a dosage of 250 mg four times a day for 5 to 7 days is the treatment of choice. Alternatively clarithromycin, azithromycin, ciprofloxacin can be given. For systemic infections, parenteral gentamycin, imipenem, or chloramphenicol can be used for 2 to 4 weeks.

17.18 *Haemophilus Influenzae* Infections

M Sabir, Mansoor Ahmed

INTRODUCTION

The name *Haemophilus* is derived from the Greek nouns 'haima' and 'philos' meaning 'blood lover'. *Haemophilus* species primarily infect human respiratory tract, skin, or mucous membranes. From these sites, organisms can invade and cause bacteraemia, meningitis, epiglottitis, endocarditis, septic arthritis, or cellulitis.

PATHOGEN

It is the first free living organism to have its entire genome sequenced. A member of the *Pasteurellaceae* family, discovered in 1892 by Richard Pfeifer, formerly called Pfeifer's bacillus or Bacillus influenzae, was mistakenly considered to be the cause of influenza (until 1933).

It is a small, pleomorphic, non-motile, non-spore-forming, fastidious, aerobic but a facultative anaerobe, Gram-negative coccobacillus. Two major categories of *H. influenzae* have been defined: encapsulated strains possessing a polysaccharide capsule, are serotyped into 6 different types (a-f) based on their biochemically different capsules, and others having no capsule are termed non-encapsulated *H. influenzae* or non-typeable *H. influenzae* (NTHi).

The most virulent strain is *H. influenzae* type b (Hib), accounts for more than 95% of *H. influenzae* invasive diseases in children and half of invasive diseases in adults.

H. influenzae type a (Hia) has been known to cause invasive disease (e.g. meningitis) clinically indistinguishable from that caused by Hib. The non-encapsulated, or NTHi, strains usually cause mucosal infections. Less commonly, these strains cause invasive disease in children but account for half of the invasive infections in adults.

EPIDEMIOLOGY

The precise prevalence and incidence of *H. influenzae* infections are unknown. This organism can be detected in the nasopharynx of both children and adults. Non-typeable *H. influenzae* can be detected in nasopharyngeal cultures of more than 70% of young children, but infection occurs in only a small proportion of colonised patients. The frequency of Hib infections is more amongst immunocompromised individuals (e.g. asplenia, splenectomy, sickle cell disease, malignancies, and congenital or acquired immune deficiencies) and unvaccinated infants.

Currently, the incidence of Hib invasive diseases has greatly decreased in developed countries because of the widespread use of the Hib conjugate vaccine (while NTHi strains have become the most common cause of invasive disease in all age groups).

However, in many developing countries, invasive Hib disease is still a significant cause of morbidity and mortality. Overall mortality from Hib meningitis is approximately 5% but morbidity rates are high. In one of the Indian study case—fatality rate was 11% overall and 20% in infants with Hib meningitis.

PATHOGENESIS AND IMMUNE RESPONSE

Humans are the only natural hosts. Transmission is by direct contact or by inhalation of respiratory tract droplets. The incubation period is not known. A larger bacterial load or the presence of a concomitant viral infection (especially in immunodeficient individuals, alcoholics and smokers) and winter season can potentiate the infection.

The colonising bacteria invade the mucosa and enter the bloodstream. The presence of antibodies, complements, and phagocytes determines the clearance of the bacteraemia. The anti-phagocytic nature of the Hib capsule and the absence of the anticapsular antibody, lead to increasing bacterial proliferation. When the bacterial concentration exceeds a critical level, it can disseminate to various sites, including meninges, subcutaneous tissue, joints, pleura, pericardia, and lungs.

Host defenses include the activation of the alternative and classical complement pathways and antibodies to the PRP capsule. The antibody to the Hib capsule plays the primary role in conferring immunity. Newborns have a low risk of infection, likely because of acquired maternal antibodies. By the age of 5 years, most children have naturally acquired antibodies. The NTHi strains colonise in the nasopharynx. The spread of bacteria by direct extension to the eustachian tubes causes otitis media, sinusitis, bronchitis and pneumonia.

CLINICAL FEATURES

Clinical manifestations of *H. influenzae* infections range from varying grades of fever, malaise and other constitutional symptoms to life-threatening disease, mostly depending on tissue or organ affected, host defenses, age of the patient, affecting strain of *H. influenzae* and bacterial load.

Meningitis

H. influenzae meningitis commonly occurs in children younger than 5 years. Adults with history of skull trauma or cerebrospinal fluid (CSF) leaks are particularly prone to it. Meningitis is the most serious manifestation of Hib infection.

Clinical manifestations are indistinguishable from other causes of bacterial meningitis. The usual presentation consists of a few days of mild illness, usually antecedent URTI, followed by ominous deterioration. Altered mental status and fever are the most common findings with headache and photophobia (common in older children) followed by seizures and coma as the disease advances. Neck rigidity is often absent in children younger than 18 months. In infants, the disease course may be fulminant, with death occurring within a few hours.

Most patients have CSF white blood cell counts greater than 1000/mm^3 and hypoglycorrhachia (low levels of glucose in CSF

with high levels of protein). CSF Gram stain shows pleomorphic gram-negative bacilli which can sometimes be mistaken for pneumococcal meningitis.

Cellulitis

Fever and a raised, indurated, tender area with indistinct margins mostly on the head and neck, particularly the buccal and preseptal areas are common. Orbital cellulitis is uncommon, and is distinguished from preorbital cellulitis based on the presence of proptosis, chemosis, impaired vision, limitation of extraocular movements, and pain with eye movement.

Epiglottitis

Hib is the commonest cause of acute epiglottitis in both children and adults. In children younger than 5 years, it is a life-threatening infection that usually presents with fever, drooling, dysphasia, and respiratory distress or stridor, which appear over the course of hours.

In adults, fever, sore throat, dysphagia and odynophagia occur. Cervical tenderness and lymphadenopathy can be found at all ages. Laryngoscopy demonstrates a swollen, cherry-red epiglottis, but should be avoided as it may precipitate acute airway obstruction.

Pneumonia

Hib pneumonia is clinically indistinguishable from other bacterial pneumonias except for its insidious onset.

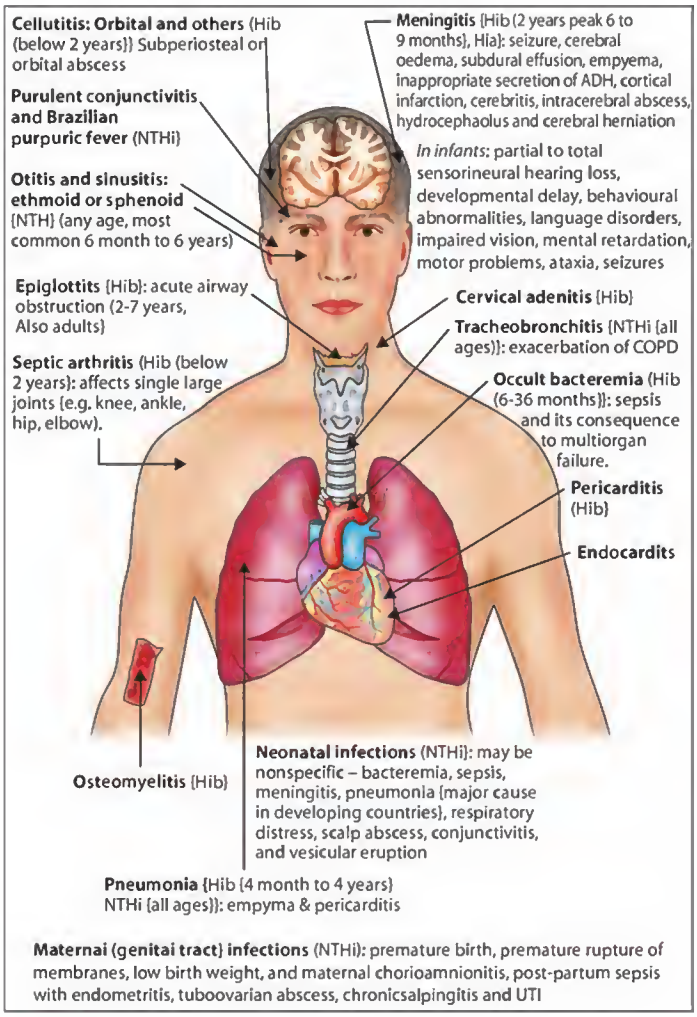

Figure 1: *H. Influenzae* infections: common age of occurrence and complications.

Infection in different organs may lead to local complications and systemic manifestations in the form of sepsis and multiorgan failure as shown in **Figure 1**.

LABORATORY STUDIES

1. Gram-negative, pleomorphic coccobacilli with polymorphonuclear cells are strong evidence of infection.
2. Bacterial culture of blood, CSF and other body fluids is the most reliable method for the diagnosis of Hib infection. It is performed on chocolate agar plate with added X (hemin) and V (nicotinamide-adenine-dinucleotide) factor at 37°C in an enriched CO_2 incubator.
3. The different strains can be identified with slide agglutination for serotyping or polymerase chain reaction for capsular typing.
4. Detection of the PRP polysaccharide capsule via countercurrent immunoelectrophoresis, latex particle agglutination, co-agglutination, and enzyme-linked immunosorbent assay is an important adjunct to culturing in establishing a rapid diagnosis.
5. Chest radiography: Patients with Hib pneumonias tend to have more pleural and pericardial involvement (50% of patients) than those with other bacterial pneumonias. Community-acquired pneumonias due to NTHi show alveolar infiltrates in patchy or lobar distributions.
6. Lateral neck radiography in epiglottitis shows dilatation of the hypopharynx and a swollen epiglottis (the thumbprint sign).
7. Head computed tomography helps identify subdural effusion and other neurological sequelae of meningitis and extent of orbital or other cellulitis.
8. ECG and echocardiography.
9. *Procedures* are performed to obtain appropriate fluid to establish an aetiologic diagnosis: lumbar puncture, bronchoscopy, aspiration (joint, lung, sinus, and soft-tissue), transtracheal aspiration, tympanocentesis, pericardiocentesis, laparoscopy and culdocentesis in women.

TREATMENT

Antibiotics and supportive care in the form of maintenance of airways, nutrition, fluids and electrolyte balance; and treatment and prevention of shock is the main stay of the treatment of *H. influenzae* infections.

Third-generation cephalosporins are highly effective in *H. influenzae* infections. Meropenem or ampicillin and chloramphenicol are alternative regimens. In an Indian study up to 60% of all isolates were resistant to chloramphenicol, ampicillin, trimethoprim-sulphamethoxazole, or erythromycin; 32% were resistant to ≥3 anti-microbial drugs, but none were resistant to third-generation cephalosporins.

Initially, patients with invasive and serious *H. influenzae* infections are best treated with an intravenous ceftriaxone (adult dose: 1 to 2 g intravenously every 12 hours) or cefotaxime (adult dose: 2 g intravenously every 6 hours).

Penicillins are useful in the management of mucosal infections caused by NTHi, but production of beta-lactamase restrict their use.

Table 1: Treatment of *H. influenzae* Infections

Diagnosis	Antibiotics		Other Measures
	Name and Route (P-parenteral, O-oral)	Duration	
Meningitis	Ceft., Cefo., Cftz., Amp., Salb., Fluq., Aztm. (P)	7-14 days	Treatment/prevention of seizures. Patency of airway and *dexamethasone* to prevent neurological complications
Cellulitis Orbital cellulitis	Same (P) till symptoms disappears than (O) Same (O)	7-10 days 14 days	
Epiglottitis	Same (P) till airway is secured, than (O)	7-10 days	Patency of airway, surgical drainage, if needed
Arthritis	Same (P) than (O) until ESR and C-reactive begins to normalise	7 days, 2-3 weeks	
Bacteremia	Same (P) for 2 to 5 days than (O)	Min.10 days*	Same
Non-encapsulated	Amox., Clavn., In penicillin-allergy Erym.,	10 days	
H. influenzae Otitis media	Sulph., Cefc., Trim., Sulx., Cefu. axetil.,Cefm., Clat., Aztm., Fluq. (mostly O)		
Sinusitis	Same (O)		
Conjunctivitis	Topical Sulm. and Erym.	15 days	
Invasive NTHi infection	Same as invasive Hib (P)	14 days	

Note: Generol Meosures – fluid ond electrolyte bolonce, treatment of shock ond other complicotions.

Ceft. *= ceftrioxone;* ***Cefo.*** *= cefotoxime;* ***Cftz.*** *= ceftozidime;* ***Amp.*** *= ompicillin;* ***Salb.*** *= sulboctom;* ***Fluq.*** *= fluoroquinolones;* ***Aztm.*** *= ozithromycin;* ***Amox.*** *= omoxicillin;* ***Clavn.*** *= clovulonote;* ***Erym.*** *= erythromycin;* ***Sulph.*** *= sulphisoxazole;* ***Cefc.*** *= cefoclor;* ***Trim.*** *= trimethoprim;* ***Sulx.*** *= sulphomethoxozole;* ***Cefu.*** *= cefuroxime oxetil;* ***Cefm.*** *= cefixime;* ***Clat.*** *= clorithromycin;* ***Sulm.*** *= sulphocetomide.*

**Potients with pericorditis, empyema, endocorditis, endophtholmitis, or osteomyelitis require ontibiotic for 3 to 6 weeks.*

The site of infection and the clinical response determine the length of antibiotic treatment (**Table 1**).

PREVENTION

Vaccination

The Hib conjugate vaccine induces protection by inducing antibodies against the PRP capsule; it does not provide protection against NTHi strains. It is used for routine immunisation of children but is not indicated in adults.

CHEMOPROPHYLAXIS

The risk of secondary disease is greater among household contacts of patients with Hib disease. Therefore, all members (except children less than 4 years who are completely immunised) should receive oral rifampicin in the doses of 600 mg/day for adults and 20 mg/kg/day for children (<12 years) for 4 days.

17.19 Legionnaires' Disease

PS Shankar

Legionnaires' disease (legionellosis) is a multi-system disorder affecting the lungs, heart, kidney, alimentary tract and central nervous system, and it is due to the infection caused by the bacteria of genus *Legionella*. Legionnaires' disease refers to the pneumonia caused by *Legionella* species. An acute and mild form of the disease, referred as Pontiac fever, is also recognised and it presents as a febrile, self-limited, flu-like illness. There are more than 49 species with more than 64 sero-groups in the family of *Legionellaceae*.

AETIOLOGY

Legionnaires' disease is caused by a Gram-negative, fastidious aerobic, coccobacillus—*Legionella pneumophila*. The serogroups 1, 4, and 6 of *Legionella pneumophila* are the most commonly involved. The *L. micdadei, L. bozemanii, L. dumoffii* and *L. longbeachae* may sometime, cause pneumonia in immunocompromised patients. These organisms are present in soil excavation, construction sites, lakes, ponds, streams, and in air-conditioning cooling towers, refrigerated water, and evaporative condensers. The organism has an affinity for water, particularly if blue-green algae are present. The source of Legionnaires' disease is water. The incidence depends on the degree of contamination of the water reservoir. Often potable water distribution system in hospitals, hotels and large buildings spread the organism. The immune status of the person exposed and the intensity of exposure play important role in the development of infection. The organism does not grow on routine microbiologic media, and can only be grown on a specialised medium of buffered-charcoal yeast extract (BCYE) agar. It needs L-cysteine for its growth.

EPIDEMIOLOGY

The bacterium was first isolated in 1943. Legionnaires' disease was first recognised in 1976 in Philadelphia, USA, when it caused an outbreak of pneumonia amongst the members attending the American Legion (small army) convention in a hotel.

The condition occurs in middle-aged or elderly persons, frequently among males. It spreads by airborne route through inhalation of aerosols, aspiration and direct instillation into the lungs. Aspiration appears to be the predominant mode of transmission. Person-to-person transmission does not take place. Though majority of the cases are sporadic, epidemics have been noted to occur frequently in hotels, and hospital surroundings, building sites and factories, which are exposed to contaminated water reservoirs. The most common risk factors for the development of Legionnaires' disease are presented in the **Table 1**.

Table 1: Risk Factors for Legionnaires' Disease

Cigarette smoking
Alcoholic liver disease
Chronic lung disease
Advanced age
Recent hospitalisation
Recent foreign travel
Immunocompromised patients
Recent surgery under general anaesthesia
Exposure to unhygienic hot-tub spa
Local epidemics around point source or potable water supply
Hairy cell leukaemia

PATHOGENESIS

It has an incubation period of 2 to 10 days. After gaining entry to the lungs, the bacterium gets attached to the host cells. It undergoes phagocytosis by pulmonary alveolar macrophages, where some organisms are killed and some proliferate within the cells till the cell ruptures. The emerging organisms are phagocytosed by newly recruited macrophages and cycle begins afresh. Bacterial uptake and multiplication are halted by cytokines produced by macrophages and lymphocytes. The natural killer (NK) cells lyse the infected macrophages. Thus, cell-mediated immunity by T-lymphocytes plays a dominant role in the immune process as compared to humoral immunity through formation of type-specific IgM and IgG antibodies.

The pathologic changes are essentially confined to the lungs where it produces an acute fibrinopurulent bronchopneumonia and the alveoli are filled with polymorphs admixed with macrophages and a large amount of fibrin. Toxins released by the bacteria may cause an acute necrosis and encephalopathy.

CLINICAL FEATURES

The condition has an acute onset with prodromal features consisting of malaise, fatigue, slight headache and anorexia. Occurrence of myalgia or arthralgia is uncommon. It is followed by high-grade fever, recurrent shaking chills, non-productive cough, dyspnoea, chest pain, breathlessness, and prostration. Later there may be mucopurulent or bloody sputum. Upper respiratory symptoms are uncommon. There can be vomiting, abdominal pain and watery diarrhoea. There may be headache, lethargy, and mental confusion. Patients are occasionally obtunded during the acute phase of illness. Many a times the non-respiratory manifestations may mask the features of pneumonia. There is relative bradycardia especially in elderly patients. Chest examination shows the presence of crackles early in the course of the disease, and later signs of consolidation. Abdominal examination may show localised or generalised tenderness.

INVESTIGATIONS

There is moderate polymorphonuclear leucocytosis. It is associated with thrombocytopaenia. The urine examination may demonstrate presence of proteinuria, microscopic

haematuria or pyuria. Chest radiograph may show patchy infiltrates, which later progress to lobar shadows either unilaterally or bilaterally. The lower lobes are more commonly involved. Pleural effusions are common. Immunosuppressed patients especially those receiving glucocorticoids may show rounded nodular opacity. Computed tomography of the chest demonstrates sharply demarcated peri-bronchial foci of consolidation. These may be unilateral or bilateral, single or multifocal ground-glass opacities. There is marked hypoxaemia, and mild-to-moderate increase in liver enzymes. Often there is hyponatraemia, hypoalbuminaemia, and hypophosphataemia. There is elevation of alkaline phosphatase, creatine phosphokinase and serum creatinine.

The Gram's staining of the sputum reveals numerous leucocytes but no organisms. The organisms may appear as small, pleomorphic, and faintly gram-negative. The *L. micdadei* organisms may be weakly or partially acid-fast. Causative agent may be demonstrated by direct immunofluorescence of the transtracheal or percutaneous lung aspirate, sputum, bronchoalveolar lavage fluid and pleural fluid by using appropriate antibody test. Recognition of the organism in histopathologic sections is easy. The fresh lung tissue imprints can be stained with Gimenez stain whereas the paraffin-embedded sections with buffered Dieterle's silver impregnation stain. The organism can be cultured on the buffered charcoal yeast extract agar (cysteine-supplemented with alpha-ketogluconate). The colonies grow slowly in 3 to 5 days. *Legionella* soluble antigen is detectable in urine in 3 days after onset of clinical manifestations and it remains positive for nearly 2 months. A four-fold rise in indirect fluorescent antibody of more than 1:128 against *L. pneumophila* develops after three weeks of infection.

PROGNOSIS

The severity of the illness ranges from a trivial cough to a rapidly progressive and lethal pneumonia. The disease is considered severe when there is confusion, urea >7 mmol/L, respiratory rate >30/min, hypotension: systolic <90 mm Hg or diastolic <60 mm Hg, and age above 65 years. There is worsening of radiologic shadows. Death occurs from respiratory failure, shock, hypotension and acute renal failure. The mortality varies with patient's underlying disease, severity of the disease, immune status, severity of pneumonia and the time of initiation of therapy. Haematogenous dissemination of organisms may affect heart, lymph nodes, liver and spleen.

TREATMENT

Legionnaires' disease is treated with macrolides and flouro-quinolones. The organisms fail to show a response to beta-lactam antibiotics (penicillin or cephalosporins) and aminoglycoside antibiotics. *Legionella* being an intracellular pathogen, antibiotics that can reach intracellular concentration greater than that of minimal inhibitory concentration are only effective. Newer macrolides, such as azithromycin or clarithromycin compared with erythromycin exhibit superior *in vitro* activity and exhibit greater intracellular activity. They reach higher concentrations in respiratory secretions and in lung tissues. Azithromycin or clarithromycin may be given in a dose of 500 mg intravenously or orally for a period of 5 to 10 days.

Fluoroquinolones (levofloxacin) are advocated for transplant patients. Doxycycline is advocated in patients intolerant of erythromycin or azithromycin. It is to be given 100 to 200 mg orally or intravenously every 12 hours. Levofloxacin 500 mg or ciprofloxacin 750 mg or ofloxacin 400 mg may be administered orally twice a day. *Legionella* is also sensitive to tetracycline and trimethoprim-sulphamethoxazole (Septran). Rifampicin in a dose of 600 mg twice a day may be used in combination with a macrolide or a fluoroquinolone, in those who are severely ill or with extensive cavitatory disease. The condition needs supportive therapy with oxygen, mechanical ventilators, volume replacement, vaso-active agents and dialysis.

17.20 Plague and Other Yersinia Infections

Veena Mittal

PLAGUE

Definition

Plague is an acute specific communicable disease caused by *Yersinia pestis*. It is primarily a zoonosis, being a disease of rodents, and man is affected incidentally. Infection is transmitted to humans typically by flea bite, less commonly by contact with infected animal tissues or airborne droplets. Three major clinical forms of disease are: bubonic, septicaemic and pneumonic plague. *Y. pestis* is considered as a potential biological warfare agent because of its transmissibility and virulence.

Plague is endemic in many countries in Africa, former Soviet Union, the Americas and Asia. From 2004 to 2009, a total of 12,503 cases of human plague, including 843 deaths, were reported by 16 countries in Africa, Asia and the Americas. In India, plague re-emerged in 1994 when outbreak of bubonic plague in Beed and pneumonic plague in Surat led to 876 cases with 54 deaths. Again in 2002, outbreak of pneumonic plague in Himachal Pradesh was reported with 16 cases and 4 deaths and in 2004 a localised outbreak of bubonic plague in Uttarkashi, Uttaranchal with 8 cases and three deaths.

Epidemiology

The epidemiology of plague is extremely complex.

Vector

Fleas are the natural vectors of plague in the world. Nearly 31 species of fleas all over the world have been incriminated as vectors of plague. In India, the fleas considered important for plague transmission are *Xenopsylla cheopis, X. astia and X. brasiliensis*. Out of these *X. cheopis* is the principal vector.

Reservoirs

A large number of mammals may be infected with *Y. pestis*. Rodents are the true natural hosts of *Y. pestis*. At least 220 species of rodents are known to be infected with plague bacillus. *Tatera indica* among the wild rodents and *R. norvegicus* and *R. rattus* among the commensal rodents are found to play an important role as reservoir of *Y. pestis*.

Modes of Transmission

The starting point is always the plague focus. Man can get the infection by bite of infected rat flea, by handling infected animals or material or by droplet infection (primary pneumonic plague).

Aetiological Agent

Y. pestis is a short, thick coccobacillus measuring 1.5-2 x 0.5-0.7 microns in size. It has rounded ends, which with polychromatic stains, i.e. Wayson, Giemsa stain gives a characteristic bipolar appearance to the organism. It is Gram-negative, nonmotile and non-sporing, oxidase and urease negative biochemically non-reactive. True capsules are seen in living tissues but are less readily seen in culture. The organism grows well on blood agar, brain heart infusion agar, Macconkey agar. The optimum temperature for growth is 28°C but for capsular material (envelope substance), organism should be grown at 37°C.

Pathogenesis

Y. pestis is highly invasive and pathogenic. The mechanism by which the organism causes disease are incompletely understood. Three plasmids encode for a variety of virulence factors and a chromosomally encoded lipopolysacchride endotoxin is important in sepsis, triggering the systemic inflammatory response syndrome and its complications.

After *Y. pestis* is inoculated into the skin by flea bite, bacteria migrate to local lymph nodes, where they are taken up but not killed by mononuclear cells. Intracellular multiplication results in development of capsular envelopes containing capsular antigen (fraction 1 antigen) and toxins are liberated. An acute inflammatory response is provoked in the lymph nodes in the ensuing 2 to 6 days (incubation period) resulting into a bubo. Haemorrhagic necrosis of lymph nodes with lysis of macrophages next occurs, from which large number of bacteria gain access to blood stream and other organs.

Primary septicaemic plague consists of sepsis in the absence of a bubo. Secondary septicaemic plague is a complication of bubonic or pneumonic plague that occurs when local host defenses are breached.

Primary plague pneumonia generally begins as a lobular process and then extends by confluence, becoming lobar and then multilobar. In advanced cases of both primary and secondary plague pneumonia, affected lung tissue is characterised by oedema, haemorrhagic necrosis with infiltration by neutrophilic leucocytes.

Clinical Features

Y. pestis infection in humans occurs in one of the three main clinical forms—bubonic, septicaemic and pneumonic.

Bubonic plague

After an incubation period of 2 to 6 days, patients typically experience a sudden onset of illness characterised by malaise, headache, shaking chills, fever and pain in the affected regional lymph nodes which get swollen (buboes) (**Figure 1**). Buboes may occur in any regional lymph node sites such as inguinal, axillary, supraclavicular, cervical, post-auricular, epitrochlear, popliteal or pharyngeal. The bubo may remain enlarged and tender for weeks following an otherwise satisfactory clinical recovery. The surrounding tissue often becomes oedematous and overlying skin may be erythematous, warm and tense. Buboes may also get suppurative. Necrotic material from such buboes may contain viable *Y. pestis*. Lymphadenitis conditions that can be confused with plague include *Staphylococcus aureus*, and Group A β-haemolytic streptococcal infection, cat-scratch disease, tularemia.

Figure 1: Patient with bubonic plague.

Septicaemic plague

This is usually secondary to bubonic plague. Primary septicaemic plague is a progressive, overwhelming infection with *Y. pestis* in the apparent absence of a primary lymphadenopathy. Plague septicaemia, whether primary or secondary to bubonic plague, may lead to metastatic infection of other organ systems. Blood stream infection may result in a wide spectrum of pathological events including disseminated intravascular coagulopathy (DIC), multiple organ failure, and acute respiratory distress syndrome (ARDS). Complications include plague pneumonia, plague meningitis, plague endophthalmitis, hepatic or splenic abscesses, or generalised lymphadenopathy. The differential diagnosis of septicaemic plague includes sepsis of other Gram-negative bacterial aetiology, meningococcaemia, and acute severe viral infections, such as hantavirus illness.

Pneumonic plague

Pneumonic plague occurs in two distinct and epidemiologically significant forms. Secondary plague pneumonia results from haematogenous spread of *Y. pestis* to the lungs. This invasive infection provokes an inflammatory response and results in bacterial multiplication in pulmonary tissue. This process then spills over into the alveolar spaces and provides a mechanism for *Y. pestis* to be expelled during coughing episodes (patient's sputum may be bloody). Spread of *Y. pestis* to contacts by the respiratory droplet route can initiate an epidemic of primary pneumonic plague.

Primary pneumonic plague is the most fulminating and fatal form of plague. The incubation period is usually 1 to 3 days. The onset of the disease is typically manifested by the sudden onset of chills, fever, headache, body pains, weakness and chest discomfort. Cough, sputum production, increasing chest pain, difficulty in breathing, hypoxia and haemoptysis become prominent as the disease rapidly progresses. Death usually ensues if specific antibiotic therapy is not begun within the first 18 to 24 hours of disease onset. Uncommon manifestations of plague include meningeal, pharyngeal, cutaneous and intestinal clinical features.

Diagnosis

A high index of clinical suspicion as well as elicitation of a thorough clinical and epidemiologic history and a careful physical examination are required for timely diagnosis and prompt institution of specific therapy.

When plague is suspected, specimens should be collected promptly for laboratory studies, chest roentgenograms should be obtained and specific anti-microbial therapy should be initiated pending confirmation. Appropriate specimen for smear and culture include whole blood, lymph node aspirate from those with suspected buboes, sputum samples, tracheal or pulmonary alveolar aspirates from those with pneumonic plague and cerebrospinal fluid (CSF) from those with suspected plague meningitis. For *Y. pestis* demonstration/isolation from the specimen smear examination (Wayson, Gram stain), Direct fluorescent antibody testing (DFA), PCR analysis and culture should be carried out. For detection of antibodies against *Y. pestis*, an acute sample and if possible a convalescent sample should be tested. In case of death, autopsy specimens from liver, spleen, lungs, buboes, bone marrow may be collected.

Laboratory confirmation of plague can be done by isolation and *Y. pestis* specific bacteriophage lysis of the isolate or demonstration of fourfold difference in antibody titres in paired sera samples.

In patients with plague, white blood cell counts range between 10,000 to 25,000/µl, with a predominance of polymorphonuclears (PMNs). In patients with plague meningitis, PMN pleocytosis and the bacilli are usually visible in stained CSF smears.

Treatment

If untreated, plague is fatal in more than 50% of cases of bubonic disease and nearly all cases of septicaemic and pneumonic plague. Streptomycin is the drug of choice for the treatment of plague, but patients with simple, uncomplicated plague diagnosed early respond well to treatment with tetracycline. Treatment with tetracycline should be started with loading oral dose of 4-6 grams followed by 500 mg 6 hourly. Doxycycline should be given 200 mg/day. Chloramphenicol should be given in dose of 50 mg/kg/day 6 hourly orally or IV. For treatment of patients with advanced bubonic plague or those with pneumonia or specticaemia, streptomycin is recommended in dose of 2 gm/dL intramuscularly in adults and 30 mg/kg/day in children. Gentamycin has been found to be effective and has special value in treatment of plague in pregnancy. For those patients with complications such as meningitis or endophthalmitis chloramphenicol should be used, it is used in combination with streptomycin or another first line agent. Standard patient-care precautions should be applied to management of all suspected plague patients and standard

droplet precautions for those with suspect or presumptive or confirmed pneumonic plague. Delay in the treatment of plague lead to complications which include DIC, ARDS, multiple organ failure and other complications of Gram-negative sepsis. The patients with these disorders require intensive monitoring and close physiologic support.

Antimicrobial therapy should be continued for 7 to 10 days or for at least 3 days after patient has become afebrile and has made clinical recovery.

Prevention and Control

Long-term prevention and control measures for plague consist of surveillance, education and environmental management. Personal protective measures include the use of repellents, insecticides and protective clothing when at risk of exposure to rodent fleas; and the wearing of gloves when handling animal carcasses. Short-term antibiotic prophylaxis is recommended for persons known to have had close contact with a patient with suspected or confirmed pneumonic plague and persons visiting areas where a plague outbreak is in progress or who may be caring patients with plague.

The preferred antibiotics are the tetracycline, doxycycline, chloramphenicol. Chemoprophylaxis is given until one week after the exposure ceases. Patients in whom pneumonic plague is suspected should be managed under respiratory droplet precautions until it is ruled out or up to 48 hours of effective anti-microbial therapy has been administered, after which standard infection-control precautions should be undertaken.

Rodent food and habitats should be eliminated in domestic, periodomestic and working environments. The control of fleas with insecticides is a key public health measure in situations where epizootic plague activity places humans at high risk.

A formalin killed plague vaccine is produced in limited quantity by Haffkine Institute, Mumbai. Vaccination is recommended only for high risk group of individuals, e.g. laboratory workers or medical or public health workers dealing with patients of plague. Vaccination is of little use during human plague outbreaks, since a month or more is required to develop protective immune response. All persons exposed to patients with suspected pneumonic plague should receive antibiotics regardless of their immunisation status as the vaccine is unlikely to provide complete protection.

OTHER YERSINIA INFECTIONS

Yersiniosis is an uncommon bacterial zoonosis caused primarily by infection with either *Y. enterocolitica* or *Y. pseudotuberculosis*. Reservoir hosts of these bacteria include swine and other wild and domestic animals and transmission to human is predominantly by oral route. Both sporadic and common source outbreaks occur. The most frequent clinical manifestations are: enteritis or enterocolitis with self limited, diarrhoea (especially with *Y. enterocolitica*) and mesenteric adenitis and terminal ileitis (especially with *Y. pseudo tuberculosis*) which can be confused with acute appendictis. Yersiniosis can be complicated by nonsuppurative, extraintestinal, inflammatory sequelae, e.g. reactive arthritis, and erythema nodosum. The diseases by these *Yersinia* are usually self limited and the treatment is symptom-based and supportive. For prevention and control, safe food handling and food preparation practices should be observed.

17.21 Clostridial Infections

MK Daga, Rakshit Kumar

The genus *Clostridia* comprises of obligate anaerobic rods that usually stain Gram-positive. Clostridial species are widespread in the environment, partly due to their ability to form resistant spores. They are commonly found in soil, faeces, sewage, marine sediments and also in large numbers as indigenous microbiota of the intestinal tract of humans and animals.

Although exogenous infections, such as tetanus, food-borne botulism and hospital acquired *C. difficile* are serious, endogenous infection by commensal clostridia can complicate head and neck infections, respiratory tract infections, gynaecological and, bone and soft tissue infections. Intravenous drug users are increasingly found to be at risk of wound botulism, soft tissue infection and toxic shock.

TETANUS

Tetanus is life threatening infection, but is non-contagious. The word 'tetanus' is derived from the Greek *tetanos* meaning 'taut', and *teinein* to 'stretch'.

Aetiopathogenesis

Once the spores of *C. tetani* gain entry into damaged tissue, they transform into rod-shaped bacteria and produce the neurotoxin tetanospasmin, which when released and activated by proteases, is carried by retrograde axonal transport to the spinal cord and brain stem where it binds irreversibly to receptors at these sites. It cleaves membrane proteins involved in neuroexocytosis, which in turn blocks neurotransmission, producing the symptoms of the disease. Damaged upper motor neurons can no longer inhibit lower motor neurons, also they cannot control reflex responses to afferent sensory stimuli. Both mechanisms produce the hallmark muscle rigidity and spasms. Similarly, a lack of neural control of the adrenal glands results in release of catecholamines, thus producing a hypersympathetic state and widespread autonomic instability.

C. tetani also produces tetanolysin, another toxin whose role in tetanus is unknown.

Clinical Features

Tetanus affects only skeletal muscle; other types of striated muscle, cardiac muscle, cannot be tetanised because of their intrinsic electrical properties. Mortality rates reported vary from 40% to 78%. The highest mortality rates are among the unvaccinated and people over 60 years of age.

The incubation period of tetanus may be up to several months but is usually about eight days. In general, the further the injury site is from the central nervous system (CNS), the longer is the incubation period. The shorter the incubation period, the more severe the symptoms and more worse the prognosis. Clinically, four different forms of tetanus have been described.

Figure 1: Risus sardonicus: contraction of facial muscles during a tetanic spasm. Retraction of the upper lip and angles of mouth, narrowing of the palpebral fissures and overactivity of the frontalis muscles with wrinkling of the forehead gives rise to the typical sneering appearance.

Generalised tetanus (80% of cases)

The first sign is trismus or lockjaw, and the facial spasms contributing to the typical facies 'risus sardonicus' (**Figure 1**), followed by stiffness of the neck, difficulty in swallowing, and rigidity of pectoral and calf muscles. Fever, sweating, elevated blood pressure, and episodic rapid heart rate are accompaniments. Spasms may occur frequently and last for several minutes with the body shaped into a characteristic bow-shaped form called opisthotonus (**Figure 2**). Spasms can continue for up to four weeks, and complete recovery may take months.

Figure 2: Opisthotonus: Note arched back.

Figure 3: Neonatal tetanus with opisthotonus: Note clenched hands and flexed limbs.

Neonatal tetanus

It is a form of generalised tetanus (**Figure 3**) that occurs in newborns. Infants born to unvaccinated mothers do not acquire passive immunity and tend to be at risk. It usually occurs through infection of the unhealed umbilical stump, particularly when the stump is cut with a non-sterile instrument.

Local tetanus

It is an uncommon and milder form of the disease, in which patients have persistent contraction of muscles in the same anatomic area as the injury. The contractions may persist for many weeks before gradually subsiding or may proceed to generalised form.

Cephalic tetanus

It is a rare form of the disease, occasionally occurring with otitis media or following injuries to the head. There is involvement of the cranial nerves, especially in the facial area.

Diagnosis

The diagnosis is on purely clinical grounds and does not depend upon isolation of the bacteria, which are recoverable from the wound in only 30% of cases and can also be isolated from patients who do not have tetanus. Laboratory identification of *C. tetani* can only be demonstrated by production of tetanospasmin in mice.

The *'spatula test'* is a clinical test for tetanus that involves touching the posterior pharyngeal wall with a sterile, soft-tipped instrument, and observing the effect. A positive test is the involuntary contraction of the jaw (biting down on the 'spatula'), and a negative test would normally be a gag reflex attempting to expel the foreign object. The spatula test has a high specificity (100%) and sensitivity (94%).

Differential Diagnosis

Tetanus must be differentiated from various acute CNS infections, such as meningitis. Cerebrospinal fluid (CSF) analysis is helpful. Trismus can occasionally develop with phenothiazine use. Strychnine poisoning is another differential diagnosis.

Prevention

General preventive measures

- Universal active immunisation with adsorbed tetanus toxoid, gives durable protection (antitoxin titre >0.01 IU/mL) for at least 10 years; after the initial basic series has been completed, single booster doses elicit high levels of immunity.
- For adolescents 11 to 12 years of age, a single dose of Tdap is recommended for routine booster, and for adolescents and adults 13 to 64 years of age, a single dose of Tdap is recommended to replace the next decennial Td booster or when indicated as part of wound prophylaxis.
- In countries with incomplete immunisation programme for children, all pregnant women should receive two doses of tetanus toxoid in the first pregnancy, with an interval of at least one month, and with the second dose at least 2 weeks prior to childbirth. Active protection should be maintained by administering booster doses of Td every 10 years, preferably before or between pregnancies.
- For immunocompromised people or those infected with HIV, tetanus toxoid is indicated in the same schedule and dose as for immunocompetent persons.

Prophylaxis in wound management

Passive immunisation with at least 250 IU of tetanus immunoglobulin IM (or 1,500 to 5,000 IU of antitoxin of animal origin, if globulin is not available), regardless of the patient's age, is indicated for patients with other than clean, minor wounds and a history of no, unknown, or fewer than three previous tetanus toxoid doses.

Treatment

General principles

The patient should be kept in a quiet room. Three principles should guide all therapeutic interventions: prevent further toxin release by debriding the wound and giving an antibiotic; neutralize toxin outside the CNS with human tetanus immune globulin and tetanus toxoid, taking care to inject into different body sites and thus avoid neutralising the antitoxin; and minimise the effect of toxin already in the CNS.

Antitoxin

The human-derived antitoxin neutralises only free toxin. For adults, human tetanus immune globulin 3000 units IM is given once; this large volume may be split and given at separate sites. Dose can range from 1,500 to 10,000 units, depending on wound severity, although some authorities feel that 500 units is also adequate. Antitoxin of animal origin is far less preferable because it does not maintain the patient's serum antitoxin level well and the risk of serum sickness is considerable. If horse serum must be used, the usual dose is 50,000 units IM or IV. General wound care is more important, rather than direct injection of immunoglobulin or anti-toxin in the wound.

Benzodiazepines

Benzodiazepines are the standard to control seizures, counter muscle rigidity, and induce sedation. Dosage varies and requires meticulous titration and close observation. The most severe cases may require 10 to 20 mg IV q3 h (not exceeding 5 mg/kg). Less severe cases can be controlled with 5 to 10 mg PO q2 to 4h. Although diazepam has been used most extensively, midazolam (adults, 0.1 to 0.3 mg/kg/h IV infusion; children, 0.06 to 0.15 mg/kg/h IV infusion) is water-soluble and preferred for prolonged therapy. Midazolam reduces the risk of lactic acidosis due to the absence of propylene glycol solvent, which is required for diazepam and lorazepam, and reduces the risk of long-acting metabolites accumulating and causing coma.

Benzodiazepines may not prevent reflex spasms, and effective respiration may require neuromuscular blockade with Vecuronium 0.1 mg/kg IV or other paralytic drugs and mechanical ventilation. Pancuronium has been used but may worsen autonomic instability.

Management of Autonomic Dysfunction

Morphine may be given q 4 to 6 h to control autonomic dysfunction, especially cardiovascular; total daily dose is 20 to 180 mg. Sudden cardiac death is a feature of tetanus, and β-blockade can increase the risk; however, esmolol, a short-acting β-blocker, has been used successfully. Atropine at high doses has also been used; blockade of the parasympathetic nervous system markedly reduces excessive sweating and secretions.

Intravenous magnesium sulphate at doses that maintain serum magnesium levels between 4 and 8 mEq/L (e.g. 4 g bolus followed by 2 to 3 g/h), has a stabilising effect, eliminating catecholamine stimulation. The patellar tendon reflex is used to assess overdosage. Tidal volume may be impaired, so ventilatory support must be available.

Pyridoxine (100 mg once/day) lowers mortality in neonates. Other drugs that may prove useful include sodium valproate, angiotensin-converting enzyme (ACE) inhibitors (which inhibit angiotensin II and reduce norepinephrine release from nerve endings), and adenosine (which reduces presynaptic norepinephrine release and antagonizes the inotropic effect of catecholamines). Corticosteroids are of unproven benefit; their use is not recommended.

Antibiotics

The role of antibiotic therapy is minor compared with wound debridement and general support. Typical antibiotics include penicillin G 6 million units IV q 6 h, doxycycline 100 mg PO bid, and metronidazole 500 mg PO q 6 to 8 h. Administration of metronidazole decreases the number of bacteria but has no effect on the bacterial toxin. Penicillin was once used to treat tetanus, but is no longer the treatment of choice, owing to a theoretical risk of increased spasms. However, its use is recommended if metronidazole is not available.

Supportive care

In moderate or severe cases, patients should be intubated. Mechanical ventilation is essential when neuromuscular blockade is required to control muscle spasms that impair respiration.

In order to survive a tetanus infection, the maintenance of an airway and proper nutrition are required. An intake of 3500 to 4000 Calories, and at least 150 g of protein per day, is given to compensate for the increased metabolic rate due to increased muscle activity. Because constipation is usual, stools should be kept soft. A rectal tube may control distention. Bladder catheterisation is required if urinary retention occurs. Full recovery takes 4 to 6 weeks because the body must regenerate destroyed nerve axon terminals.

Chest physiotherapy, frequent turning and forced coughing are essential to prevent pneumonia. Analgesia with opioids is often needed.

Prognosis

Tetanus has a worldwide mortality rate of 50% and 80% to 90% in neonates, even if treated. Mortality is highest at the extremes of age and in drug abusers. The prognosis is poorer if the incubation period is short and symptoms progress rapidly or if treatment is delayed. The course tends to be milder when there is no demonstrable focus of infection. Contaminated lesions about the head and face are more dangerous than wounds on other parts of the body. Tetanus infection does not confer immunity due to the extreme potency of tetanospasmin; patients who have recovered from clinical tetanus should be fully vaccinated.

BOTULISM

Botulism is a paralytic disease caused by the botulinum toxin, produced by *C. botulinum*. Four toxin types A, B, E, and F cause human disease. Botulinum toxin is a zinc metalloprotease that cleaves a specific component of the synaptic vesicle membrane docking and fusion complex at the neuromuscular junction blocking release of the neurotransmitter acetylcholine. Naturally occurring botulism occurs in one of three forms: food-borne botulism, infant botulism, or wound botulism. Food-borne botulism is caused by ingestion of preformed toxin present in canned, smoked, or vacuum-packed foods, such as home-canned vegetables, smoked meats and vacuum-packed fish. Infant botulism (associated with ingestion of honey) and wound botulism (which typically occurs in association with injection drug use) result from organisms present in the gut or a wound that elaborate toxin *in vivo*.

Botulism and Bioterrorism

- Botulism toxin is the most toxic substance known to man; lethal dose is less than 1 mcg. A deliberate release may involve airborne dissemination of toxin, or contamination of food or water supplies with toxin or bacteria.
- Water treatment inactivates the toxin, the toxin cannot penetrate intact skin and it loses activity within a few days.
- The most likely scenarios would therefore be:
  - A deliberate contamination of foodstuffs; large doses may lead directly to neurological symptoms without the gastrointestinal symptoms of nausea, vomiting, and diarrhoea followed by constipation.
  - Aerosol release; most effective in an enclosed environment. After inhalation, the onset of symptoms may be as rapid as within 1 hour. However, in cases of accidental inhalation, symptom onset can be after 3 to 4 days.

Clinical Findings

Twelve to thirty six hours after ingestion of the toxin, visual disturbances appear, particularly diplopia and loss of accommodation. Ptosis, cranial nerve palsies with impairment of extra-ocular muscles, and fixed dilated pupils are characteristic signs. The sensory examination is normal. Other symptoms are dry mouth, dysphagia and dysphonia. Nausea and vomiting may be present, particularly with type E toxin. The sensorium remains clear and the temperature normal. Paralysis progressing to respiratory failure and death may occur unless mechanical assistance is provided.

Laboratory Findings

Toxin in patients' serum and in suspected foods can be demonstrated by mouse inoculation and identified with specific antiserum.

Differential Diagnosis

Differential diagnosis is limited because of the typical presentation. Cranial nerve involvement may be seen with vertebrobasilar insufficiency, the Miller-Fisher variant of Guillain-Barré syndrome, myasthenia gravis, or any basilar meningitis (infectious or carcinomatous). Intestinal obstruction or other types of food poisoning are considered when nausea and vomiting are present.

Treatment

Trivalent antitoxin should be administered in a dose of 50.000 units IV stat and may be repeated after two hours. Skin testing is recommended to exclude hypersensitivity to the antitoxin preparation. Antitoxin should be administered as early as possible, ideally within 24 hours of the onset of symptoms or signs, to arrest progression of disease; its administration should not be delayed for laboratory confirmation of the diagnosis. Guanidine hydrochloride, orally, in doses of 15-20 mg/kg may help reverse neuromuscular blockade. Respiratory failure is managed with intubation and mechanical ventilation. Parenteral fluids or alimentation should be given while swallowing difficulty persists. Nasogastric suction and urinary catheterisation are indicated for paralytic ileus and atonic bladder, respectively. The removal of unabsorbed toxin from the gut may be attempted by using laxatives if paralytic ileus is absent. Any remnants of suspected foods should be assayed for toxin.

CLOSTRIDIUM DIFFICILE INFECTION

C. difficile is a Gram-positive, anaerobic, spore-forming bacillus that is responsible for the development of antibiotic-associated diarrhoea and colitis. The disturbance of the normal bacterial flora of the colon, colonisation with *C. difficile*, and release of toxins A and B cause mucosal inflammation and damage. The chief risk factor is exposure to antibiotics, commonest being cephalosporins, ampicillin/amoxicillin, and clindamycin. Prolonged and multiple antibiotic courses (even antibiotics traditionally used to treat *C. difficile* colitis) have been shown to cause disease. Other risk factors include – advanced age (more than 60 years) prolonged hospitalisation, antineoplastic agents principally methotrexate, immunocompromised state and enteral feeding.

C. difficile infection commonly manifests as fever, mild-to-moderate diarrhoea, occasionally with abdominal cramping, and rarely as acute abdomen and fulminant life-threatening colitis. Approximately 20% of hospitalised individuals acquire *C. difficile* during hospitalisation, but symptomatic illness is relatively rare in India due to widespread use of metronidazole.

The diagnosis should be suspected in any patient with diarrhoea who has received antibiotics within the previous two months and/or when diarrhoea occurs 72 hours or more after hospitalisation. Differentials include inflammatory bowel disease, irritable bowel syndrome, malabsorption and bacterial gastroenteritis.

Laboratory Studies

- Complete blood counts: Leucocytosis may be present.
- Stool examination: Faecal leucocytosis is present in 50% patients and occult blood may be positive in severe colitis.
- Stool assays: Stool culture is the most sensitive (sensitivity 90% to 100% and specificity 84% to 100%) but results are slow and may lead to delay in diagnosis if used alone. Glutamate dehydrogenase enzyme immunoassay (EIA) is very sensitive (sensitivity 85% to 100% and specificity 87% to 98%). This test detects the presence of glutamate dehydrogenase produced by *C. difficile*. The stool cytotoxin test (demonstration of a cytopathic effect) is expensive, and it requires an overnight incubation and a tissue culture facility. Enzyme immunoassay for detecting toxins A and B is used in most laboratories. The sensitivity is moderate (79% to 80%) and specificity is excellent (98%).

Endoscopy may demonstrate the presence of raised, yellowish-white, 2 to 10-mm plaques overlying an erythematous and oedematous mucosa. These plaques are termed pseudomembranes. Typical pseudomembranes are beyond the limit of flexible sigmoidoscopy in 10% of patients. Therefore, colonoscopy is required.

Biopsy of pseudomembranous plaques reveals an inflammatory exudate composed of mucinous fibrinous material containing polymorphonuclear cells.

Treatment

Initial therapy: In mild cases (i.e. patients without fever, abdominal pain, or leucocytosis), cessation of causative antibiotics may be the only treatment necessary. Specific therapy aimed at eradicating *C. difficile* is indicated if symptoms are persistent or if antibiotics cannot be discontinued safely.

- Oral metronidazole and vancomycin have similar efficacy for mild to moderate disease. Metronidazole 200 mg PO QID for 10 days is the drug of first choice because of its lower cost.
- For severe cases, vancomycin 125 mg PO QID for 10 days is considered first line and higher dosing 250 mg PO QID may be used if poor absorption is a concern due to situations such as ileus. For patients who are unable to tolerate oral medication, IV metronidazole is effective. IV vancomycin is ineffective. Fidaxomicin, a newer antibiotic (not yet approved) has shown better efficacy than vancomycin in phase 3 trials.

In relapsed and resistant cases, prolonged therapy and agents like probiotics, intravenous immunoglobulin (IVIG) and cholestyramine are used. Anti-diarrhoeal agents (e.g. diphenoxylate with atropine) have been reported to increase the duration and severity of symptoms. Fulminant colitis and toxic megacolon may require operative intervention.

GAS GANGRENE (CLOSTRIDIAL MYONECROSIS)

Gas gangrene or clostridial myonecrosis is produced by any one of several clostridia (*C. perfringens, C. ramosum, C. bifermentans, C. histolyticum, C. novyi*, etc). Trauma and injection drug use are common predisposing conditions. Toxins produced in devitalised tissues under anaerobic conditions result in shock, hemolysis, and myonecrosis.

Clinical Findings

The onset is usually sudden, with rapidly increasing pain in the affected area, hypotension and tachycardia. Fever is present but

is not proportionate to the severity of the infection. In the last stages of the disease, severe prostration, stupor, delirium and coma occur.

The wound becomes swollen, deeply discoloured, with coalescent, red, fluid-filled vesicles and serosanguinous foul smelling discharge. Gas may be palpable in the tissues. Intravascular haemolysis by aflatoxin may lead to jaundice, haemoglobinuria and acute renal failure.

Laboratory Findings

Gas gangrene is a clinical diagnosis, and empiric therapy is initiated in suspected cases. Radiography may demonstrate gas within the soft tissues, but this finding is not specific. Smear from wounds shows absence of neutrophils and the presence of Gram-positive rods. Anaerobic culture confirms the diagnosis. Other bacteria can produce gas in infected tissue, e.g. enteric Gram-negative organisms or anaerobes.

Treatment

Penicillin, 2 MU IV q 3h is effective. Tetracycline, clindamycin, metronidazole, chloramphenicol, or cefoxitin can also be used. Antitoxin is of doubtful value but may be administered as 10,000 units of polyvalent serum, followed by 50,000 units six hourly. Adequate surgical debridement and exposure of infected areas are essential, with radical surgical excision often necessary. Hyperbaric oxygen at three atmospheres for 1-2 hr, three times in a day dramatically relieves constitutional symptoms.

17.22 Diphtheria

Sandeep B Bavdekar

Diphtheria is an acute infectious disease caused by *Corynebacterium diphtheriae*. The incidence of the disease has decreased dramatically due to the implementation of vigorous public health control measures. However, some countries have witnessed re-emergence of diphtheria due to waning immunity amongst adults, decreasing immunisation coverage amongst infants and children, movement of large groups of people and irregular vaccine supply.

AETIOLOGY AND PATHOGENESIS

Corynebacterium diphtheriae is not an invasive organism. A lysogenic bacteriophage confers toxin-producing potential to it. The toxin inhibits protein synthesis and mediates DNA fragmentation and cytolysis.

Patients with diphtheria and asymptomatic carriers are the sources of infection. Infection spreads through airborne respiratory droplets or direct contact with respiratory secretions or exudate from infected skin lesions. The toxin induced local necrosis and inflammatory reaction results in the formation of a pearly-grey membrane. As the toxin production increases, the area of necrosis and inflammation increase leading to extension of the membrane. On entry into the systemic circulation, the toxin can damage various organs and systems, predominantly the heart and the nervous system.

CLINICAL MANIFESTATIONS

Clinical manifestations appear after an incubation period of 1 to 6 days and depends upon site of infection, host immunity and if toxin has entered the systemic circulation.

Nasal Diphtheria

It begins with mild rhinorrhoea without much of systemic symptoms; gradually progressing to a serosanguinous and mucopurulent discharge with foul odour. It causes excoriation and shallow ulceration of the external nares and upper lip. A white membrane is noticed on the nasal septum. Differential diagnosis include common cold, sinusitis, adenoiditis and nasal foreign body.

Tonsillar and Pharyngeal Diphtheria

It begins as an insidious but more severe form of the disease. Sore throat is universal and anorexia, malaise, low-grade fever and headache are noted in some patients. Within 1 to 2 days a white or grey membrane appears (may not develop in partially immune individuals). The adherent membrane may cover the tonsils and pharyngeal walls and even extend on to the uvula, soft palate, larynx and trachea. Attempts to remove the membrane lead to bleeding. Associated lymphadenitis and soft tissue oedema in the neck is referred to as 'bull neck'.

Differential diagnosis include streptococcal pharyngitis (usually characterised by severe dysphagia, high fever, non-adherent membrane limited to the tonsils), infectious mononucleosis (associated with membrane limited to tonsils whose removal does not lead to bleeding, presence of lymphadenopathy and splenomegaly), primary herpetic tonsillitis (usually characterised by the presence of gingivitis, stomatitis, and discrete lesions of the tongue and palate), agranulocytosis, thrush, Vincent angina (associated with the involvement of the gums and presence of necrotic and ulcerative lesions on the pharynx).

Laryngeal Diphtheria

It is a downward extension of pharyngeal membrane and presents with noisy-breathing, dry cough, hoarseness and progressive stridor. Supra-sternal and supra-clavicular retractions reflect severe laryngeal obstruction, which may be fatal unless alleviated.

Infection at Other Sites

Cutaneous diphtheria presents as a superficial, non-healing ulcer with a sharp border and grey-brown membranous base. Purulent and ulcerative conjunctivitis, aural diphtheria (otitis externa with a purulent and foul-smelling discharge) and purulent and ulcerative vulvovaginitis are manifestations of infection at other sites.

DIAGNOSIS

A presumptive diagnosis of diphtheria is made on purely clinical grounds. Confirmation is by culturing *C. diphtheriae* from the infection site. However, therapy should be initiated on the basis of clinical diagnosis as any delay in starting therapy has grave consequences.

COMPLICATIONS

Complications, especially those related to elaboration of toxin or respiratory obstruction are responsible for the morbidity and mortality associated with diphtheria. Toxic myocarditis commonly occurs in the second (range: 1 to 6) week of the illness. Its manifestations include tachycardia, muffled heart sounds, murmurs, arrhythmias (varying degree heart blocks, atrioventricular dissociation and ventricular tachycardia) and congestive heart failure. A prolonged PR interval and changes in ST-T wave on an electrocardiographic tracing are relatively frequent findings.

Neurological complications appear after a variable latent period (2 to 12 weeks). Paralysis of the soft palate is most common and generally appears in the third week. It presents with nasal twang or regurgitation and difficulty in swallowing. Cranial neuropathies usually occur in the 5th week. They lead to oculomotor and ciliary paralysis and manifest with strabismus, blurred vision and difficulty with accommodation. Paralysis of the diaphragm and peripheral neuropathy involving the limbs occur from 10 days to 3 months after oropharyngeal infection. When these manifestations occur with elevated cerebrospinal fluid protein content, the manifestations mimic those of

Guillain-Barre syndrome. Rarely, affliction of vasomotor centres 2 to 3 weeks after the onset of illness manifests with tachycardia, hypotension and cardiac failure.

Secondary bacterial infection may occur. Extension of membrane into the larynx or its detachment and tissue oedema can lead to life-threatening airway obstruction. Gastritis, hepatitis, nephritis and haemolytic-uraemic syndrome are known to occur following diphtheria.

PREVENTION

Diphtheria-pertusis-tetanus (DPT) vaccine containing diphtheria toxoid is administered at the age of 6, 10 and 14 weeks and a booster is provided at 18 months. The second booster consisting of diphtheria and tetanus toxoids (DT) is administered at the age of 5 to 6 years. Although immunisation does not totally prevent subsequent infection with *C. diphtheriae*, it decreases the severity of local manifestations, diminishes the frequency and severity of toxic complications, reduces the probability of transmission of infection and provides herd immunity when at least 70% of the population is immunised.

TREATMENT

Specific therapy includes administration of anti-toxin (anti-diphtheritic serum) of equine origin, which neutralises the free circulating toxin. Subjects sensitive to antitoxin should undergo desensitisation before receiving the full dose. The dose of anti-toxin to be administered is empirically based on the site of infection, duration of illness and severity of manifestations as follows: mild nasal or pharyngeal diphtheria: 20,000 to 40,000 units, nasopharyngeal lesions: 40,000 to 60,000 units, moderately severe pharyngeal diphtheria: 80,000 to 100,000 units and severe pharyngeal or laryngeal diphtheria, symptoms involving multiple sites, presence of brawny oedema or illness over 48 hours: 120,000 units. The antitoxin should be administered as an intravenous infusion over 60 minutes to ensure rapid inactivation. Intravenous immunoglobulin (IVIG) preparations are not recommended for the treatment of diphtheria, as they contain only low-titres of anti-diphtheria antibodies.

Antibiotics, such as penicillin and erythromycin, help in halting toxin production, treating localised infection and preventing transmission of organisms to contacts. Appropriate therapy consists of using aqueous crystalline penicillin G (100,000-150,000 U/kg/day divided q 4 hr IV or IM), procaine penicillin G (25,000-50,000 U/kg/day divided q 12 hr IM) or erythromycin 40-50 mg/kg/day divided in 6 hourly doses; maximum 2 gm/day, orally). Amoxicillin, rifampin and clindamycin may also be effective. Therapy should be continued for 14 days, elimination of organism should be documented by obtaining two negative cultures taken at least 4 hours apart.

PROGNOSIS

Infancy, inadequate immunity, high virulence of organisms, extensive pharyngeal infection and delay in administration of toxin are associated with poor prognosis. Recovery, when it occurs, is usually complete.

17.23 Pertusis—Whooping Cough

YK Amdekar

INTRODUCTION

Whooping cough (pertusis) is a highly contagious disease caused by *Bordetella pertusis*. It is a respiratory tract infection characterised by paroxysmal cough. Bordet first identified this organism as a cause of whooping cough in the year 1906, and hence, the organism came to be known as *Bordetella pertusis*. *Bordetella parapertusis* is also known to cause whooping cough in humans. Prior to the advent of vaccination against whooping cough, the disease had high morbidity and mortality especially in infants and young children. Vaccine against whooping cough was introduced in the year 1940 along with diphtheria and tetanus. Disease prevalence did go down significantly thereafter. In spite of advances in the field of control of infectious diseases, whooping cough still continues to be a major public health concern. In fact, wider coverage of vaccination in children has resulted in epidemiological shift to adolescent and adult age groups. However, there have been outbreaks reported in adults from different parts of the world. This has necessitated change in policies to control this disease.

PATHOPHYSIOLOGY

Humans are the sole reservoirs of *Bordetella pertusis* and *parapertusis*. It is a gram-negative pleomorphic bacillus that spreads through aerosolised droplets from coughing of infected individuals. Organism attaches itself to the ciliated respiratory epithelium and damages it. Typically incubation period varies from 3 to 12 days.

CLINICAL FEATURES

Disease runs about 6 weeks of course and its pattern of presentation is broadly divided into three stages: catarrhal, paroxysmal and convalescent stages. Each stage lasts for about 2 weeks.

In stage 1, catarrhal stage, symptoms are indistinguishable from common respiratory infection as it presents with rhinorrhoea, congested eyes and often low-grade fever. It is in this stage that the patient is most infectious and infectivity diminishes over next few weeks and becomes non-infectious at the end of 4 weeks.

In stage 2, paroxysmal stage, is characterised by bouts of severe cough that is often followed by a whoop, a loud noise as a result of air rushing through narrow airway during inspiration, and hence, the name, whooping cough. However, whoop is not seen in adults, and therefore, diagnosis is easily overlooked. In young infants less than 6 months of age, severe bout of cough is followed by apnoeic spell that may even endanger life due to hypoxia. Post-tussive vomiting and redness of face are common after bout of cough.

In stage 3, convalescent stage, chronic cough gradually diminishes in severity till patient recovers completely.

PHYSICAL EXAMINATION

It is almost not contributory as there are no positive findings on physical examination. Periorbital oedema, congestion of face and sub-conjunctival haemorrhage are some of the findings suggestive of severe cough but not specific to whooping cough. Umbilical or inguinal hernia and rectal prolapse may develop during the course of the disease as a result of straining at the time of severe bouts of cough. Infants and young children may show considerable loss of weight.

DIFFERENTIAL DIAGNOSIS

Adenoviral infection mimics whooping cough to an extent that it is not possible to differentiate one from the other. However, course of progression in classical whooping cough may help to define correct diagnosis.

Respiratory syncitial virus infection also presents with severe cough but has signs of lower respiratory tract involvement, such as crepitations and wheeze.

Mycoplasma or *Chlamydia pneumoniae* may mimic whooping cough but systemic symptoms are more prominent, such as high fever and also have lower respiratory tract involvement.

In older infants and toddlers, inhaled foreign body may be mistaken for whooping cough. Abrupt onset of severe cough in inhaled foreign body and absence of progression of cough as in whooping cough helps to differentiate it from pertusis.

Cough variant asthma presents with severe cough without any other systemic symptoms and may be devoid of physical signs at the time of physical examination. Past history of similar illness and atopic diathesis or family history of atopy would help to make correct diagnosis.

LABORATORY DIAGNOSIS

Diagnosis of whooping cough is largely clinical. It is not easy to confirm diagnosis of whooping cough through laboratory tests. Lymphocytic leucocytosis is non-specific as it is seen in many other diseases as well; though severe neutrophilic leucocytosis is considered as a marker of severe infection. Classically low ESR may at times be seen.

Bacteriological diagnosis is the 'gold standard' and may be attempted by deep posterior nasopharyngeal swab or direct cough plate culture. Special culture media need to be used, such as Regan-Lowe, Bordet-Gengoi agar or Strain and Scholt culture medium. Positive yield on culture is most likely in early stages of the disease but not later than 4 weeks of the onset of symptomatology.

Serology is non-specific and not useful. Direct fluorescent assay is unreliable. Polymerase chain reaction is highly sensitive but not widely available and costly for routine application.

IMAGING STUDIES

They are of little use in the diagnosis of whooping cough. In an uncomplicated whooping cough, there is no need for imaging study. However, in case of doubtful diagnosis or in case of complications, such as pneumonia, chest radiograph may be useful. Subtle findings such as small segmental emphysema may help in diagnosing inhaled foreign body. Fluoroscopy may demonstrate mediastinal flutter in case of inhaled foreign body and it can also be picked-up by chest radiograph done in both phases of respiration that demonstrates retained air in a segment during the phase of expiration. Reactivation of tuberculosis (TB) may be diagnosed by imaging. Computed tomography of chest is of no help in the diagnosis.

COMPLICATIONS

Most of the patients recover without complications. However, infants and young children are prone to complications, such as pneumonia or encephalopathy and convulsions. Young infants less than 6 months age are at a risk of death due to severe apnoeic spell that may result in asphyxia. Umbilical or inguinal hernia and rectal prolapse may develop as a result of straining during severe bouts of cough, especially in malnourished children.

Reactivation of TB is known to occur after recovery from whooping cough in children harbouring silent dormant TB. Malnutrition may result after long illness that disturbs feeding especially in infants and toddlers.

MANAGEMENT

Mainstay of the management in acute illness is mostly supportive. Goal of therapy is to minimise severity of paroxysms of cough, providing assistance during severe bout of cough especially in infants and maximising nutrition.

Hospitalisation is indicated in infants less than 6 months of age and also in children suffering from co-morbid conditions, such as congenital heart defects or chronic respiratory disease and severe malnutrition. It is important to ensure adequate oxygenation during apnoeic spells.

During early stages of the disease, child may have to be isolated to prevent spread of infection, until 4-5 days after antibiotic therapy is started. It is not easy to suppress severe bouts of cough once disease has gone past catarrhal stage. Cough suppressants, such as dextromethorphan, pholcodine or codeine, may be tried. Steroids are generally of no great benefit.

Macrolides are the antibiotics of choice against whooping cough. They may abort the attack and further progression of the disease if administered early in the course of illness. As diagnosis is usually delayed beyond catarrhal stage, antibiotic may not be useful in a given patient but is necessary to ensure prevention of spread of infection to other contacts. Antibiotic is continued for 7-10 days irrespective of clinical progress.

PREVENTION

Immunisation is the best way of prevention of whooping cough. Expanded immunisation programme in India recommends three primary doses at the interval of 4 to 8 weeks starting early in infancy at 6 to 8 weeks of age followed by booster doses at 18 months and 4 to 5 years of age. Immunisation against whooping cough has not been recommended beyond 5 years of age due to consideration of disease not being common beyond that age and also fearing high reactogenicity of the whole cell pertusis component of the vaccine. However, increasing prevalence of whooping cough beyond early childhood into adolescents and adults has made it necessary to revise vaccination schedules recently. With the availability of acellular component of pertusis in DTaP vaccine, there is no fear of severe reactions at any age.

Evidence is overwhelming that parents and older siblings constitute the major source of infection to infants and young children, and therefore, adolescents and adults need protection to control infection in children. With the availability of small dose of diphtheria toxoid and acellular component of pertusis along with tetanus toxoid in usual dose in a combined vaccine (TdaP), American Academy of Paediatrics has approved use of TdaP for adolescents since December 2005.

FUTURE CONSIDERATIONS

As vaccination coverage in children increases in population, there is always a possibility of epidemiological shift in the disease prevalence into adolescents and adults. Coming decade may witness adult vaccination programmes in India as most of the infectious diseases are acquired by children from infected adults and it is not possible to control such diseases in children without adequate control in adult population.

17.24 Syphilis

Debabrata Bandyopadhyay

Syphilis is a chronic infective disease caused by the pathogenic spirochaete *Treponema pallidum* subspecies *pallidum*. Syphilis is mainly transmitted through the sexual route, but transplacental transmission can also occur, causing congenital disease. The protean manifestations of syphilis have been described for centuries and the disease is aptly designated as the 'great imitator'. The clinical course of untreated disease, which may last for decades, is characterised by periods of activity with intervening asymptomatic periods of clinical latency.

EPIDEMIOLOGY

Syphilis occurs throughout the world, the prevalence varying significantly with geographic location. According to the World Health Organisation (WHO) estimates, the annual global incidence of syphilis is approximately 12.2 million cases, mostly occurring in the developing countries of Asia and Africa. The prevalence of pregnant seropositive cases may exceed 10% in many developing countries and congenital syphilis remains a significant global problem. Small high-risk groups of core transmitters such as female sex workers, men who have sex with men, and injecting drug users serve as the main source of transmission to the general population.

AETIOLOGY

The causative spirochaete of syphilis, *Treponema pallidum* sub species *pallidum*, was discovered by Schaudinn and Hoffmann in 1905. It is pathogenic only to humans. It cannot be cultured in artificial media, but can be grown in rabbits as a source of *T. pallidum* for use in diagnostic tests. The generation time is 30 to 33 hours and the bacteria is susceptible to heat, drying, freezing, soaps, and mild disinfectants. It is a slender cork-screw shaped organism with a length of 6 to 20 µm and a diameter of 0.10 to 0.18 µm making it invisible by light microscopy. The organism is actively motile and the movements demonstrated by dark-field microscopy are pathognomonic. Sequencing of the genome of *T. pallidum* has showed that it lacks many vital biosynthetic and metabolic pathways explaining the organism's extreme host-dependence for survival.

TRANSMISSION

The disease is almost exclusively transmitted during sexual intercourse. Although it can penetrate intact mucosa, it more readily enters the body through breaks in the skin caused by microtraumas induced by sex. Congenital syphilis is caused by mother-to-child transmission through transplacental route. The likelihood of transmission is inversely proportional to the duration of the disease in the mother. Syphilis can very rarely be transmitted by blood transfusion or accidental puncture.

PATHOGENESIS AND NATURAL COURSE

The natural course of untreated syphilis (**Figure 1**) had been documented by large-scale long-term studies (some are ill-famous for being highly unethical). After inoculation, *T. pallidum* readily penetrates intact mucosa or microabrasions in the skin to reach the systemic circulation via the lymphatics and disseminate widely before the appearance of the chancre. The length of the primary incubation period (9 to 90 days) is inversely proportional to the size of the inoculum. The primary lesion develops as a local disease at the site of inoculation and heals spontaneously within weeks with development of immune response. After about 6 to 12 weeks, there occurs widespread proliferation of the bacteria leading to the secondary stage of the systemic disease. Antigenic variation of the bacteria is believed to be responsible for its escape from immune response and proliferation. The secondary stage may last for weeks to months and heals spontaneously. The disease then enters a period of latency in which there are no clinical manifestations but the serology is positive. Although

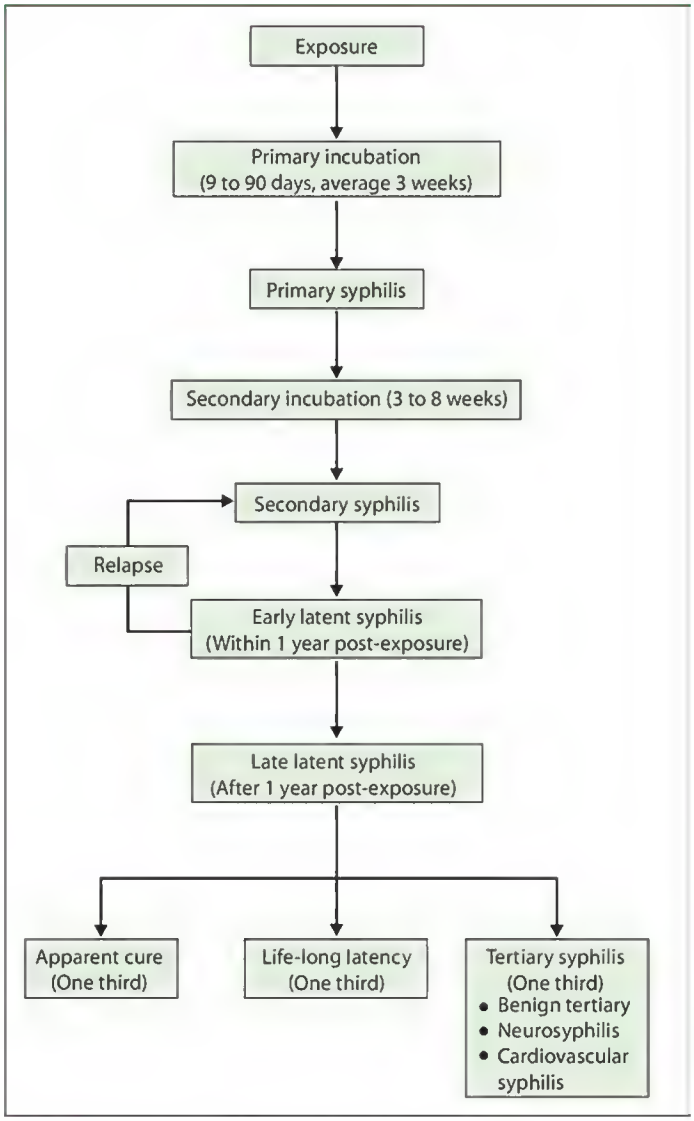

Figure 1: Natural course of untreated syphilis.

transplacental transmission can still occur, sexual transmission does not occur during late syphilis.

CLINICAL FEATURES

Primary Syphilis

Although *T. pallidum* disseminate systemically soon after the infection, the first clinical manifestation of the disease occurs locally, at the site of inoculation. The most common site of the lesion is the genitalia. The coronal sulcus, prepuce, glans, and shaft of penis are the usual sites in males and the vulva, fourchette, cervix, and vagina in the females. Anal and rectal ulcers may occur following anal sex. Extragenital inoculation may lead to lesions on the lips, breast, fingers, and tongue.

The classical ulcer of primary syphilis (the 'Hunterian chancre') is a solitary, painless and non-tender, circular or oval ulcer with a raised well-defined margin and a rubbery, firm base. Classical lesions, however, are less commonly found and multiple ulcers and mixed ulcers (with chancroid or herpes genitalis) are not infrequent. Regional lymphadenopathy develops within a week; it is generally bilateral with genital ulcers, and unilateral with extragenital lesions. The nodes are painless and non-tender, discrete, mobile, and have a rubbery consistency. Untreated, the lesions of primary syphilis heal spontaneously in 3 to 8 weeks.

Secondary Syphilis

Three to ten weeks after the ulcer appears, features of secondary syphilis set in. At this stage, the systemic nature of the illness becomes clinically apparent. The chancre may still be present in a minority. Constitutional features such as fever, malaise, headache, weight loss, arthralgia, and sore throat may be present.

The characteristic syphilitic rash develops in most of the patients. The rash is generalised, symmetrical, and usually asymptomatic. Starting as faint macules of rose-pink colour, these roundish lesions gradually evolve into dull red scaly papules characteristically involving the palms and soles in addition to other areas of the body. The lesions, however, may be polymorphic and follicular, annular and pustular lesions may also occur. Skin lesions at warm, moist sites may become broad, flat, and moist (condyloma lata). These lesions are commonly seen around the anus, on the scrotum, vulva, axilla, or under the breast. Mucosal ulcers ('mucous patches') may occur on any mucosal surface including oral cavity, pharynx, larynx, or the genitalia. Exudative secondary syphilitic lesions are highly infective.

Generalised lymphadenopathy is a common finding. Neurological involvement occurs in a minority but cerebrospinal fluid abnormality may be found in about a third of the patients. A variety of other manifestations may also occur in the secondary stage. These include diffuse or localised ('moth-eaten') alopaecia, hepatosplenomegaly, hepatitis, conjunctivitis, iridocyclitis, and nephrotic syndrome.

Latent Syphilis

With or without treatment, the manifestations of secondary syphilis resolve after 4 to 12 weeks, the patient becomes asymptomatic, and a period of latency begins. Latent syphilis is diagnosed on the basis of positive serology in the setting of no clinical evidence of disease. Latent syphilis is divided into the *early latent stage* (within one year of infection) and *late latent stage* (beyond one year post-infection). Lesions of secondary syphilis may relapse in a portion of patients during the early latent period and the patient may be infectious. If the period of infection cannot be reliably ascertained from history, the patients are regarded as having late latent disease.

Tertiary Syphilis

In the pre-antibiotic era the manifestations of tertiary syphilis used to occur in one third of untreated patients. These are now very rarely seen with the exception of neurosyphilis in the setting of HIV infection. The various manisfestations of tertiary syphilis have been briefly described in **Table 1**.

Table 1: Manifestations of Tertiary Syphilis

Late benign (gummatous) syphilis
Cutaneous nodules and noduloulcerative lesions
Gummatous lesions of bone, liver, tongue, myocardium, or GI tract
Cardiovascular syphilis
Uncomplicated aortitis
Aortic incompetence
Aortic aneurysm
Coronary artery stenosis
Neurosyphilis
Asymptomatic neurosyphilis
Early
Late
Acute syphilitic meningitis
Meningovascular syphilis
Cerebral form
Spinal form
Parenchymatous neurosyphilis
Cerebral form (General paresis)
Spinal form (Tabes dorsalis)
Optic atrophy
Gummatous neurosyphilis
Cerebral form
Spinal form

Late benign syphilis (gummatous syphilis)

Granulomatous, chronic inflammatory, proliferative and destructive lesions of syphilis (gummas) most commonly occur in the skin in the form of nodular or noduloulcerative lesions that heal with scars.

Cardiovascular syphilis

Cardiovascular syphilis may develop after a latency period of 15 to 30 years. Obliterative endarteritis of the vasa vasorum of proximal aorta may lead various complications.

Neurosyphilis

Neurosyphilis may be asymptomatic, while cerebrovascular disease in syphilis results from infarctions resulting from syphilitic endarteritis, parenchymatous neurosyphilis (general paresis and tabes dorsalis) is caused by direct treponemal invasion of the brain. Gummas may also involve the CNS.

Congenital Syphilis

Transplacental transfer of *T. pallidum* can occur throughout pregnancy, but foetal damage usually occurs after the fourth month of gestation, after the foetus becomes immunocompetent. Untreated maternal infection may lead to foetal loss, prematurity, neonatal death, or congenital syphilis. Congenital syphilis is divided into three stages: early congenital syphilis (<first 2 years' of life), late congenital syphilis (after >2 years), and the residual stigmata.

Early congenital syphilis

Symptoms generally appear within the first three months of life. Rhinitis or 'snuffles' is generally the first sign of the disease; this is followed by features which include a generalised rash with blisters and later papulosquamous lesions, mucous patches, and condylomata lata. Skeletal changes including osteochondritis, osteitis, and periostitis; generalised lymphadenopathy; hepatosplenomegaly; jaundice; anaemia, and thrombocytopaenia occur commonly. Pneumonitis, nephrotic syndrome, and congenital neurosyphilis may also occur.

Late congenital syphilis

Late congenital syphilis corresponds to the tertiary stage of acquired syphilis but cardiovascular disease develops rarely. Interstitial keratitis is the commonest lesion. Other manifestations include eighth-nerve deafness and recurrent arthritis. Neurosyphilis and gummatous syphilis may occur. Gummas may involve the skin, viscera and bones and may lead to perforated nasal septum and palate.

Stigmata

The stigmata are the residual consequences of the inflammatory lesions of early congenital syphilis. These include perioral radial scars (rhagades), frontal bossing, saddle-nose, saber tibias and Clutton's joints. Hutchinson's teeth (incisors shaped like tip of a screwdriver, often notched), together with interstitial keratitis and eighth nerve deafness forms the Hutchinson's triad.

DIAGNOSIS

Syphilis is diagnosed on the basis of history, physical examination, examination of lesional material for treponemes, and serological tests.

Demonstration of Treponemes

Dark-field microscopy is the main diagnostic method for primary syphilis. Moist lesions of secondary syphilis, such as condyloma lata can also be similarly tested. Direct fluorescent-antibody testing for *T. pallidum* (DFA-TP) can also be done. None of these, however, can distinguish *T. pallidum* from the other pathogenic treponemes.

Serologic Tests for Syphilis (STS)

These remain the mainstay of laboratory diagnosis for secondary, latent, and tertiary syphilis.

Nontreponemal tests

Nontreponemal tests include the venereal disease research laboratory (VDRL) and the rapid plasma reagin (RPR) card tests. Nontreponemal tests detect an antibody against cardiolipin (generated from damaged mammalian cell membranes) that is present in the syphilitic sera. Limitations on these tests are their lack of sensitivity in early primary syphilis and false-positive reactions. False-positive reactions may result from advanced age, pregnancy, and autoimmune diseases, and some viral, protozoal, or mycoplasma infection. Quantitative nontreponemal tests are useful for evaluating disease activity and response to treatment.

Treponemal tests

These tests use treponema-specific antigens and include the serum fluorescent treponemal antibody absorption test (FTA-ABS), *Treponema pallidum* haemagglutination assay (TPHA) and the microhaemagglutination test for *T. pallidum* (MHA-TP). These tests have high sensitivity and specificity and are used to confirm the results of positive VDRL tests. These tests, however, remain positive for years after successful treatment of syphilis and cannot be used as indicators of disease activity.

Other Tests

Tissue biopsy using special stains such as silver stain may be used to visualise treponemes. Nucleic acid amplifications tests (polymerase chain reactions) may be valuable in detecting small numbers of treponemes in tissues, but these tests are not routinely available.

SYPHILIS AND HIV INFECTION

Syphilis may cause several-fold increase in the risk of transmission of HIV. The course of syphilis in HIV-coinfected patients is generally similar to that in patients without HIV infection. In advanced immunosuppression, however, clinical features could be severe, serological test results may be unpredictable, and response to treatment may be impaired. There may be early and more frequent incidence of neurosyphilis in presence of HIV infections.

TREATMENT

Parenteral penicillin is the recommended first-line treatment for all stages of syphilis. Although alternative regimens are available, for syphilis in pregnancy and neurosyphilis, penicillin is the only drug with proven efficacy and even in penicillin-allergic patients it is preferable to administer penicillin after desensitisation (see **Table 2** for different regimens for treatment of syphilis).

PREVENTION AND CONTROL

Primary prevention of syphilis consists of modification of risk behaviours, such as avoiding multiple sexual partners and correct and consistent use of condoms. Targeted intervention for high-risk groups such as female sex workers should include regular health check-ups including syphilis serology, education and condom promotion. Modes of secondary prevention include early diagnosis and treatment, partner management, and education and counselling regarding risk reduction. Every patient with sexually transmitted infections should be screened for syphilis serology. An antisyphilitic drug is incorporated in the regimens for the syndromic case management of genital ulcer disease. Routine antenatal maternal screening and treatment of pregnant women is a time-tested strategy for prevention of congenital syphilis.

Table 2: Treatment of Syphilis

Early syphilis (primary, secondary, and early latent syphilis)		
Recommended	:	Benzathine penicillin 2.4 million units IM single dose or procaine penicillin 1.2 million units IM OD for 10 days
Alternative regimen for penicillin allergic patients	:	Doxycycline 100 mg orally BID for 14 days or tetracycline 500 mg orally QID for 14 days or ceftriaxone 1 g IM or IV OD for 8-10 days or azithromycin 2 g orally OD single dose
Late latent (more than 1 year post-infection or unknown duration), cardiovascular, or gummatous syphilis		
Recommended	:	Benzathine penicillin 2.4 million units IM weekly for 3 doses or procaine penicillin 1.2 million units IM OD for 20 days
Alternative regimen for penicillin allergic patients	:	Doxycycline 100 mg orally BID for 28 days, or tetracycline 500 mg orally QID for 28 days
Neurosyphilis		
Recommended	:	Aqueous penicillin G 3-4 million unit IV 4 hourly for 10-14 days or procaine penicillin 2.4 million units IM OD plus probenecid 500 mg QID both for 10-14 days
For penicillin allergic patients	:	Desensitise and administer penicillin or ceftriaxone 1 g IM or IV OD for 10-14 days
Pregnancy		
Recommended	:	Benzathine penicillin 2.4 million units IM weekly for 2 (early syphilis) or 3 (late syphilis) doses or procaine penicillin appropriate for stage
For penicillin allergic patients	:	Desensitise to penicillin or azithromycin 500 mg OD for 10 days or ceftriaxone 1 g IM/IV OD for 10-14 days
HIV infection		
Benzathine penicillin 2.4 million units IM weekly for 3 doses or aqueous penicillin G 3-4 million unit IV 4 hourly for 10-14 days		
Congenital syphilis		
Neonates with proven or highly probable disease or born to mother with untreated early syphilis: Aqueous penicillin G, 50000 U/kg IV 12 hourly for first 7 days then 8 hourly for 3 days or, procaine penicillin 50000 U/kg IM once daily for 10 days		
Neonates with no sign of disease born to mother with adequately treated syphilis		
Benzathine penicillin G 50000 U/kg IM single dose

17.25 Non-Syphilitic Treponematoses

Taru Garg

Infections caused by treponemes include venereal syphilis and non-venereal (endemic) treponematoses. Non-venereal treponematoses include distinctive spirochaetal infections, such as Yaws, Pinta, and endemic syphilis. Endemic treponematoses are restricted to certain remote areas of few developing countries. The causative organisms cannot be distinguished morphologically or serologically from *Treponema pallidum*. Diagnosis relies mainly on clinical features and epidemiology. However, occasionally clinical resemblance is striking.

YAWS

The term yaws is thought to be of Caribbean origin. Locally used synonyms in some of the endemic areas are: *Pian* (French), *framboesia* (Dutch), *buba* (Spanish), *parangi* (Sri Lanka). Considered as one of the neglected tropical diseases by World Health Organisation (WHO), yaws is a chronic infectious disease, characterised clinically by early, late and latent stages. Clinically, it causes skin lesions and bone pains, and has the potential to cause significant deformity and disability.

Epidemiology

The disease mainly affects children less than 15 years of age. It occurs in South-East Asia, Western Pacific and Africa. After significant steps taken by the WHO to control the disease, it is now endemic to few countries like Indonesia, Timor Leste, etc. Approximately 7000 new cases of yaws are estimated to occur annually in South-East Asia. In India, it was first observed in 1887 in tea plantation workers in Cachar district of Assam. It was endemic in several states including Andhra Pradesh, Assam, Chattisgarh, Gujarat, Jharkhand, Madhya Pradesh, Maharashtra, Tamil Nadu and Uttar Pradesh (**Figure 1**). In India, the disease is mostly known by the name of the tribe affected most in that area: Maharashtra (*Madia rogam*), Andhra Pradesh (*Koya rogam*), Uttar Pradesh (*Vyadhi, Dakhinia*). The disease is transmitted by close contact with an infected person with infectivity being greatest in the early stages. The organism gains entry through an abrasion or a scratch. Conditions that favour the disease transmission are low socioeconomic status, poor hygiene, overcrowding and sparse clothing. Hot and humid climate also promotes the disease transmission. Indirect transmission of disease by insects and fomites probably occurs. Vertical transmission is not known.

Aetiopathogenesis

The disease is caused by *Treponema pallidum* subspecies *pertenue (T. pertenue)*, which was discovered by Castellani in 1905. The organism cannot be cultured in artificial media. The initial lesion develops at the site of entry of organism after an incubation period of 9 to 90 days. Generalised dissemination of treponemes occurs during the incubation period. After a gap of 3 to 6 weeks, multiple scattered skin lesions appear. This stage is called early yaws. Environment may influence the early skin lesions. In dry season few macular lesions occur, while humidity favours papillomas, especially involving body folds, such as axillae and anal cleft. For the first few years there can be multiple spells of cutaneous and/or bone lesions with intervening periods of latency, following which the condition either remains latent or evolves into late yaws.

Clinical Features

The skin lesions of early yaws are highly infectious, exuding serum rich in treponemes. Skin and bone involvement occur both in early and late yaws. However, the process is more destructive in late yaws.

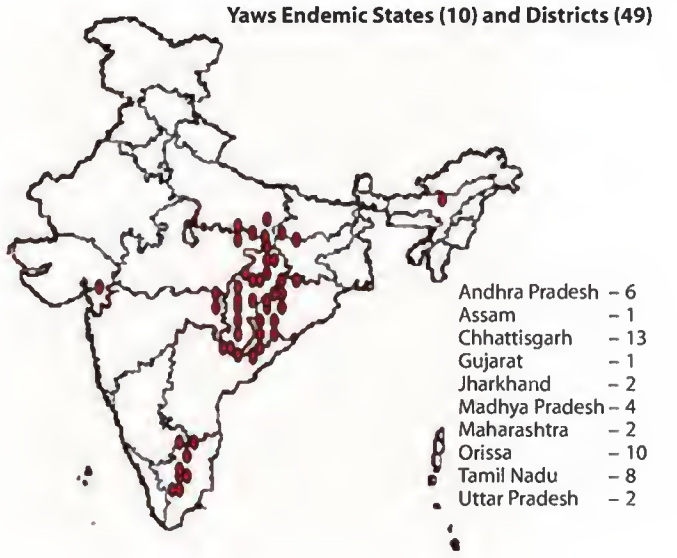

Figure 1: Sketch map of India showing yaws endemic districts (one dot represents one district).

Early yaws

It comprises of primary and secondary stages. In the primary stage, an erythematous papule (mother yaws) forms at the site of contact. It may gradually enlarge in size, or become ulcerated. It persists for a few months, and then heals spontaneously leaving behind an atrophic scar. During the secondary stage, a crop of skin lesions appear (daughter yaws). The skin lesions can be of varying morphologies, such as erythematous macules (resembling roseolar syphilis) with or without scaling, papules, plaques, nodules or papillomas. Papillomas are the characteristic lesions of early yaws. In the moist areas of the body these can mimic condyloma lata of secondary syphilis. Mucous membranes are also involved with similar lesions. Palms and soles have erythematous scaly macules, papillomas or hyperkeratotic lesions. Papillomas may lead to painful walking (crab yaws). Osteoperiostitis especially affects the long bones. Hypertrophic osteoperiostitis of nasal process of maxilla is known as goundou. Polydactylitis involving the phalanges is common.

Late yaws

Late yaws develops in about 10% of cases after 5 to 10 years. It is characterised by cutaneous lesions (plaques, nodules, noduloulcerative), juxta-articular nodes, osteitis and periostitis. The ulcers are either superficial with coarse granular floor, or deep resembling gummas of venereal syphilis. Ulcers heal with significant scarring, contractures, and depigmentation. Juxta-articular nodes are fibrosed areas overlying sacrum, greater trochanter, elbows, etc. Bone lesions are very destructive, as opposed to early yaws. It causes destruction of palate and nasal bones called, rhinopharyngitis mutilans (gangosa). Neuro-ophthalmological findings have been reported with yaws. However, generally yaws does not involve eyes, nervous system, or cardiovascular system.

Attenuated yaws

In areas with low endemicity of yaws, only few clinical cases are identified for many sub-clinical cases and that too in mild form. This may cause difficulty in diagnosis.

Diagnosis

Diagnosis can be made on clinico-epidemiological grounds. Clinically, it should be differentiated from impetigo, echthyma, scabies, leprosy, lupus vulgaris, chromomycosis, tropical ulcers, warts, callosities, etc. Treponemes can be demonstrated from the infectious lesions on dark ground microscopy. Histopathology shows acanthosis, papillomatosis and neutrophilic micro-abscesses, and dermal infiltrate comprised mainly of plasma cells. Treponemes can be demonstrated in epidermis by silver impregnation stains, or by immuno-fluorescence. Treponemal and non-treponemal serological tests are important aids for diagnosis. Periostitis may be evident on bone radiographs.

Treatment

Patients and their contacts should be treated with benzathine penicillin 1.2 MU in patients above 10 years of age and half the dose for younger patients. Tetracycline, doxycycline or erythromycin can be used in penicillin-sensitive patients.

Course and Prognosis

Early treatment causes regression of early yaws and prevents development of destructive lesions in late yaws. Sero-reversion does not occur with the treatment. Untreated disease causes significant destruction of skin, bones and cartilage culminating into gross deformity.

Prevention and Control

Between 1952 to 1964, WHO and United Nations International Children Educational Fund (UNICEF) had taken measures to control the disease in a few countries. Recurrence of yaws was observed in many countries in 1970. Government of India approved yaws eradication programme in Koratpur district of Orissa in 1996-1997. In 1999, it was extended to cover 49 districts in 10 states. The number of cases declined from 3571 in 1996 to nil in 2004. Following successful implementation of the programme, the disease has been eliminated from India in 2006. South-East Asia region of WHO has set a goal of regional eradication of yaws by 2012. Factors favourable for the eradication of disease are:

1. Man is the principal reservoir.
2. Patients with early lesions are the main source of infection.
3. Effective treatment for cure available.
4. Disease restricted to a few backward tribal communities.
5. Mass campaigns aimed at total population examination to detect cases and treat them along with contacts have greatly reduced the prevalence and transmission.

PINTA

Pinta is a Spanish word to describe mottled appearance. It is most benign of the endemic treponematoses where only skin is involved. The disease is characterised clinically by papules and plaques in the early stage and pigmentary changes at the late stage.

Epidemiology and Aetiology

Pinta is caused by *Treponema carateum*. The organism is morphologically indistinguishable from other treponemes. Mode of transmission is same as for yaws. It mainly affects children. The disease is mainly restricted to isolated areas of Central and South America.

Clinical Features

Primary lesion develops on exposed site after an incubation period of 7 to 21 days. It is an erythematous papule or plaque associated with regional lymphadenopathy, which heals spontaneously. After several months or years, multiple widely disseminated similar lesions appear (pintids). Pintids may persist as such for years, or may become depigmented. Late stage develops after 2 to 5 years, with conspicuous pigmentary changes and atrophy. At first there is hyperpigmentation of varying shades, followed by achromia and atrophy. Different stages may present simultaneously.

Diagnosis

Clinically dyschromic lesions should be differentiated from, erythema dyschromicum perstans, Riehl's melanosis, pityriasis alba, pityriasis versicolor, vitiligo and leprosy. Investigations and treatment are the same as for yaws.

17.26 Leptospirosis

AP Sugunan

Leptospirosis is a zoonosis caused by spirochaetes of the genus *Leptospira*. Manifestations range from mild febrile illness to severe disease with multiple organ dysfunctions. Haemorrhages and renal failure are common causes of death. Weil's disease is a severe form characterised by renal failure, jaundice and haemorrhages.

BACTERIOLOGY

Leptospires are motile helical bacteria measuring 0.1 μ by 6 to 20 μ in size. Motility is characterised by flexion, extension and rotation about the longitudinal axis. The genus *Leptospira* is classified into several genospecies. Pathogenic species include *L. interrogans*, *L. kirschneri*, *L. borgpetersenii*, *L. santarosai*, *L. weilii*, *L. noguchii*, *L. alexandrei* and *L. alstoni*. Based on antigenic similarities pathogenic leptospira are further classified into more than 230 serovars arranged in 24 serogroups. Some genospecies and serovars of leptospira cause more severe disease than others, e.g. *L. interrogans* serovar icterohaemorrhagiae is highly pathogenic, though such an association cannot always be demonstrated. Species and serovar specific host preference is also documented.

Leptospires are aerobes utilising long chain fatty acids as source of carbon and energy. In culture media, fatty acids should be detoxified with albumin. Commonly used culture media include Ellinghausen McCullough Johnson Harris (EMJH) medium containing bovine serum albumin and Fletcher's and Stuart's media containing rabbit serum as fatty acid detoxifiers. Pathogenic leptospira produce cytochromes c, c1, oxidase and catalase and some strains of lipases. Several genes coding for predicted haemolysins were identified in the genome of *L. interrogans* including a pore-forming protein and a sphingomyelinase. These haemolysins may play a fundamental role in the toxic process leading to the pathogenesis of leptospirosis.

EPIDEMIOLOGY

Any mammalian species can be a potential carrier of leptospira but rodents are the most important reservoirs. Infection in rodents is usually asymptomatic and results in lifelong carrier state. Infected domestic animals may become temporary carriers. In warm and wet environments the organisms can survive for long period and probably also multiply. Acidity, salinity, desiccation and disinfectants are detrimental to their survival. Infection may occur directly from carrier animals or indirectly through environmental vehicles of transmission. Leptospira enter human body through abraded skin, mucous membrane or possibly through intact skin when the skin is sodden by prolonged contact with water. People exposed to potential carrier animals or contaminated environment, such as farmers, sewage workers, abattoir workers, veterinarians and participants of water sporting events are at risk of infection. Floods or flash-floods expose large numbers of people to wet environment and trigger epidemics.

Leptospirosis is endemic in South Asia (including India) and Southeast Asia, the Amazon delta regions of South America and many island nations of Indian and Pacific Oceans. Sporadic cases and small clusters of cases do occur in developed countries also. Many states on the west and east coasts of India, such as Gujarat, Maharashtra, Kerala, Tamilnadu and Andaman and Nicobar Islands are endemic to leptospirosis. The peak incidence coincides with southwest monsoon on west coast and northeast monsoon in Tamilnadu. Large outbreaks occurred in Orissa in 1999 after a cyclone and in Mumbai following flash floods in 2005.

PATHOGENESIS

The usual incubation period is one to two weeks, but could be in the range of 2 to 30 days. Rotational motion of the bacteria, chemotaxis and degradation of extracellular matrix proteins by collagenase and metalloprotease facilitate invasion of host tissues. Once the tissue barriers are crossed, leptospires spread by haematogenous dissemination and establish systemic infection. Leptospiral lipopolysaccharide has low endotoxic potency and therefore, fulminating disease does not occur during the leptospiraemic phase. Vascular endothelial damage is the primary lesion and this leads to capillary leakage, haemorrhage, vasculitis and localised ischaemia in organs. In severe disease coagulation cascade is activated leading to disseminated intravascular coagulation (DIC). Pro-inflammatory cytokines released as a result of immune-killing of leptospires mediate tissue inflammation and damage. TNF-α is also believed to play a key role in disease progression.

Renal involvement is characterised by tubulo-interstitial nephritis induced by outer membrane components and mediated by inflammatory cytokines. In liver, phagocytosis of leptospirae by Kupffer cells induces production of oxygen radicals and release of inflammatory cytokines that initiate hepatocyte damage and elevation of hepatic enzymes. Myocarditis with myocyte necrosis and intra-myocardial and pericardial haemorrhages are observed in the heart.

The pathogenesis of leptospirosis-associated pulmonary haemorrhage syndrome (LPHS) presenting with acute lung injury and massive pulmonary bleeding appears to be different from that of Weil's disease. Lung tissues have high amounts of leptospiral DNA, but few intact organisms. Immunoglobulin and complement are deposited along alveolar basement membrane and in intra-alveolar spaces suggesting an underlying autoimmune mechanism. The main lesion in the lung is vascular endothelial damage.

CLINICAL FEATURES

About 70% to 80% of persons with serologically confirmed leptospiral infection remain asymptomatic. Majority of

symptomatic infections result in mild febrile illness. A small proportion progress to severe disease with multiple organ dysfunctions. Severe disease may have two distinct phases, a leptospiraemic phase and an immune phase. The leptospiraemic phase begins with remittent fever (38°C to 40°C), chills, rigors, headache, myalgias, nausea and vomiting. Conjunctival suffusion without purulent discharge and muscle tenderness most notable in calf and lumbar areas are characteristic findings. Diarrhoea, macular or maculopapular rash, sub conjunctival haemorrhage, lymphadenopathy, hepatomegaly and splenomegaly are seen less frequently. Symptoms subside within a week and, in a subset of patients, the disease progress to immune phase after a remission lasting for 1 to 3 days.

The immune phase, which coincides with the appearance of antibodies and disappearance of the organisms from blood, is characterised by manifestations of organ dysfunctions. Renal pathology is a combination of interstitial nephritis and acute tubular damage, which may be due to direct toxic effect or due to the indirect effect of hypovolaemia and ischaemia. Oliguria and hyperkalaemia have been identified as predictors of foetal outcome. Non-oliguric forms have better prognosis. Acute renal failure may also present as a non-oliguric hypokalaemic state. Although the pathological changes in the liver may be non-specific and mild, functional disturbances could be disproportionately high. Death due to liver failure virtually never happens in leptospirosis. Aseptic meningitis presents with frontal and bitemporal headache and occasionally delirium. Severe neurologic complications are rare. Cardiac arrhythmias occur in about two-thirds of the patients and include atrial fibrillation, AV blocks, bundle-branch blocks, alterations in ventricular repolarisation, supraventricular and ventricular extrasystole. Myocarditis, pericarditis, congestive cardiac failure, cardiogenic shock, adult respiratory distress syndrome and necrotising pancreatitis have been occasionally reported. LPHS is the most common cause of fatality in several case series. It can also occur in the absence of hepatic and renal dysfunctions and sometimes even in the leptosiraemic phase. Uveitis is a recognised delayed complication of leptospirosis.

DIAGNOSIS

Anaemia and leucocytosis are usually present. ESR is elevated. Thrombocytopaenia may be present in patients with renal failure. Urine analysis shows erythrocytes, leucocytes, granular or hyaline casts and proteinuria. Bilirubin levels may rise markedly accompanied by rise in alkaline phosphatase and modest rise in aminotransferases, which are usually below 200 U/L. Blood urea nitrogen and serum creatinine levels are elevated. CPK level may be elevated and this helps to distinguish leptospiral hepatitis from viral hepatitis. CSF shows elevated protein and normal glucose concentrations and predominance of polymorphs and at later stages mononuclear cells. Radiographic abnormalities of the lungs are more often seen in lower lobes and include nodular opacities to patchy alveolar infiltrates and occasionally confluent consolidation. Darkground microscopic examination of clinical specimens to visualise leptospira is unreliable. The most reliable serological test is microscopic agglutination test (MAT) using live pathogenic leptospira as antigen. A four-fold rise in titre on two samples obtained 5 to 7 days apart confirms the diagnosis. When a single sample is used, the optimum cut-off titre is 1 in 100 in non-endemic areas and 1 in 200 in endemic areas. MAT using killed leptospira or live saprophytic strains is used by some laboratories, but are of doubtful accuracy. IgM ELISA and several rapid test kits for detection of antibodies are available and can be used for a presumptive diagnosis. Isolation of leptospires from blood, urine or CSF is a definite proof of infection. Blood and CSF samples for culture should be obtained during the first week and urine samples after first week. PCR assays using primers G1/G2, B64-I/B64-II and A/B are sensitive, but do not detect all cases.

DIFFERENTIAL DIAGNOSIS

It is difficult to differentiate between mild anicteric leptospirosis and other febrile illnesses such as malaria, dengue and enteric fever. Icteric leptospirosis may mimic viral hepatitis and haemorrhagic form can mimic other haemorrhagic fevers, such as Hantavirus infection, rickettsial diseases and dengue haemorrhagic fever. Epidemiological information may aid in differentiating leptospirosis from other diseases and positive serological test or PCR confirms the diagnosis.

TREATMENT

Pathogenic strains of leptospira are susceptible to a range of anti-microbial drugs including penicillins, cephalosporins, carbapenems, tetracyclines, macrolides and fluoroquinolones. Recommended anti-microbial drugs for the treatment and prophylaxis of leptospirosis are summarised in **Table 1**. A recent cost-benefit analysis has concluded that empirical treatment of suspected cases with oral anti-microbial drugs is the most beneficial strategy unless reduction in antibiotic use is a health policy priority. Although there are conflicting reports about the role of anti-microbial drugs in severe leptospirosis, anti-microbial therapy is recommended and will shorten morbidity and dysfunction. Early initiation of therapy improves prognosis, but even if the patient reports late, anti-microbial therapy still has a role. Jarisch-Herxheimer reaction may rarely occur as a complication of anti-microbial therapy.

Table 1: Recommended Anti-Microbial Drugs for the Treatment and Prophylaxis of Leptospirosis

Indication	Anti-Microbial Drug	Dose
Chemoprophylaxis	Doxycycline	200 mg PO per week
Treatment of mild leptospirosis	Doxycycline	100 mg PO bid
	Ampicillin	500-750 mg PO qid
	Amoxycillin	500 mg PO qid
Treatment of moderate/severe leptospirosis	Penicillin G	1.5-2 MU IV qid
	Ampicillin	1 g IV qid
	Ceftriaxone	1 g IV OD

Patients with renal failure may require dialysis. Peritoneal dialysis is used as a supportive care, but some studies indicate that blood exchange therapies (haemodialysis, haemofiltration) may reduce mortality and shorten recovery time. Assisted ventilation, glucocorticoid pulse therapy, cyclophosphamide and plasma exchange are reported to improve the survival of patients with pulmonary haemorrhage. However, this is not based on controlled clinical trials and requires confirmation.

PREVENTION AND CONTROL

Measures for prevention and control may target rodent reservoirs, domestic animal carriers, environment or the population at risk. Rodent control, vaccinating, testing and treating domestic animals, decontamination of environmental sources and use of personal protective devices at workplace are all effective risk reduction methods. When there is a short-term high risk of infection in a defined population group as in the case of travellers from non-endemic to endemic areas, participation in water sporting events or natural disasters chemoprophylaxis with doxycycline can be used. In spite of decades of research, human vaccine development is still unsuccessful.

17.27 Lyme Disease, Rat Bite Fever and Other Spirochaetal Infections

Kamlesh Tewary

LYME DISEASE

Lyme disease is a systemic infection caused by the spirochaete *Borrelia burgdorferi*. The bacterium is inoculated into the skin by a tick bite. The tick is almost always of the genus *Ixodes*. Lyme disease was recognised in 1975 in Lyme county of Connecticut, in children suffering from arthritis.

Pathophysiology

While active infection by the spirochaete causes many manifestations, others may be caused by immunopathogenic mechanisms. The bacterium is introduced into the skin with a bite from an infected *Ixodes* tick (**Figure 1**). Once in the skin, the spirochaete can:

1. Be overwhelmed and eliminated by host defense mechanisms.
2. Remain viable and localised in the skin where it produces the pathognomonic skin lesion, or erythema migrans (EM) (**Figure 2**).
3. Disseminate through the lymphatics or blood. Haematogenous dissemination can occur within days to weeks of initial infection; the organism can travel to the skin, heart, joints, central nervous system (CNS), and other parts of the body.

Clinical Features

The disease is classically divided into stages:

I. *Early localised disease* refers to isolated EM and patients with an undifferentiated febrile illness.

II. *Early disseminated disease* refers to the extra-cutaneous manifestations and secondary skin lesions that occur during the first weeks to months after infection.

III. *Late disease* refers to manifestations (usually in the nervous system and joints) that occur months to years later.

Systemic manifestations

1. Fever
2. Fatigue
3. Myalgias and arthralgias
4. Flu like illness
5. Nausea and vomiting

Figure 1: Ixodes tick.

Figure 2: Erythema migrans.

Cutaneous symptoms

1. EM is present in about 75% of patients.
2. Borrelial lymphocytoma, a nodule usually found on the ear lobe or areola of the nipple, develops in some patients early in the course of disease.
3. Acrodermatitis chronica atrophicans is a rash that patients describe as inflammation or thinning of the skin, usually on the distal legs and hands.

Neurologic symptoms

1. Headache can herald CNS penetration and lymphocytic meningitis.
2. Facial weakness is similar to a typical Bell's palsy and bilateral in 25% of cases.
3. Late Lyme disease can cause paraesthesias or pain due to peripheral neuropathy and personality, cognitive and sleep disturbances from chronic encephalopathy.

Cardiovascular involvement

Palpitations, light-headedness and syncope may be a manifestation of varying degrees of heart block, including complete heart block. Chest pain and dyspnoea can occur in the setting of Lyme pericarditis and myocarditis.

Musculoskeletal involvement

Migratory pains in and around the joints and muscles; may occur from myositis, tendonitis, and bursitis.

Ocular

Red, itchy eyes from conjunctivitis.

Diagnosis

A clinical history of tick bite and characteristic rash are diagnostic of the condition. The CDC recommends a 2-step procedure consisting of a screening ELISA or immunofluorescent assay and a confirmatory Western blot for specimens that have positive or equivocal results with ELISA. A negative Lyme test result does not indicate the absence of disease, nor does a positive result indicate the presence of disease.

Treatment

Solitary EM

Oral antibiotics (e.g. amoxicillin, doxycycline, cefuroxime, erythromycin, azithromycin, amoxicillin-clavulanate) should be administered for 10 to 30 days.

Early disseminated disease findings, such as isolated facial palsy or secondary skin lesions (not meningitis) or disease with first-degree heart block (not a high-degree heart block) is treated with oral antibiotics for 21 to 30 days.

Early disseminated disease with meningitis or a high-degree heart block is treated with intravenous ceftriaxone for 2 to 4 weeks.

RAT BITE FEVER

Rat bite fever includes: Streptobacillary fever; Streptobacillosis; Haverhill fever; Epidemic arthritic erythema; Spirillary fever; and Sodoku.

Rat bite fever is an infectious disease transmitted by the secretions of the mouth or nose or the urine of an infected rodent. Rat-bite fever can be caused by two different organisms, *Streptobacillus moniliformis* and *Spirillum minus*. Most people acquire rat-bite fever through contact with urine or oral (mouth) or conjunctival (eye or nose) secretions from an infected animal. This most commonly occurs via a bite, yet some cases may occur simply through contact with these secretions. Apart from rats, squirrels, weasels and gerbils can also be the source.

In rat bite fever due to *Streptobacillus moniliformis*, fever, chills, headache, and muscle pain usually occur within 10 days of exposure (incubation period 1 to 22 days). This is followed within 3 days by a diffuse rash, primarily in the extremities. One or several large joints may become swollen, red, and painful. If untreated, severe complications including infection of the heart valves may occur.

The illness caused by *Spirillum minus* is common in Asia, particularly Japan, where it is called sodoku. In this form of rat bite fever, a particular skin rash characterised by red or purple plaques is frequently seen, and the previously healed wound at the site of the bite may re-activate and open. Joint involvement is rare.

Diagnosis is made by the detection of the organism in skin, blood, joint fluid or lymph nodes. Blood antibody tests may also be used.

Rat bite fever is usually treated with penicillin or tetracyclines for 7 to 10 days. The prognosis is excellent with early treatment.

Complications include pericarditis, endocarditis, parotitis, tenosynovitis and abscesses of the brain or soft tissue.

COMMON SPIROCHAETAL INFECTIONS

The common spirochaetal infections are listed in the **Table 1** below.

Table 1: Common Spirochaetal Infections

Organism	Condition
Borrelia recurrentis	Relapsing fever
Borrelia vincentii	Vincent's angina
Borrelia burgdorferi	Lyme disease
Leptospira icterohaemorrhagiae	Weil's disease
Leptospira andamana	Weil's disease of Andamans
Leptospira canicola	Canicola fever
Treponema pallidum	Venereal syphilis
Treponema pertenue	Yaws
Treponema carateum	Pinta

17.28 Anaerobic Infections

R Sajithkumar

INTRODUCTION

Anaerobic infections are caused by bacteria which require reduced oxygen tension for growth (oxygen concentration below 18%). Most of these organisms occur as commensals in mouth, gastrointestinal tract, skin and female genital tract and become pathogenic in presence of tissue injury, ischaemia or necrosis, along with breakdown of anatomic barriers. Their growth is usually inhibited by oxygen. These infections are usually caused by mixed organisms. Anaerobic infections must be kept in mind in patients presenting with low grade fever, abscesses, with foul smelling and brownish/blackish discharges or gas production, especially following a rupture of the viscous or procedures therein. They are associated with late diagnosis and high mortality in many settings. Special culture media, techniques and difficulty in growing these organisms hinder timely diagnosis and correct data. Many commensal organisms also grow in healthy adults. They produce a spectrum of illnesses ranging from localised abscesses to multi system involvement. The response to therapy is good with surgical management (if needed), combined with antibiotics *(Tetanus, botulism and food poisoning are covered in other chapters).*

The organisms are classified for practical purposes as shown in **Table 1**.

Table 1: General Classification of Anaerobic Organisms

Gram-positive bacilli
Clostridium (tetani, botulinum, perfringens, histolyticum, septicum), Spore forming
Actinomyces (israelii, odontolyticus)
Propionibacterium acnes
Gram-negative bacilli
Bacteroides (fragilis, ovatus, vulgatus, uniformis, melaninogenicus)
(renamed as *Porphyromonas gingivalis*, asaccharolytica, *Prevotella oralis*)
Fusobacterium (nucleatum, necrophorum, varium)
Gram-positive cocci
Peptostreptococcus (micros, magnus, asaccharolyticus, anaerobius)
Gram-negative cocci
Veillonella parvula, montpellierensis

The virulence of the organism is related to the production of exoproteins, endotoxins, cytokines and chemokines like interleukins 8, 17, tumour necrosis factor, etc., which facilitate chemotaxis of polymorphonuclears, adhesion to host tissues and abscess formation. These are also important in creating a disseminated intravascular coagulation (DIC) like state.

CLINICAL MANIFESTATIONS

Infections of the mouth and gums can lead to necrotising ulcerative gingivostomatitis (Vincent's stomatitis) characterised by sudden onset swelling, bleeding gums and foul smell. It can spread to teeth, mandible or maxilla. Acute necrotising tonsillitis/pharyngitis with lymphadenopathy and leukocytosis are common. Peritonsillar, perimandibular abcesses and infections of paranasal sinuses, middle ear or meninges may occur by contiguous spread (*Fusobacterium*, *Peptostreptococcus* and *Bacteroides* are the common organisms in this group). Ocular infections (corneal ulcer, endophthalmitis and panophthalmitis) occur following trauma.

Pleuropulmonary infections occur following aspiration of oropharyngeal contents. Low grade fever, malaise and sputum production bring the patient to the hospital. These are also seen in patients with a defective gag reflex. Necrotising pneumonia, anaerobic lung abscesses, empyema, etc. can occur (*Peptostreptococcus* and *Bacteroides* are the common organisms).

Intra-abdominal infections are manifested as enterocolitis, peritonitis, appendicitis, hepatic and splenic abscess and diarrhoea. Patients with necrotising enterocolitis present with fever, abdominal pain, tenderness and distension (*Bacteroides*, *Actinomycetes* and *Clostridium* species are involved). Antibiotic associated *C. difficile* pseudomembranous colitis presents with diarrhoea.

Skin and soft tissue infections are usually triggered by an injury, trauma, ischaemia or surgery. These usually occur in areas closer to respiratory or faecal contamination. There may be crepitant cellulitis, oedema, fasciitis and gangrene. Localised pain and foul smelling pus are usual (*Bacteroides*, *Peptostreptococcus*, clostridia are the usual organisms).

Osteomyelitis due to *Actinomycetes*, *Clostridium* and *Fusobacterium* are described following trauma. Peptostreptococcal infection can occur following implants.

Bacteremia due to *B. fragilis* following dental procedures, gastrointestinal procedures, etc., are associated with high mortality. Endocarditis due to *B. fragilis* and peptostreptococci may be associated with pericarditis as well.

Genitourinary system is a favoured site for anaerobes. The organisms are found in the vagina of healthy women. *B. fragilis*, peptostreptococci and clostridia can produce purulent vaginitis, endometritis, tubo-ovarian, pelvic abscesses. Septic abortions and pelvic inflammatory diseases can occur. *Actinomycetes* infection can occur following intrauterine device (IUD) insertions. Neonatal sepsis with anaerobic organisms are also reported following vaginal infection.

DIAGNOSIS

The diagnosis of anaerobic infections is difficult and requires a high index of suspicion. Sites where multiple pathogens are suspected along with presence of necrotic tissue or gas in tissues and no growth on routine culture techniques suggests the possibility of anaerobic infections. Culture of the aetiological

agent is paramount for the diagnosis and proper treatment. Proper specimen collection, rapid transport to the laboratory in specialised anaerobic transport media and proper handling of specimens in the laboratory are all critical steps to isolate the pathogen. Infections at sites of poor vascularity or in close proximity with urine/faeculent material, necrotic tissue or debris at the site of infection and a foul smelling discharge from the site along with numerous pleomorphic bacilli and cocci on Gram's stain of the pus, are highly suggestive of anaerobic infections.

TREATMENT

The treatment of anaerobic infections should include measures to: (i) reduce the microbial growth; (ii) remove the precipitating environment; and (iii) supportive care. Surgical resection, debridement and drainage are done on emergency basis. The areas of necrosis, ischaemia and trauma must be explored. Exposure of the tissues to air/oxygen will itself inhibit the organisms significantly.

Supportive care includes correction of shock, bleeding tendencies, immobilisation of affected extremity, adequate nutrition, maintenance of fluid and electrolyte balance, etc. Hyperbaric oxygen and antitoxins have only doubtful value.

The possibility of mixed infections (including aerobic) must be kept in mind. Isolation of the organism and antibiotic susceptibility testing is difficult and controversial. Most pathogenic strains (including *B. fragilis*) are developing resistance to penicillin G which was extensively recommended earlier. Combination of beta-lactamase inhibitors (clavulanic acid, sulbactam, tazobactam) with a beta lactam antibiotic (ampicillin, amoxicillin, ticarcillin, piperacillin) can overcome this. Newer anti-microbials (cefoxitin, meropenem, imipenem, etc.) are reported to have less resistance. Metronidazole is very effective against many organisms and good concentrations are achieved even in abscesses, but inactive against aerobes. High dose parenteral therapy instituted as quickly as possible is effective in many clinical settings. Quinolones like trovafloxacin and moxifloxacin are useful in soft tissue infections.

Specific Recommendations

An anti-Gram-negative enteric agent is generally added to treat *Enterobacteriaceae* when treating intra-abdominal infections. Penicillin is added to metronidazole to cover microaerophilic *Streptococci, Peptostreptococci,* and *Actinomycetes* species in intracranial and dental infections. Beta lactam resistance must be expected in all head and neck infections. Oral infections can be treated with metronidazole or clindamycin. Lung abcesses caused by *B. fragilis* or *Fusobacterium* respond more easily to clindamycin than penicillin G. Chloramphenicol, Metronidazole and Penicillin cross blood-brain barrier and are advocated for intracranial infections. Intra-abdominal infections require one of the carbapenem antibiotics with metronidazole. In case of septic thrombophlebitis, anticoagulation may be needed. Doxycycline effective against chlamydial and mycoplasmal infections, is added to most regimens when treating pelvic infections.

17.29 Atypical Mycobacteria

PD Khandelwal

INTRODUCTION AND CLASSIFICATION

Atypical mycobacteria are also called non-tuberculous mycobacteria (NTM) or mycobacteria other than tuberculosis (MOTT). They are ubiquitous in environment. Therefore their diagnosis is not confirmed if they are isolated from sites which remain unsterile, normally like urine, sputum, skin or faeces. Runyon classified these mycobacteria on the basis of colony, rate of growth, pigment formation and simple biochemical reaction into four types (**Table 1**). In India, *Mycobacterium tuberculosis* infection has always overshadowed true prevalence of NTM. Though the exact magnitude of NTM is difficult to predict as culture is not a routine part of diagnosing tuberculosis in India, it varies from 1 to 28 per cent. NTM cause pulmonary and generalised infections in immunocompromised individuals and cervical lymphadenitis in children. The important NTM are *M. kansasii*, *M. xenopi*, *M. fortuitum-chelonei* complex and *Mycobacterium avium-intracellular* complex group (MAIC). MAIC infections were commonly seen in pre-acquired immunodeficiency syndrome (AIDS) era in patients with chronic obstructive pulmonary disease (COPD), bronchiectasis and occupational lung diseases like silicosis, etc. However, MAIC infections are common with AIDS when CD4 count falls below 50/mm^3. *M. genavense* is a new atypical mycobacterium seen in AIDS patients.

Table 1: Classification of Non-tuberculous Mycobacteria

A.	Photochromogens	*M. kansasii* *M. marinum* *M. simiae*
B.	Scotochromogens	*M. scrofulaceum* *M. gordonae* *M. avium*
C.	Non-chromogens	*M. tuberculosis* *M. avium intracellulare* *M. xenopi* *M. ulcerans* *M. terrae*
D.	Rapid growers	*M. fortuitum* *M. chelonae* *M. smegmatis* *M. phlei*

*Non-culturable Mycobacterium is *M. leprae*. ** *A, B and C are together classified as slow-growers.*

DIAGNOSIS

The clinical features overlap with *M. tuberculosis*. Chest radiograph may show suggestive features like thin walled cavities with less parenchymal infiltrates in upper lobe. In high-resolution computed tomography (HRCT) scan, clusters of small nodules associated with areas of bronchiectasis in lower and middle-zone are common. When patient has not showed response on adequate regimen of standard anti-tuberculous drugs, diagnosis of NTM must be kept in mind. Clinical presentation and treatment are listed in **Table 2**.

Table 2: Summary of Recommended Treatment of Non-tuberculous Mycobacterial Infections

Mycobacterial species	Commonest clinical features	Recommended treatment
Kansasii	Pulmonary disease	Streptomycin [first three months], rifampicin, isoniazid and etham butol for at least two years. Consider resection surgery
Marinum	Swimming pool and fish tank granuloma	Usually heal spontaneously. Trimethoprim and sulpha-methoxazole, minocycline
Avium	Lymph nodes Pulmonary disease	At least four drugs rifabutin, streptomycin, clarithromycin, ethambutol for two years Consider resection surgery
Scrofulaceum	Cervical lymph node in children	Rifampin/rifabutin, clarithromycin, ethambutol as for avium
Xenopi	Pulmonary disease in hot water supply of hospital	As for avium but may be possible to modify as some strains are sensitive to a number of drugs, quinolones, ethionamide
Ulcerans	Skin ulcers (Buruli ulcers)	Surgical excision and skin graft; rifampicin, clofazimine in addition to other 2-3 drugs
Fortuitum	Injection abscess Pulmonary disease Post cardiac surgery	Resistant to primary ATT. Clarithromycin, amikacin, doxycycline, imipenem, cefoxitin, quinolones
Chelonae	Injection abscess, Post cardiac surgery, Rarely mycobacterial septicaemia, dissemination after renal homografts	Four drugs from gentamicin, amikacin, streptomycin, erythromycin and ethionamide according to sensitivity test

Other methods are culture on Lowenstein-Jensen medium or radiometric system (BACTEC), identification of isolates by biochemical tests, molecular methods by gene probes, polymerase chain reactions using gene amplification methods and determining the sensitivity profile of NTM.

TREATMENT

The treatment of NTM is usually with a combination of 4-5 drugs for 2 years or 12 months after the culture is negative. Dosages are as per standard chemotherapy for *M. tuberculosis* and drugs are given depending on sensitivity pattern, if available. Surgical options may need to be explored in individual cases.

17.30 Brucellosis

BG Mantur

A specific-pathogen now called *Brucella melitensis* causing brucellosis was recognised in 1887 by David Bruce and clinical features were comprehensively described in 1897 by Hughes. Brucellosis is also known as Malta fever and undulant fever.

EPIDEMIOLOGY

Brucellosis—a leading zoonosis has been recognised for more than 100 years and continues to be an important public health problem worldwide, particularly in Latin America, Southern Europe, Africa and Asia. Brucellosis has been endemic in India for many years. Animals are almost exclusively the source of infection for people. The major reservoirs include goats and sheep (*B. melitensis*), cattle (*B. abortus*), swine (*B. suis*), and dogs (*B. canis*). Infection occurs through consumption of infected raw milk and their products, or raw meat. It is also transmitted by direct contact with infected animals or abortive material. Inhalation of infected aerosols is also an important route of transmission. In adults, brucellosis is an occupational hazard for veterinarians, abattoir workers, farmers, shepherds, butchers, dairy workers, hunters and laboratory workers. It is estimated that there are 50-100 million nomads and seminomads in the developing world. Living in close contact with sheep, goats, and cattle exposes nomads to a great risk of brucellosis. Person to person transmission is a rare occurrence. However, it is a common imported disease in developed world, being in the list of travel-related infections.

AETIOPATHOGENESIS

Brucella spp. are Gram-negative, facultative intracellular cocco-bacilli. *B.melitensis, abortus, suis, canis, pinnipediae, cetaceae* are reported to infect humans; *B. melitensis* being the most important zoonotic agent.

Brucella organisms are virulent due to their ability to survive, adapt to acidic environment and even multiply within cells of the mononuclear-phagocytic system. Humoral as well as cell mediated immune responses do develop after the infection; antibodies are not protective but are useful in serodiagnosis, while cellular immunity provides protection against re-infection.

CLINICAL FEATURES

Brucellosis is a re-emerging infection that affects both farm and wild animals as well as humans. Brucellosis can affect people of any age. Males are affected more often than females. The incubation period ranges from 7 to 90 days. The disease presents as an acute (<2 months), subacute (2 to 12 months) or chronic infection (>12 months). The clinical presentation is non-specific and heterogeneous in its course and severity and it presents as a multi-system disease invading many organs and tissues. The main clinical symptoms are fever, night sweats, arthralgia, and weight loss. Hepatomegaly and or splenomegaly and arthritis are presenting signs. However, the most common presenting symptom is fever. Most frequently reported complications include arthritis, epididymo-orchitis, meningitis, brain abscess, endocarditis and hepatitis. Mortality rate is less than 2%; 80% of deaths being attributed to endocarditis. Brucellosis during pregnancy results in spontaneous abortion or intrauterine transmission of infection to the infant.

DIAGNOSIS

Human brucellosis is a protean disease. The wide spectrum of clinical features and general inexperience with the disease contribute vastly to its underdiagnosis. It is often misdiagnosed as typhoid, malaria, tuberculosis, rheumatoid arthritis. Brucellosis, therefore, could be missed if it is not considered seriously in making a differential diagnosis and diagnosis should always be supported by laboratory tests. The diagnosis is generally made when a standard tube agglutination test shows antibody titre of 1:160 or more in the presence of compatible clinical manifestations. In endemic areas, a titre of 1:320 as cutoff makes the test more specific. However, a firm diagnosis should be based on either a positive blood culture or a rise in antibody titre between acute and convalescent phase serum specimens obtained 2 weeks apart and performed in the same laboratory.

TREATMENT

The treatment in adults is the combination of oral rifampicin 600 to 900 mg and doxycycline100 mg twice daily for 6 weeks, and in place of rifampicin, injectable streptomycin (1 gm/d) for two to three weeks is also endorsed. Patients require three to seven days to become afebrile. Average relapse rates are ~10% especially in patients on short courses and significantly higher with monotherapy. The use of antituberculosis drugs especially rifampicin should be reduced to a minimum especially in endemic areas for both brucellosis and tuberculosis to prevent the development of community resistance to rifampicin. Fluoroquinolones have been suggested to be a useful option. The search for alternatives becomes a necessity in the view of today's treatment regimens incorporating antituberculosis drugs. **Table 1** lists the treatment in special situation.

Table 1: Therapy for Special Situations

Complications and relapsed patients	
	Standard regimen extending treatment to 12 weeks.
Brucellosis during pregnancy	
	Oral rifampicin for 8 weeks together with intramuscular streptomycin for initial 2 weeks.
	or
	Oral rifampicin and cotrimoxazole 960 mg twice daily for 8-12 weeks.
Indications for steroids	
	Severe toxaemia
	Thrombocytopaenia
Indications for surgery	
	Thrombocytopaenia leading to gastrointestinal bleeding and anaemia (splenectomy)
	Endocarditis in presence of congestive heart failure, abscess formation and involvement of prosthetic valves (valve replacement)

PREVENTION AND CONTROL

Vaccines have varying degrees of success in controlling brucellosis in animals. There are still no approved human vaccines available, and the animal vaccines currently in use are pathogenic to humans. Because brucellosis is preventable, an organized effort must be done in order to eradicate *Brucellae* from animals. Increasing public awareness, and educating the public regarding the health hazards of ingesting raw milk and its products is important for prevention of the disease.

RECOMMENDED READINGS

1. Corbel MJ. Brucellosis: an overview. *Emerg Infect Dis.* 1997; 3: 213-21.

17.31 Donovanosis

Dwijendra Nath Gangopadhyay

DEFINITION

Donovanosis is an uncommon chronic granulomatous ulcerative disease of the genitalia caused by *Klebsiella granulomatis* being transmitted sexually. It is also known by various names like granuloma inguinale, granuloma venereum or sclerosing granuloma.

EPIDEMIOLOGY

It is endemic in the tropical and subtropical countries among the backward classes with poor hygienic habits, being more common in the male than in female.

AETIOLOGY

It is caused by a Gram-negative intracellular bacillus *Klebsiella granulomatis* formerly known as *Calymmatobacterium granulomatis*. The infectivity of the bacillus is low so that repeated exposure is needed before occurrence of the disease.

Incubation Period

It is difficult to assess the true incubation period of the disease because of its low infectivity and the asymptomatic nature of the disease in its initial phase. It may vary between 1 week and 3 months, usually 1 to 4 weeks.

CLINICAL FEATURES

The lesions are mostly found on the genitalia (90%), sometimes in the surrounding area. The disease begins as small subcutaneous nodules that soon rupture producing beefy-red, velvety (**Figure 1**), relatively painless ulcer that bleeds easily on touch. The disease progresses slowly and relentlessly through surface continuity without any tendency to spontaneous healing. There is no involvement of local lymph nodes. Subcutaneous nodules in the inguinal region may mimic inguinal lymphadenopathy (pseudobubo) which eventually rupture to form ulcer. The ulcer is commonly seen in males over the prepuce, coronal sulcus, frenum, and in females over the labia minora, fourchette. In addition, the lesions may spread to thighs and lower abdomen and scrotum in male and cervix in female.

Figure 1: Donovanosis: Beefy-red velvety ulcerogranulomatous masses.

Four clinical types are recognised:

(a) Ulcerogranulomatous type—the most common type; as described above.

(b) Hypertrophic type—the ulcer presents with a raised cauliflower-like margin.

(c) Necrotic type—a deep ulcer is seen.

(d) Sclerotic type—when there is excessive scar formation.

DIAGNOSIS

It is difficult to culture the organism. The most effective method is direct visualisation of the organism within the macrophages as bipolar staining, safety pin-shaped intracytoplasmic inclusions known as Donovan bodies in tissue crush smear stained by Wright or Giemsa stain. Histopathological examination of biopsy material from the edge of an ulcer is the 'gold standard' in the diagnosis of Donovanosis. Recently a diagnostic PCR has been developed to detect the organism.

TREATMENT

The ulcer responds to common broad-spectrum antibiotics early after initiation of therapy. However, it needs prolonged therapy for complete healing of the ulcer and prevention of recurrence. Recommended regimen includes doxycycline 100 mg twice daily for at least 3 weeks or until the ulcers heal completely. Other antibiotics that may be used are:

- Azithromycin 1 g once weekly on empty stomach
- Ciprofloxacin 750 mg twice daily
- Erythromycin base 500 mg four times daily
- Sulphamethoxazole-trimethoprim combination double strength one tablet twice daily.

The antibiotic irrespective of choice should be continued for at least three weeks for complete healing and prevention of recurrence. Injection streptomycin or gentamicin may be added if the lesions fail to respond to above medication within few days.

Since it is a sexually transmitted disease (STD), patient's sex partners should be traced and managed as necessary. If there

is no sign of active disease in the sex partner, prophylactic therapy is not recommended because of low infectivity of the bacteria.

FOLLOW-UP

Even after total clearance of the ulcers the patient should be followed-up for prolonged period as recurrence has been reported even one year after successful treatment.

COMPLICATION

The disease tends to continue without any tendency of self-healing. It leads to extensive scarring that may cause much mutilation of the genitalia. Dissemination of the infection to distant parts of the body may be seen, particularly to bones. The tibia is involved in 50% of the cases of dissemination. Systemic spread is accompanied by general symptoms like fever, malaise, etc. Dissemination is more common among females. Elephantiasis of the genitalia secondary to scarring may be seen more frequently among females. Malignant changes have been reported occasionally over the scar.

PREVENTION

Since presence of any genital ulcerative disease is an increased risk for transmission of HIV, an attempt to prevent the occurrence of the disease should be undertaken. However, usual promotion of condom may not be able to prevent this disease. Sex contacts of a patient should be kept under surveillance and early treatment of the condition is the only preventive measure.

17.32 Actinomycosis and Nocardiosis

A Muruganathan

INTRODUCTION

Actinomycosis is a chronic disease characterised by abscess formation, draining sinus tracts, fistulae and tissue fibrosis. It can mimic a number of other conditions, particularly malignancy and granulomatous disease. *Actinomycetes* are a group of aerobic and anaerobic bacteria in the order *Actinomycetales*.

AETIOPATHOGENESIS

Actinomycosis is a subacute-to-chronic bacterial infection caused by filamentous, Gram-positive, non acid-fast, anaerobic-to-microaerophilic bacteria.

Actinomycetes are prominent among the normal flora of the oral cavity. They require a break in the integrity of the mucous membranes and the presence of devitalised tissue to invade deeper body structures and to cause human illness. Furthermore, actinomycosis is generally a polymicrobial infection, with isolates numbering as many as 5 to 10 bacterial species. Haematogenous dissemination to distant organs may occur in any stage of actinomycosis, whereas lymphatic dissemination is unusual. Moisture helps their survival and ability to produce infection.

EPIDEMIOLOGY

Actinomyces are not found in the environment and humans are the only natural reservoir. Predisposing factors include the following:

1. Dental caries and extractions
2. Gingivitis and gingival trauma
3. Infection in erupting secondary teeth, poor oral hygiene
4. Diabetes mellitus
5. Immunosuppression
6. Malnutrition
7. Local tissue damage caused by neoplastic disease or irradiation

CLINICAL FEATURES

Cope, in 1938, classified actinomycosis infection into 3 distinct forms: (1) cervicofacial (50%); (2) pulmonothoracic (30%); and (3) the abdomino-pelvic (20%).

Patients with cervicofacial actinomycosis present with nodular lesion(s), usually located at the angle of the jaw. These gradually increase in size and number (i.e. multiple abscesses) and ultimately form sinuses that open onto the cheek or submandibular area. Sulphur granules may be seen in the exudate. Nodules may be tender in the initial stages but are typically non-tender and woody hard in the later stages. Lymphadenopathy is typically absent. Trismus is present if the mastication muscles are involved. Fever is variably present.

Thoracic actinomycosis has the following features:

Aspiration of oropharyngeal secretions containing actinomycetes is the usual route of infection. Fever, cachexia, abnormal breath sounds, cough, haemoptysis are the presenting symptoms. Sinus tracts with drainage from the chest wall (i.e. pleurocutaneous fistula).

Abdominal actinomycosis is characterised by:

It presents as scar(s) from antecedent abdominal surgery. Low-grade fever and cachexia are variably present. Mass is most often located in the right lower quadrant, less frequently in the left lower quadrant, typically firm-to-hard in consistency, non-tender, often fixed to underlying tissue. Haematogenous spread occurs to liver, kidney and presents as liver abscess and perinephric abscess. Sinus tracts with drainage from either the abdominal wall (i.e. peritoneocutaneous fistula) or the perianal region.

Pelvic actinomycosis usually presents as pelvic mass and menometrorrhagia.

MYCETOMA

Mycetomas are chronic, slowly progressive infections of the subcutaneous tissue, usually of the foot and rarely of other parts of the body. The disease was originally reported by Gill (1842) from Madurai. It is commonly known as Madura mycosis or Madura Foot. It is seen mainly in the tropics. Bacterial mycetomas are usually caused by—*Actinomycetes (A. israelii, A. bovis), Nocardia (N. asteroides, N. brasiliensis. N. caviae), Actinomadura (A. madurae, A. pelletieri), Streptomyces (S. somaliensis).*

Diagnosis

A Gram-stained smear of the specimen may demonstrate the presence of beaded, branched, Gram-positive filamentous rods, suggesting the diagnosis of actinomycosis.

Nocardia can be differentiated from *Actinomycetes* by its acid fastness due to the mycolic acid content of the cell wall. *Nocardia* grow under aerobic conditions while *Actinomycetes* grow under anaerobic conditions.

Cultures should be placed immediately under anaerobic conditions in a suitable media and incubated for 48 hours or longer; the isolation and definitive identification of actinomycetes may require 2 to 3 weeks.

Actinomycosis needs to be differentiated from tuberculosis, mycosis, granulomatous diseases or malignancy. Demonstration of sulphur granules in discharge and histopathology are diagnostic. Sun Ray appearance is typically seen. A culture of tissue or fluid shows *Actinomycetes* species.

Prognosis

When actinomycosis is diagnosed early and treated with appropriate antibiotic therapy, the prognosis is excellent.

Treatment

The current recommended therapy includes 4 weeks of high dose intravenous penicillin followed by a 3 to 6 month course of oral penicillin, continuing treatment even after total resolution of symptoms. Other anti-microbials that have been found to be effective include tetracycline, erythromycin,

clindamycin, ceftriaxone and imipenem. These can be used in penicillin-allergic patients with good success rates. Amoxicillin/clavulanic acid can be used in mild to moderately severe cases of actinomycosis; covers both pathogenic *Actinomycetes* and companion bacteria, which frequently are resistant to penicillin. Ciprofloxacin has been used for treatment of recalcitrant cases.

Surgery

For more complicated cases, surgery for excision of recalcitrant fibrotic lesions or necrotic tissue or for drainage can be done.

Prevention

Maintenance of good oral hygiene and adequate regular dental care are important. Patients and physicians alike should be aware of the increased risk of infection associated with insertion of IUCD.

NOCARDIOSIS

Introduction

Nocardiosis is an acute, subacute or chronic suppurative infection. Two characteristics of nocardiosis are its ability to disseminate to virtually any organ, particularly the central nervous system and its tendency to relapse or progress despite appropriate therapy.

Aetiopathogenesis

Nocardiosis is an uncommon Gram-positive bacterial infection caused by aerobic *Actinomycetes* in the genus *Nocardia*. *Nocardia* species are found worldwide in soil, decaying vegetable matter and aquatic environments and can become airborne, particularly on dust particles. Inhalation of free-living organism is the likely route of infection of the pulmonary system. Haematogenous spread can occur to all organs of the body. Ingestion of contaminated food may produce disease via gastrointestinal tract. Localised cutaneous or lymphocutaneous infections occur after contamination of an abrasion and may result in abscess.

Classic histologic lesion of nocardiosis is an abscess with predominant neutrophils and prominent necrosis. T-cell population capable of direct lymphocyte-mediated cytotoxicity is necessary to kill the *Nocardia*.

Risk Factors

The risk of nocardial infection is increased in immunocompromised patients particularly those with defects in cell-mediated immunity, glucocorticoid therapy, human immunodeficiency virus (HIV) infection, malignancy and diabetes mellitus. Chronic lung disease and alcoholism are additional risk factors for pulmonary nocardiosis.

Clinical Features

The clinical features and differential diagnosis of nocardiosis is given in **Table 1**.

Table 1: Clinical Features, Differential Diagnosis and Treatment of Cutaneous, Pulmonary and Disseminated Nocardiosis

Clinical Presentation	Cutaneous Nocardiosis	Pulmonary Nocardiosis	Disseminated Nocardiosis
Susceptible patients	Agricultural workers, traumatic exposure	Chronic pulmonary disease, deficient cell-mediated immunity	Deficient cell-mediated immunity
Main clinical features	Dermo-hypodermitis, lymphangitis, or mycetoma	Onset of pulmonary nocardiosis may be acute, subacute, or chronic and is not distinguished by any specific signs or symptoms. Fever, night sweats, fatigue, anorexia, weight loss, dyspnoea, cough, haemoptysis and pleuritic chest pain have all been described	The hallmark of CNS nocardiosis is formation of a parenchymal abscess that can occur in any region of the brain. Brain abscesses may have no signs or symptoms or may present with headache, seizures and coma and CSF usually does not show nocardia
Main clinical differential diagnosis	Sporotrichosis and other subcutaneous mycoses, fungal mycetomas	Complications, such as empyema, mediastinitis, pericarditis and superior vena cava syndrome Bacterial lung abscesses, tuberculosis, aspergillosis and other opportunistic fungal infections.	Pyuria is seen in kidney involvement; other sites of involvement have been reported include sinuses, eyes, spleen, liver, adrenal glands, pancreas, thyroid gland, prostate, and testicles Bacterial brain abscesses, abscesses in other organs, aspergillosis and other opportunistic fungal infections
Suggested initial treatment	TMP-SMX TMP/SMX + fluoroquinolone minocycline is alternative oral drug in a dose of 100-200 mg twice daily	TMP-SMX TMP-SMX + ceftriaxone TMP-SMX + moxifloxacin Imipenem + amikacin	Imipenem + amikacin TMP-SMX + imipenem + amikacin TMP-SMX + ceftriaxone + amikacin
Comments	Fluoroquinolone must be considered for deep infections, especially mycetoma	TMP/SMX monotherapy only in immunocompetent patients with mild disease Combination therapy is preferred in the immunocompromised patients	Linezolid could replace any of the proposed drugs At least 2 weeks of initial intravenous treatment is recommended Surgical treatment must be considered for deep abscesses

Anti-microbiol susceptibilities should be performed on oll Nocordio isolotes os o guide to theropy. Potients on immunosuppressive theropy or underlying diseose theropy should be continued. In immunocompromised patients whose immunosuppression connot be reversed, indefinite mointenonce suppressive theropy with TMP-SMX (Doxycycline is a reosonoble olternotive); the dose is 10-20 mg/kg in two divided dosoges.

TMP-SMX: Trimethoprim-sulphomethoxozole.

Diagnosis

A definitive diagnosis of nocardiosis requires the isolation and identification of the organism from a clinical specimen.

Staining with modified acid-fast stain and especially Gram stain is particularly important to provide a rapid presumptive diagnosis while awaiting the results of the culture which may take from 48 hours to 3 weeks. The typical colonies are usually seen after 3 to 5 days. In general, the colonies have a chalky white or cotton-ball appearance because of the presence of abundant aerial filaments.

Imaging Studies

Plain radiography and computed tomography (CT) of chest are useful in the evaluation of pulmonary nocardiosis. The common radiographic findings are parenchymal nodules, infiltrates, lung abcesses and rarely pleural effusion.

All patients with nocardiosis, except of mycetoma, should be subjected to brain imaging in the form of CT or MRI head as asymptomatic brain abscess are a common finding and can help in making a diagnosis if the abscess is spreading to the contiguous structures.

Treatment

The treatment of nocardiosis can be divided into medical care and surgical care. The medical treatment of nocardiosis is outlined in **Table 1**. Localised abscesses generally require prompt surgical therapy. Prognosis depends upon the severity and site of infection.

Patients with nocardiosis must be educated about the need for protracted anti-microbial therapy with periodic follow-up by the treating physician.

CONCLUSION

The diagnosis actinomycosis and nocardiosis can be challenging, as signs and symptoms are not specific and a high index of clinical suspicion is necessary. Each case needs a careful multi-disciplinary evaluation.

17.33 Bartonella Infections

Pallavi Bhargava

The *Bartonella* species are small Gram-negative bacilli that adhere to mammalian erythrocytes and endothelial cells. The genus *Bartonella* was first described by Dr AL Barton in 1909. The three most common species responsible for human infections are: *B. bacilliformis, B. henselae* and *B. quintana.* Depending on the species and host immunity, these agents cause a wide variety of clinical illnesses, viz. cat-scratch disease (CSD), bacillary angiomatosis (BA), peliosis hepatis, oroya fever, Verruga peruana, trench fever and endocarditis. BA is the only *Bartonella* infection reported in the literature from India.

The clinical syndromes, modes of transmission, risk factors and treatment are described in **Table 1**.

BACILLARY ANGIOMATOSIS

BA was first described as a vascular skin lesion occurring in acquired immunodeficiency syndrome patients. But now it is well-known that BA caused by *B. henselae* and *B. quintana* in immunocompromised patients can disseminate to involve many organ systems particularly liver (peliosis hepatis). The skin legions of BA are red or purple vascular papules or nodules (**Figure 1**).

BA is characterised by angiogenesis and a neutrophilic inflammatory response to the organisms. The diagnosis of BA is confirmed on histopathological examination. Differential diagnosis is from Kaposi's sarcoma and pyogenic granuloma. Cutaneous lesions respond well to a 3-week course of either macrolides or tetracycline.

Figure 1: Cutaneous bacillary angiomatosis in an AIDS patient from India.

CAT-SCRATCH DISEASE

Cat-scratch disease is usually a self-limited disease characterised by regional lymphadenopathy presenting 1 to 2 weeks after scratch by a cat and lasting for several weeks to months. A papule or pustule can sometimes be seen preceding the lymphadenopathy. Systemic symptoms, like malaise, anorexia or weight loss may be present. Rarely encephalitis, meningitis, transverse myelitis, seizures, liver, spleen involvement and osteomyelitis have been reported. Acute neuroretinitis and

Table 1: Clinical Syndrome, Mode of Transmission and Treatment (for Bartonella Infections)

	Disease	Transmission/Risk factor	Treatment
Bartonella henselae	Cat-scratch disease	Cat-scratch or cat bite	Azithromycin, ciprofloxacin Doxycycline (5 days)
	Bacillary angiomatosis	Cat-scratch or cat bite Immunocompromised state, especially HIV infection	Erythromycin, rifampicin Doxycycline, ciprofloxacin (3 to 6 weeks)
	Peliosis hepatis endocarditis	Exposed to cats and cat flea	Azithromycin, doxycycline (4 to 6 months)
Bartonella quintana	Bacillary angiomatosis	HIV infection Infestation by body louse	Erythromycin, doxycycline Azithromycin, doxycycline
	Trench fever	Homelessness Body louse homelessness	(4 to 6 weeks)
	Endocarditis	As above	Ceftrioxone, doxycycline Gentamicin Valve replacement
Bartonella bacilliformis	Oroya fever	Sandfly (*Lutzomyia)* bite	Chloramphenicol, ciprofloxacin (3 weeks)
	Verruga peruana	Convalescent phase of Oroya fever or chronic infection	Rifampicin, ciprofloxacin Chloramphenicol (1 to 2 weeks)

HIV = Human immunodeficiency virus.

Perinaud's oculoglandular syndrome can occur with conjunctival inoculation by *B. henselae*. Suspect Cat-Scratch disease if skin lesions and lymphadenopathy are seen in a patient with exposure to cats. Diagnosis is confirmed by histopathologic examination of lymph nodes. The bacterial clumps can also be seen if tissue is stained with Warthin-Starry stain. Oral azithromycin for 5 days is reserved for patients with severe manifestations. Erythromycin, rifampicin, doxycycline and ciprofloxacin are other active drugs.

TRENCH FEVER

Trench fever was first described as a relapsing and debilitating febrile illness in soldiers fighting during World War I. It is caused by *B. quintana* transmitted from person to person by body lice. Lately Trench fever has re-emerged in France and United States in urban homeless people with history of alcohol abuse. Clinical features are high grade fever, headache, malaise, aseptic meningitis and severe musculo-skeletal pain. Diagnosis is established by growing *B. quintana* in blood culture. A 4 to 6 week course of doxycycline (100 mg BD) or erythromycin (2 gm/day) or azithromycin (500 mg/day) is effective.

OROYA FEVER AND VERRUGA PERUANA

B. bacilliformis causes both these infections. Oroya fever presents with fever, severe anaemia and high mortality without treatment. Sandfly found in Andes mountains transmits the illness to non-immune individuals. *Verruga peruana* presents as skin lesions in patients recovering from Oroya fever or patients with chronic infection with *B. bacilliformis*. Diagnosis of Oroya fever is confirmed by culturing bacteria from blood while *Verruga peruana* is diagnosed on histopathological examination. Oroya fever in South America is treated with intravenous chloramphenicol while rifampicin is the drug of choice for *Verruga peruana*.

ENDOCARDITIS

Some of the culture-negative endocarditis is caused by *Bartonella* species. Once diagnosis is confirmed by blood culture or serology, treatment is modified to include drugs that are active against *Bartonella* (azithromycin or doxycyline). Duration of treatment is 4 to 6 months.

17.34 Melioidosis

Kavitha Saravu

The name melioidosis is derived from the Greek word 'melis' referring to distemper of asses. Melioidosis, caused by *Burkholderia pseudomallei*, has a wide spectrum of presentations with acute and chronic form, localised form to systemic disease and asymptomatic to septicaemic illness.

EPIDEMIOLOGY AND AETIOLOGY

Melioidosis is endemic in Northern Australia, Thailand, Singapore, Malaysia, Myanmar and Vietnam. In India, it is sporadic with increasing trend in Southern states. *B. pseudomallei* is a Gram-negative, motile bacillus isolated from soil and surface water. The disease is acquired by inoculation through abraded skin, inhalation or ingestion. Its incubation period ranges from 24 hours to many years. It produces necrotising inflammation, abscess or granuloma with multinucleated giant cells.

CLINICAL FEATURES

Melioidosis is more common in males aged 40 to 60 years. Other risk factors are diabetes, alcoholism, malignancy, chronic kidney and lung diseases. It occurs in farmers exposed to soil and surface water and the incidence is highest during monsoon. Depending upon the innoculum size, route, virulence factors and host responses, the *B. pseudomallei* infection can have several disease outcomes—asymptomatic seroconversion, acute or chronic disease or latent infection. Severe disease or septicaemia occurs in patients with risk factors.

Clinical disease may present acutely or chronically with more than 2 months of fever. Localised disease presents as skin ulcers, and subcutaneous abscesses or pneumonia. Disseminated disease can present with pneumonia, abscesses in liver, spleen, kidney, prostate, skin and subcutaneous tissue, septic arthritis and osteomyelitis with or without septicaemia. Meningo-encephalitis or subdural empyema are rare presentations. Lymph nodal swelling with necrosis can occur as part of disseminated melioidosis or local forms. Relapse may occur after many years.

DIAGNOSIS

In systemic disease, laboratory tests indicate anaemia, neutrophilic leucocytosis, elevated ESR, CRP and plasma sugar. Liver enzymes may be elevated with alkaline phosphatase more than transaminases. Renal failure may be present in septicaemia. Forty to sixty percent of patients are bacteremic.

On Gram-staining *B. pseudomallei* has a characteristic bipolar staining with 'safety pin' appearance. It can be cultured easily from blood, pus, sputum and urine, but may be mis-identified as *B. cepacia*, *Pseudomonas stutzeri*, or other Pseudomonas species. *B. pseudomallei* is identified by the characteristic colony morphology and biochemical reactions.

TREATMENT

Anti-Microbial Therapy

Initially intensive parenteral therapy is with ceftazidime 50 mg/kg (up to 2 g) q6h or meropenem 25 mg/kg (up to 1 g) q8h, or imepenem 25 mg/kg (up to 1 g) q6h with or without sulphamethoxazole/trimethoprim 40/8 mg/kg (up to 1600/320 mg) q12h for 10 to 14 days. Deep seated collections, extensive pulmonary disease, osteomyelitis, septic arthritis and neurological melioidosis require 4 to 8 weeks of intensive phase.

Subsequent oral eradication therapy is required to prevent recrudescence or relapse. Sulphamethoxazole/trimethoprim with doxycycline 2 mg/kg, (up to100 mg) q12h is recommended for 12 to 20 weeks. Amoxicillin-clavulanate 20/5 mg/kg q8h is recommended in pregnancy.

Adjunctive Therapy

Abscesses need surgical drainage. Septicaemic melioidosis patients require aggressive therapy with management of septic shock, renal failure, respiratory failure and hyperglycaemia.

PROGNOSIS AND PREVENTION

Overall mortality ranges from 19% to 44% with relapse rate of 9.7%. Prevention is by avoidance of contact with *B. pseudomallei* in the environment and adequate chlorination of water supplies.

17.35 Rickettsial Infections

Raminder Singh

INTRODUCTION

Rickettsial infections are re-emerging and are prevalent throughout the world. In India, they are reported from Maharashtra, Tamilnadu, Karnataka, Kerala, Jammu and Kashmir, Uttaranchal, Himachal Pradesh, Rajasthan, Assam and West Bengal. In view of low index of suspicion, non-specific signs and symptoms and absence of widely available sensitive and specific diagnostic test, these infections are notoriously difficult to diagnose. Failure of timely diagnosis leads to significant morbidity and mortality. With timely diagnosis, treatment is easy, affordable and successful. The pattern of rickettsial infections is given in **Table 1**.

Table 1: Classification of Rickettsial Agent

Disease	Rickettsial Agent	Geographical Area	Insect Vector	Mammalian Reservoir
Spotted fever group				
Rocky mountain spotted fever	*R. rickettsii*	United States	Tick	Rodent, dogs
Mediterranean spotted fever, Boutonneuse fever, Kenya tick typhus, South African tick fever, Indian tick typhus	*R. conorii*	Africa, India, Mediterranean regions	Tick	Rodent, dogs
Queensland tick typhus	*R. australis*	Eastern Australia	Tick	Rodents
Siberian Asian tick typhus	*R. sibirica*	Siberia, Mongolia	Tick	Rodents
African tick bite fever	*R. africae*	Rural sub-Saharan Africa, Eastern Caribbean	Tick	Cattle
Rickettsial pox	*R. akari*	United States, Korea	Mite	Mice
Typhus group				
Epidemic (louse-borne) typhus	*R. prowazekii*	South America, Central Africa	Louse	Human, flying squirrels
Endemic (murine) typhus	*R. typhi*	Worldwide	Flea	Rodents
Scrub typhus group				
Scrub typhus	*Orientia tsutsugamushi*	Southeast Asia, Japan, Australia, Western Siberia	Mite	Rodents
Other				
Q-fever	*Coxiella burnetii*	Worldwide	None	Cattle, sheep, goat
Ehrlichiosis and anaplasmosis				
Human monocytic	*Ehrlichia chaffeensis, Anaplasma equi, Ehrlichia canis*	Southeastern United States	Tick	Dogs
Human granulocytic	*Anaplasma phagocytophilum, Ehrlichia ewingii*	Northeastern United States	Tick	Rodent, deer, sheep

PATHOLOGY

The *Rickettsia* species are small, pleomorphic coccobacilli and obligate intracellular pathogens that depend on the host as a source of energy. Humans are accidental host for these organisms and are usually infected by means of an arthropod vector like tick, mite, louse and flea. *Rickettsia* multiplies at the bite site, invade the bloodstream and establish an infection by infecting endothelial cells throughout the microvasculature. Subsequent vascular lesions caused by damage to endothelial cells account for the pathological changes that occur throughout the body. The damage is most marked in Rocky Mountain Spotted Fever. *Rickettsia* are diverse collections of organisms categorised by antigenic similarities, they cause illness from mild to life threatening or recrudescent.

DIAGNOSIS

Haematology

Leucocytosis and low platelet counts may be present with high ESR.

Biochemistry

Hyponatraemia, hypoalbuminaemia, elevated hepatic transaminases and blood urea are frequently present.

Serology

Serology is used for detection of convalescent antibodies by various tests like microimmunoflorescence, immunoperoxidase

assay, latex agglutination, indirect haemagglutination, enzyme-linked immunosorbent assay, dot blot immunoassay (including dipstick test) and Weil-Felix test.

- *Weil-Felix Test* is positive 7 days after infection, uses agglutinins from OX-2, OX-19 and OX K strains of Proteus bacteria and causes them to clump; a four fold rise in titre is seen.
- *Indirect fluorescent antibody:* This test is considered as 'gold standard'.
- *Polymerase chain reaction assay:* It can be used to detect rickettsial DNA in whole blood, buffy coat fraction or tissue specimen. It is most rapid assay for the diagnosis.
- *Immunohistological detection* of microorganisms in skin biopsy.
- *Isolation of rickettsial agents*

TICK AND MITE BORNE-SPOTTED FEVERS

Rocky Mountain Spotted Fever (RMSF)

The causative agent *R. rickettsii* is transmitted to humans by the bite of Rocky Mountain wood tick, *Dermacentor andersoni* in Western United States and by the bite of American dog tick *Dermacentor variabilis* in Eastern United States. The symptoms begin with fever, chills, headache, nausea, myalgia, restlessness and irritability, pneumonitis may develop. Delirium, lethargy, seizure and coma may appear. The face is flushed and conjunctiva injected. The rash (faint macules that progress to maculopapules and petechiae) appear on palms and soles and spread to whole body. In some cases there is hepato-splenomegaly, jaundice, myocarditis, uraemia or ARDS. The mortality rate for RMSF is 70% in untreated elderly due to cardiac or respiratory failure.

The drug of choice is doxycycline (200 mg/dL) orally or chloramphenicol (50 mg/kg/day). Patient usually responds within 48 hours.

Rickettsial Pox

The causative agent is *R. akari* and is maintained by mice and their mites, is recognised principally in New York City and others states of USA. A papule appears at the site of mite bite and develops a central vesicle that becomes painless black crusted eschar surrounded by erythematous halo. Lymph nodes draining the area of eschar appear. After 10 to 14 days, fever, headache, chills, myalgia occur along with a macular rash which turns into papules, vesicles and crusts that heal without scarring. Disease resolves within 6 to 10 days and is non-fatal.

Treatment options are doxycycline (100 mg bid for 1 to 5 days), ciprofloxacin (750 mg bid for 1 to 5 days), and chloramphenicol (500 mg qid for 7 to 10 days).

Other Tick Borne Spotted Fevers

Other tickborne spotted-fever-group rickettsial infections include Mediterranean spotted fever, African tick-bite fever, Queensland tick typhus, Siberian tick typhus, Japanese spotted fever, Flinders Island spotted fever, tick-borne lymphadenopathy (TIBOLA), and *R. parkeri* infection.

TIBOLA is not usually associated with a generalised rash; rather, this unusual rickettsiosis is characterised by a localised area of scalp alopaecia. The alopaecia typically follows the development of a crusted lesion at the site of a resolving tick bite. Localised hair loss may be prolonged. Cervical or regional lymphadenopathy is common in TIBOLA. Only a minority of TIBOLA patients have fever, and rash occurs in fewer than 10% of patients.

Infection with a newly recognised rickettsial agent, *R. mongolotimonae*, has been seen in southern France. In the few cases reported to date, clinical manifestations have typically been similar to those of Mediterranean spotted fever.

All of these illnesses respond to treatment with tetracyclines or chloramphenicol. Most are milder in course and severity than RMSF, although Mediterranean spotted fever may, in rare cases, be fatal.

FLEA AND LOUSE-BORNE TYPHUS GROUP RICKETTSIOSES

Endemic Murine Typhus (Flea-Borne)

It has worldwide distribution and caused by *R. typhi* and transmitted by rat flea (Xenopsylla cheopis). Humans become infected when *Rickettsia* laden flea faeces are scratched into pruritic bite lesions. Initial symptoms include headache, malaise, fever, chills. The pink rash appears on 5th day and spreads to whole body but do not involve palms and soles. Pulmonary disease is common and chest radiograph shows interstitial pneumonia, pulmonary oedema and pleural effusions. Abdominal pain, confusion, stupor, coma and jaundice occur less commonly. Treatment with doxycycline (100 mg bid for 7 to 15 days) or chloramphenicol (500 mg qid for 7 to 15 days) is effective.

Epidemic Louse-Borne Typhus

R. prowazeki is carried by body louse (Pediculus humanus corpori) was responsible for deaths of millions of people during World War I and II. It is now most commonly reported from Northeastern, Central Africa, Himalayan regions of India, Pakistan and Afghanistan. After incubation period of one week, there is abrupt onset of high fever, headache, cough and myalgia. Rash appears on trunk on fifth day and spreads to involve all body surface except face, palms and soles. Confusion, coma, skin necrosis and gangrene of digits are noted. Untreated disease is fatal because of multiorgan involvement. Treatment is with doxycycline (200 mg daily till patient becomes afebrile).

Brill-Zinsser Disease

It is a recrudescent and mild form of disease that occurred years ago, treatment is same as above.

Scrub Typhus

Disease is prevalent in rural Asia. *Orientia tsutsugamushi*, agent of scrub typhus is transmitted by infected larva of trombiculid mite or chiggers in areas of heavy scrub vegetation during wet season. It causes mild to fatal disease; there is eschar at the site of chigger feeding, lymphadenopathy and maculopapular rash. Severe cases include encephalitis and interstitial pneumonia. A 7 to 15 days course of doxycycline (100 mg bid) or chloramphenicol (500 mg qid) is effective.

Q-FEVER (QUERY FEVER)

Coxiella burnetti a small Gram-negative organism causes Q-fever. This disease name originated in 1935 with an outbreak of febrile

illness of unknown aetiology in nine abattoir workers in Brisbane, Australia. The organisms exist in highly infectious or phase I form within humans and animals or as an avirulent phase II form.

Q-fever is a zoonosis that occurs worldwide. The primary sources of human infection are sheep, cattle and goat. At parturition the organism is dispersed as an aerosol, and infection usually follows inhalation.

Acute Q fever: Presents as flu like syndrome, fever, pneumonia, hepatitis, myocarditis meningoencephalitis. CXR shows multiple rounded opacities highly suggestive of Q fever pneumonia. Treatment is with doxycycline (100 mg bid for 14 days).

Chronic Q fever: Q fever valvular endocarditis presents exclusively in patients with previous valvular heart disease, in transplant recipients. Aortic and prosthetic valves are commonly involved. Hepatosplenomegaly, purpuric rash, renal insufficiency and embolism may be seen. Treatment is with at least two drugs. The combination of rifampicin (300 mg daily) plus doxycycline (100 mg bid) or ciprofloxacin (750 mg bid) is given for 18 months to 3 years.

EHRLICHIOSIS AND ANAPLASMOSIS

Human Ehrlichiosis was first recognised in the United States in 1986 as a life-threatening tick-borne illness similar to Rocky Mountain spotted fever, but with a much lower incidence of rash. *Ehrlichia* are small Gram-negative intracellular bacteria that grow in cytoplasmic vacuoles to form clusters called morulae.

Human Monocytotropic Ehrlichiosis (HME)

This is caused by *E. chaffeensis* and tick vector is *Amblyomma americanum*. Patient develops fever, headache, myalgia, nausea, vomiting, diarrhoea. Complications include toxic shock syndrome, respiratory distress, meningoencephalitis and haemorrhage. Bone marrow shows non-caseating granulomas. Morulae are rarely seen in peripheral smear. Treatment is doxycycline (100 mg bid) or tetracycline (500 mg qid) is effective and should be continued for 3 to 5 days until defervescence.

Ehrlichiosis ewingii

It is caused by *E. ewingii* and tick vector is *Amblyomma americanum*. It resembles HME but is less severe, seen in immunocompromised patients. Treatment is same as for HME.

Human anaplasmosis

It is caused by *A. phagocytophilum* and tick vector is *Ixodes scapularis*. It presents as influenza-like illness. Respiratory insufficiency, toxic shock syndrome and opportunistic infections are troubling complications. It should be considered as severe presentation of Lyme disease as they share the *Ixodes scapularis* vector. Treatment with doxycycline is effective. Pregnant woman may be treated with rifampicin.

PREVENTION

These diseases are prevented by debugging, use of protective clothing, removal of ticks, tick repellents along with good personal hygiene. Flea control can be achieved with the use of BHC, 10% DDT or 1% malathion.

17.36 Chlamydial Infections

TK Suma

Chlamydia are small, Gram-negative, obligate intracellular organisms. Three of them are pathogenic to humans: *Chlamydophila* (formerly *Chlamydia*) *pneumoniae*, *Chlamydophila* (formerly *Chlamydia*) *psittaci*, and *Chlamydia trachomatis*. Infection occurs in humans either through aerosol inhalation, when the upper and lower respiratory tracts are affected or via the sexual route involving the genitourinary system or through direct contact as in trachoma. All three species can cause pneumonia in humans.

EPIDEMIOLOGY

C.pneumoniae is estimated to cause 10% to 20% of community-acquired pneumonia cases among adults. Approximately 50% of young adults and 75% of elderly persons have shown serological evidence of previous infection. Approximately 5% to 22% of pregnant women are thought to have *C. trachomatis* infection of the cervix, and 30% to 50% of neonates born to infected mothers show culture evidence of infection. Among these neonates 15% to 25% present with clinical conjunctivitis and/or nasopharyngitis that in some cases develop into neonatal pneumonitis. Studies including those from India have suggested an association between *C. trachomatis* and HIV infections and re-inforced the need for routine screening for *C. trachomatis*. Cases of ornithosis caused by *C. psittaci* have declined after the introduction of antibiotic-laced bird feed. The mortality from pneumonias caused by Chlamydiae is estimated to be 5.4% to 9.8%.

CHLAMYDIA BIOLOGY

Chlamydiae possess both DNA and RNA, and have a cell wall and ribosomes. The unique feature of chlamydiae is the reproductive cycle with two morphological forms: the extracellular, elementary body (EB) which is the infectious form and the intra-cellular, reticulate body (RB) which is non-infectious. The EBs (0.3-0.4 μ) bind to receptors on epithelial, respiratory or genital cells of host and initiate infection. They are internalised by endocytosis and/or by phagocytosis. Within the host cell endosome, the EBs reorganise and become RBs. The entire intra-cellular life cycle of the chlamydia occurs within the endosome. The RBs replicate by binary fission and reorganise into EBs within 36 hours prior to exocytosis (cell lysis). The resulting inclusions may contain 100 to 500 progeny. Eventually the cells and inclusions lyse in case of *C. psittaci* or extruded by reverse endocytosis in *C. trachomatis* and *C. pneumoniae*. The released EBs then infect the adjacent cell or transmit infection from one person to another.

PNEUMONIA

Chlamydia pneumoniae is the causative agent of an atypical pneumonia similar to those caused by *Mycoplasma pneumoniae* and *Legionella pneumophila*. Humans are the only known reservoir and mode of transmission is via infected respiratory secretions. Immunity is short-lived and re-infection can occur. *C. pneumoniae* can be isolated from the nasopharynx of about 2% to 5% of healthy asymptomatic adults and children. Over half the adult population has serologic evidence that suggests previous or persistent infection. It can precipitate onset of asthma in adults.

Clinical Features

The incubation period is approximately 3 to 4 weeks. The onset is usually gradual or may be biphasic. Symptoms of bronchitis or pneumonia follow upper respiratory tract symptoms, like rhinitis, laryngitis, pharyngitis and/or sinusitis after 1 to 4 weeks. Horder's spots (pink maculopapular eruption), erythema marginatum and urticaria may be present on the skin. Hoarseness of voice is more common in *C.pneumoniae* infection than in mycoplasmal or other pneumonias. Fever is more often present in the first few days and could be absent by the time of examination. Cough could be predominant with scanty sputum. In patients with a pre-existing obstructive lung disease, it may be responsible for exacerbation. Rhonchi and crackles are present even in mild disease. Complete resolution could take about 5 to 6 months.

Complications include otitis, erythema nodosum, endocarditis, Guillain-Barré syndrome and encephalitis. New onset asthma has been observed after *C. pneumoniae* infection.

The first suggestion of an association between *C. pneumonia* and atherosclerosis came from sero-epidemiological studies from Finland. Evidence of presence of the organism in the atherosclerotic tissue in coronary and other arteries has been presented by various techniques including PCR, immunohistology and micro-immunofluorescene (MIF). The presence of *C. pneumoniae* in atherosclerotic lesions raised the possibility that antibiotic treatment might have a favourable effect on the course of coronary artery disease (CAD). But large randomised antibiotic trials did not show any beneficial effect of long-term antibiotic therapy in patients with established acute or chronic CAD and concluded that, there is no role for long-term antibiotic treatment in secondary prevention of CAD. Studies from the West and also from India could not establish definite pathogenic mechanisms for initiation or progression of atherosclerotic plaques by *C. pneumoniae*. In conclusion, though there is a strong association of *C. pneumoniae* with atherosclerotic CAD, there is lack of sufficient data to establish an aetiologic relationship between the two.

Laboratory Diagnosis

The commonly used serologic criteria are an IgM titre exceeding 1:16 or a 4-fold increase in the IgG titre by specific MIF. The absence of detectable antibodies several weeks after the onset of infection does not exclude a diagnosis of acute *C. pneumoniae* pneumonia because the IgM antibody response may take as long as 6 weeks and the IgG antibody response may take as

long as 8 weeks to appear in primary infections. It is of little use in determining treatment. *C. pneumoniae*-specific DNA can be demonstrated in pharyngeal swab, bronchoalveolar lavage, sputum, or tissue by PCR and is the most promising rapid test. Cell culture with oropharyngeal swabs is probably the best test, but it requires specialised culture techniques, which are expensive and difficult to perform.

Treatment

Doxycycline (100 mg PO bid) is the treatment of choice except in children and in pregnant women. Treatment should be continued for at least 10 to 14 days after defervescence. If symptoms persist, a second course with a different class of antibiotics is usually effective. Alternatives include erythromycin (500 mg qid), clarithromycin (1 g qid) for 7 to 10 days or azithromycin (total dose of 1500 mg in five days). Telithromycin is the first antibiotic in a new class called ketolides and is approved for *C. pneumoniae* pneumonia by the US FDA but has many drug interactions and adverse drug reactions. It is contraindicated in patients with *Myasthenia gravis*. Fluoroquinolones, including levofloxacin (500 mg PO/IV qid) and moxifloxacin (400 mg PO/IV qid) for 10 to 14 days also have some activity, although less than that of tetracyclines or macrolides.

PSITTACOSIS

C. psittaci infection (psittacosis or ornithosis) occurs among pet bird's (pigeon and parrot) owners and poultry (chicken and duck) farmers. The respiratory tract is the main portal of entry. Infection is by inhalation of organisms from infected birds or their droppings. Person-to-person transmission is rare. From the lungs the organisms enter the blood stream and are transported to the liver and spleen. The bacteria replicate at these sites where they produce focal areas of necrosis. Haematogenous spread to the lungs and other organs also occurs. A lymphocytic inflammatory response in the alveoli and interstitial spaces leads to oedema, infiltration of macrophages, necrosis and sometimes haemorrhage. Mucous plugs may develop in the alveoli causing cyanosis and anoxia.

The illness develops after an incubation time of 7 to 15 days. Symptoms include fever, chills, headache and a mild pneumonitis. The pneumonic form is the most common and is characterised by a non-productive cough with very few signs on examination of the chest. Chest radiograph, however, reveals extensive multilobar patchy consolidation out of proportion to the clinical findings. In uncomplicated cases, the disease subsides by 5 to 6 weeks after infection. Asymptomatic infections are common. In complicated cases, convulsions, coma and death (5% mortality rate) can occur. Other complications include endocarditis, hepatosplenomegaly, glomerulonephritis, meningitis. Treatment is with oral doxycycline 100 mg twice daily for 21 days.

TRACHOMA

C. trachomatis species is divided into three biovars (biological variants): trachoma, lymphogranuloma venereum (LGV) and mouse pneumonitis. The human biovars have been further subdivided into several serovars (serological variants) that differ in their major outer membrane proteins and are associated with different diseases. The organisms stimulate infiltration of polymorphonuclear cells and lymphocytes which leads to lymphoid follicle formation and fibrotic changes. Infection does not stimulate long lasting immunity and re-infection results in an inflammatory response and subsequent tissue damage.

Chronic infection or repeated re-infection with *C. trachomatis* (biovar: trachoma A, B and C) results in trachoma, which is a common cause of blindness in endemic countries. Infection spreads from person to person, especially where there is shortage of water, numerous flies and crowded living conditions. The infection begins in the conjunctiva, causing follicles in the lower lid and tenderness of the regional preauricular nodes. Repeated episodes of re-infection cause chronic follicular or intense conjunctival inflammation (active trachoma), which leads to tarsal conjunctival scarring. The scarring distorts the upper tarsal plate, and in some individuals, leads to entropion and trichiasis (cicatricial trachoma). The end result includes corneal abrasions, corneal vascularisation, corneal scarring, opacification and ultimately blindness.

Inclusion conjunctivitis is also caused by the same biovar, associated with genital infections (serovars: D to K). In neonates infection results from passage through an infected birth canal and becomes apparent after 5 to 12 days. Ear infection and rhinitis can accompany the ocular disease. Infants can develop pneumonia at birth preceded by neonatal conjunctivitis. Recurrence occurs in 35% of the cases.

Trachoma is treated with single dose oral azithromycin 1 g and tetracycline ointment applied locally to the conjunctiva twice or thrice daily for 2 to 3 months. After control of active infection, surgical reconstruction of the eyelids and keratoplasty for removal of corneal opacities may be required. WHO guidelines for the community-based management of trachoma include integrated SAFE strategy—surgery for trichiasis, community wide antibiotic treatment, facial cleanliness, education and environmental improvements.

GENITOURINARY INFECTIONS

C. trachomatis immunotypes D to K cause non-gonococcal urethritis, epididymitis, and prostatitis in males and cervicitis, salpingitis, and endometritis and perihepatitis (Fitz-Hugh-Curtis syndrome) in females. It is responsible for tubal infertility, ectopic pregnancy and pelvic inflammatory disease.

Reiter's syndrome, a triad of conjunctivitis, polyarthritis and urethritis is also associated with *C. trachomatis*. Approximately 50% to 65% of patients have an acute *C. trachomatis* infection at the onset of arthritis and greater than 80% have serological evidence for *C. trachomatis* infection. The pathogenesis remains obscure.

Treatment for urethritis and cervicitis is with a single oral dose of 1 g azithromycin. For more severe illness, alternative regimens are oral doxycycline 100 mg twice daily or oral erythromycin 500 mg given four times daily for two weeks.

LYMPHOGRANULOMA VENEREUM

Lymphogranuloma venereum (LGV) is caused by LGV serovars. The primary lesion of LGV is a small painless and inconspicuous vesicular lesion that appears at the site of infection, often in the penis or vagina. The patient may also experience fever, headache and myalgia. The second stage of the disease presents as a marked inflammation of the draining lymph nodes 1 to 3 weeks later. The enlarged nodes become painful 'bubo' that can

eventually rupture and drain to form multiple discharging sinuses. The important differential diagnosis at this stage are tuberculosis, pyogenic abscesses, tularaemic plague or neoplasms. The healing that follows results in extensive tissue scarring.

Proctitis is common in females as the genital lymph drains into peri-rectal glands. The healing that follows this results in rectal strictures. Therefore, in females, this condition needs to be clinically differentiated from ulcerative colitis and rectal neoplasm.

Laboratory diagnosis is confirmed by the isolation of the LGV strains of *C. trachomatis;* immunofluorescence and use of monoclonal antibodies to identify organism in pus obtained from a bubo; and rising titres in serum when complement fixation tests are done. The intradermal Frei's test is non-specific and unreliable.

The LGV is treated with oral doxycycline 100 mg administered twice daily for 2 to 3 weeks. *As C. trachomatis* is susceptible to sulphonamides, trimethoprim/sulphamethoxazole 160/800 mg thrice daily for 21 days can also be used. Surgical drainage may be required when bubo is present.

17.37 *Mycoplasma* Infections

Dilip Mathai

MYCOPLASMA

Mycoplasma, previously called L-forms (Lister), Eaton agent, and pleuro-pneumonia-like organisms (PPLO), is the smallest free-living bacterium (0.1 to 0.3 µm) and the most common bacterial agent to cause 'atypical pneumonia'.

Aetiopathogenesis

Human infections are caused by two main genera: *Mycoplasma* and *Ureaplasma*. As a group, they lack a cell wall and the cytoplasmic contents are limited by a cell membrane containing sterols. They are distributed worldwide and colonise human oropharyngeal, respiratory and genitourinary mucosa. Their tissue pathogenicity is difficult to establish.

About 11 species of *Mycoplasma* colonise the body, four of them causing human infections. *M. pneumoniae* causing atypical pneumonia is the only confirmed pathogen; *M. hominis* is believed to cause cervicitis, vaginitis, pelvic inflammatory disease, post partum fever and pyelonephritis in women, conjunctivitis in men and sepsis in neonates. *M. orale* and *M. salivarum* colonising oropharynx are suspected to cause periodontal disease.

Non-gonococcal urethritis (NGU) may be due to *Mycoplasma;* a few of the genital *Mycoplasma* can cause non-genital disease.

Clinical Features

Atypical pneumonia

Mycoplasma pneumoniae is one of the leading aetiological agents causing community acquired atypical pneumonia. Other agents are influenza virus, adenovirus, respiratory syncitial virus (RSV), cytomegalovirus (CMV), *Legionella*, *Pneumocystis jirovecii*, and numerous other viral agents. One sixth of the adult pneumonias seen in the community could be attributed to *Mycoplasma*. The illness occurs during the winter months, with a long incubation period of 2 to 3 weeks. Outbreaks are seen to occur within families and among residents in institutions, as spread occurs via the inhalation of aerosolised droplets. Epidemics occur with four to seven year periodicity and may be non-seasonal. *Mycoplasma* is an extra-cellular organism that binds itself to the surfaces of both ciliated and non-ciliated respiratory epithelial cells. Intra-cellularly, it inhibits the catalase enzyme in the host-cell resulting in the accumulation of hydrogen peroxide that is toxic to the cell. Smoking and low pre-existing IgG levels are strongly associated with *M. pneumoniae* respiratory infection. These findings emphasise the importance of immunity and cessation of smoking for the prevention of disease.

The onset of illness is typically insidious with moderate fever, ranging between 101 and 102°F, malaise, headache with the characteristic gradually worsening cough resembling tracheo-bronchitis. The characteristic non-productive, severe and incessant cough (a hallmark of the atypical pneumonia it causes) is due to ciliostasis and the destruction of the superficial epithelial cell layer. It is called a 'walking pneumonia' as patient remains ambulant without manifesting chills, rigors or toxicity that commonly occur in pneumonias caused by bacteria, such as pneumococcus or *Klebsiella* species. The chest pain is pleuritic, and must be distinguished from the non-descript myalgia that occurs with a viral infection. Bullous myringitis is rare in active illness. Most patients recover in two weeks with normalisation of the chest radiography in 6 weeks. The disease can be protracted, with cough and X-ray appearances lasting for 3 to 4 weeks. Bronchiolitis obliterans is seen in some patients and is characterised by respiratory insufficiency.

Extra-pulmonary complications though rare, can occur at any time during the illness and may occasionally dominate the clinical picture. They include myocarditis and pericarditis. Cardiac conduction defects, or congestive cardiac failure, rashes and erythema multiforme (Stevens-Johnson syndrome); coagulopathies, haemolytic anaemia (sickle-cell disease is associated with more severe illness), thrombocytopaenia, Raynaud's phenomena, monoarticular arthritis, meningo-encephalitis and transverse myelitis.

Diagnosis

The diagnosis of *M. pneumoniae* causing respiratory illness is infrequent, primarily because of the lack of standardised, rapid and specific diagnostic tests. Light microscopy is not useful as these lack a cell wall and are too small to be seen. They are fastidious to cultivate and cultures take 4 to 6 weeks. Rapid bedside test demonstrating a raised erythrocyte mean corpuscular volume (MCV) is a useful clue. Cold agglutinins (IgM antibodies) that bind to the antigen on the surface of the RBCs occur in over half of the cases but are not specific for *Mycoplasma*. Early in the course of the infection low titres (less than the significant value 1:64) may be seen. The diagnosis is confirmed by a rising antibody titre (four-fold increase) or a diagnostic titre more than 1:128. Detection of IgM antibodies during the second week by direct immunofluorescent antibody test (IFAT) or other more specific serological testing methodology such as ELISA. Complement fixation (CF) or immunofluorescence (IF) are useful. Commercial kits with PCR probes directly applied on to clinical materials (sputum, nasopharyngeal swab or bronchoalveolar lavage) to detect antigen have been used with a high-degree of specificity and sensitivity. However, laboratory performance of such tests cannot be assessed.

Treatment

Erythromycin 500 mg qid or doxycycline 100 mg administered twice daily for 2 to 3 weeks are the most effective. Penicillin is ineffective as *Mycoplasma* lack a cell wall. Alternate choices are the newer azalides, (azithromycin and clarithromycin) or the fluoroquinolone (sparfloxacin), all of which achieve adequate *in situ* levels. Due to lack of tests that reliably support the diagnosis of *Mycoplasma*, treatment is usually empirical.

UREAPLASMA

Ureaplasma urealyticum (previously called T-strain) as it is extremely tiny, causes urethritis (non-gonococcal) and upper genitourinary infections in the female. The prevalence of genital infection caused by such organisms depends on several factors like age, sex (more common in women), socioeconomic status and number of sex partners. *Ureaplasma* may also play a role in male infertility as a result of the production of antisperm antibodies. Genital infections can be prevented by using barrier precautions during sexual intercourse. Infants can get colonised during passage through the birth canal of the infected mother. Colonisation in pregnant women is associated with a decrease in birth weight and gestational length of infants.

Erythromycin 500 mg qid for 2 to 3 weeks is the drug of choice.

17.38 Basic Considerations of Viral Diseases

Usha K Baveja

INTRODUCTION

The word '*virus*' is Latin in origin and literally means 'toxin or poison'. Viruses are ultra small, metabolically inert particles which can cause endemic, epidemic and pandemic outbreaks of sometimes life-threatening infections in man, animals, plants and bacteria. Viruses can't exist outside the living cells, as viruses use the living cell machinery to replicate, establish and may or may not cause harm to the system. Viruses have emerged and are emerging as serious pathogens. Since the initial discovery of tobacco mosaic virus by Martinus Beijerinck in 1898, about 5,000 viruses have been described in detail, although there are millions of different types. Viruses are found in almost every ecosystem on earth. The origins of viruses in the evolutionary history of life are unclear: some may have evolved from plasmids —pieces of DNA that can move between cells, while others may have evolved from bacteria.

STRUCTURE

Each virus is made of three components. These are DNA (single stranded or double stranded) or RNA (double stranded or single stranded) in the centre surrounded by protein coat formed from identical protein subunits called capsomeres which may be organised to form a helical or icosahedral or more complex symmetry and a lipid envelope derived from host cell membrane, which carries the specific receptors for attachment to host cells. A virus has either DNA or RNA genes and is called a DNA virus or a RNA virus, respectively. Proteins associated with nucleic acid are known as nucleoproteins, and the association of viral capsid proteins with viral nucleic acid is called a nucleocapsid. The nucleic acid of the virus carries all the genes and information required to replicate. In general, there are four main morphological virus types: helical, icosahedral, enveloped and complex.

There are 'prions' and 'viroids' that were earlier considered as viruses. Prions do not have nucleic acid and viroids do not have the protein coat, just are naked nucleic acid. Prions are infectious proteins that cause an infection in sheep called scrapie and cattle bovine spongiform encephalopathy ('mad cow' disease). In humans they cause Kuru and Creutzfeldt-Jakob disease. They are able to replicate because some proteins can exist in two different shapes and the prion changes the normal shape of a host protein into the prion shape. This starts a chain reaction where each prion protein converts many host proteins into more prions, and these new prions then go on to convert even more protein into prions which cause the diseases.

GENOMIC DIVERSITY AMONG VIRUSES

Genetic diversity is very common in viruses. Viruses undergo genetic change by a process called genetic drift where individual bases in the DNA or RNA mutate to other bases. Most of these point mutations are 'silent'—they do not change the protein that the gene encodes—but others can confer evolutionary advantages, such as resistance to anti-viral drugs. Antigenic shift occurs when there is a major change in the genome of the virus. This can be a result of recombination or reassortment (the DNA breaks into pieces and different pieces join together to form a changed DNA, **Figure 1**). When this happens with influenza viruses, pandemics might result. RNA viruses often exist as quasi-species or swarms of viruses of the same species but with slightly different genome nucleoside sequences (as seen in HIV). Such quasi-species are a prime target for natural selection.

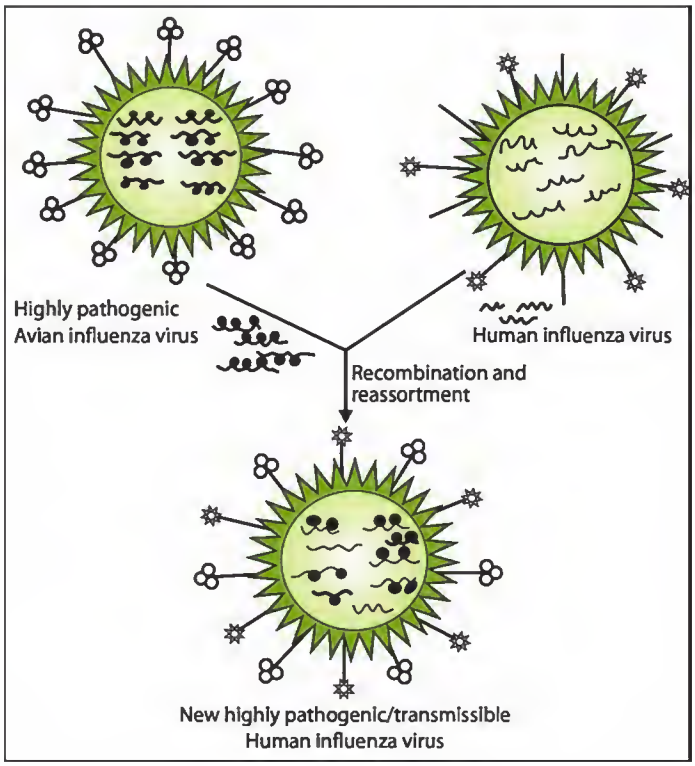

Figure 1: Recombination and reassortment resulting in a new strain (human avian influenza virus).

VIRAL REPLICATION

Viruses are acellular and they use the host cell machinery and metabolism to produce multiple copies of themselves, *assemble* in the cell and get out either by budding or after lysis of the host cell. The life cycle of different viruses varies to some extent. The basic stages in replication are the same for all viruses as shown in **Figures 2 and 3**.

- *Attachment/adsorption* is a specific binding between viral capsid proteins and specific receptors on the host cellular surface. For example, HIV infects only human T cells, because its surface protein, gp120, can interact with CD4, and receptors on the T cell's surface. Attachment to the receptor can induce the viral-envelope protein to undergo conformational changes that results in the fusion of viral and cellular membranes.

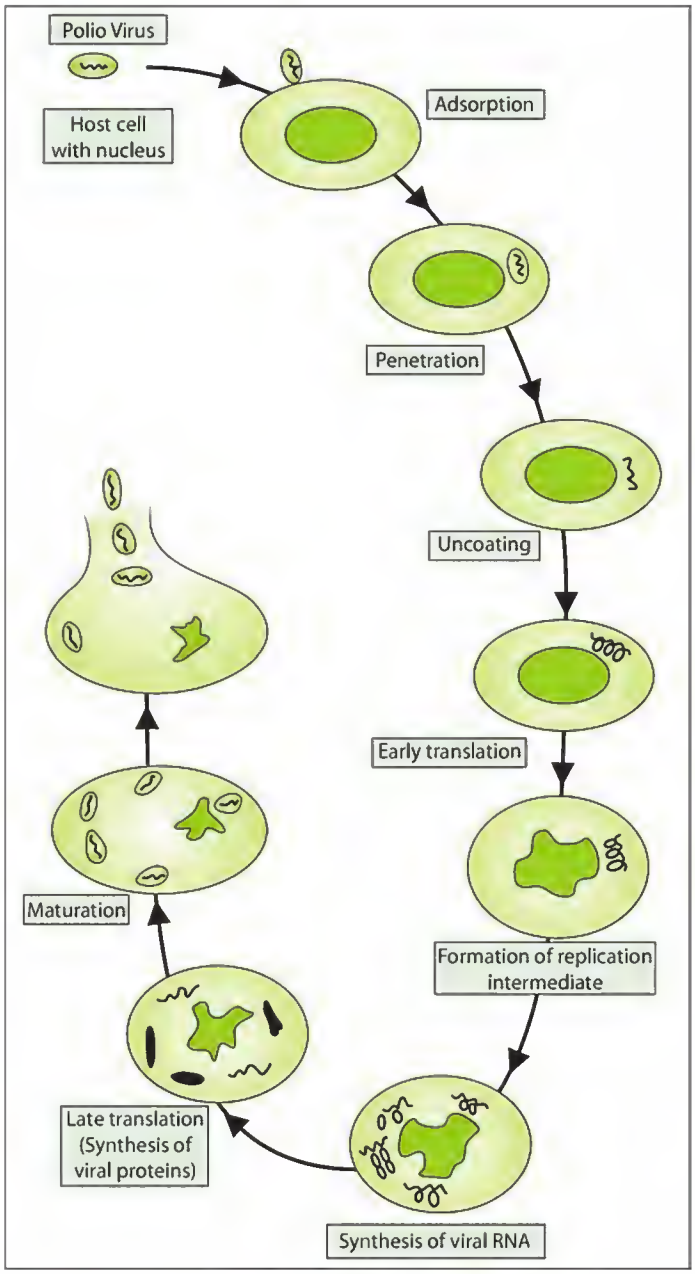

Figure 2: Virus replication cycle-RNA virus (Polio-virus) diagrammatic representation.

- *Fusion and entry into the host cell* follows attachment: viruses enter the host cell through receptor mediated endocytosis or membrane fusion. Some viruses have evolved mechanisms that inject their genome into the bacterial cell while the viral capsid remains outside (as in bacteriophages).
- *Uncoating* is a process in which the viral capsid is degraded by viral enzymes or host enzymes, thus, releasing the viral genomic nucleic acid.
- *Replication* involves synthesis of viral messenger RNA (mRNA) for viruses except positive sense RNA viruses, viral protein synthesis and assembly of viral proteins and viral genome replication.
- *Assembly* of the virus particles: post-translational modification of the viral proteins often occurs. In viruses such as HIV, this modification (sometimes called maturation) occurs *after* the virus has been released from the host cell.
- *Release* from the host cell by lysis: A process that kills the cell by bursting its membrane. Enveloped viruses (e.g. HIV) typically are released from the host cell by budding. During this process the virus acquires its envelope, which is a modified piece of the host's plasma membrane.

Most DNA viruses replicate in the cell's nucleus after entry and are entirely dependent on the host cell's DNA and RNA synthesising machinery, and RNA processing machinery.

RNA viruses carry their genetic information encoded in RNA. Replication usually takes place in the cytoplasm. RNA viruses use their own RNA replicase enzymes to create copies of their genomes.

Reverse transcribing viruses replicate using reverse transcription, which is the formation of DNA from an RNA template. Reverse transcribing viruses containing RNA genomes use a DNA intermediate to replicate (HIV), whereas those containing DNA genomes use an RNA intermediate during genome replication. Retroviruses often integrate the DNA produced by reverse transcription into the host genome. They are susceptible to antiviral drugs that inhibit the reverse transcriptase enzyme, e.g. zidovudine and lamivudine.

CLASSIFICATION

Viruses are classified on the basis of the type of nucleic acid, presence or absence of the envelope, type of structure (as described above), site of replication, etc.

On the basis of nucleic acid viruses are classified into DNA viruses and RNA viruses. DNA viruses further can be those which are ssDNA viruses and dsDNA viruses. RNA viruses are +ssRNA viruses and – ssRNA viruses. On the basis of presence or absence of envelope, viruses can be enveloped or naked (non-enveloped), respectively. On the basis of structure viruses can be icosahedral (cubical), helical or complex. Viruses can replicate in host cell nucleus or cytoplasm and some can replicate in both.

PATHOGENESIS OF VIRAL DISEASES

Viruses produce disease by different mechanisms in the host. The degree of virulence, that is the ability to cause disease and severity of diseases, produced largely depends on the viral species. Mechanisms at the cellular level primarily include cell lysis caused by replication of virus either in the cytoplasm or the nucleus. The virus release subsequent to replication is either by breaking open of cell wall or punching holes in cell wall due to budding and release of virus and subsequent death of the cell. When there is viraemia and large number of cells in different organs are involved, the disease symptoms manifest. Although viruses cause disruption of healthy homeostasis, resulting in disease, sometimes they may exist relatively harmlessly within a host. An example, would include the ability of the herpes simplex virus, which causes cold sores, to remain in a dormant state within the human body. This is called latency and is a characteristic of all herpes viruses including the Epstein-Barr virus, which causes glandular fever, and the Varicella zoster virus, which causes chickenpox. Some viruses like HIV, HBV and HCV cause chronic, lifelong infections.

HOST DEFENCE MECHANISMS

The first line of defense against viruses is the innate immune system. It comprises cells and other mechanisms that defend

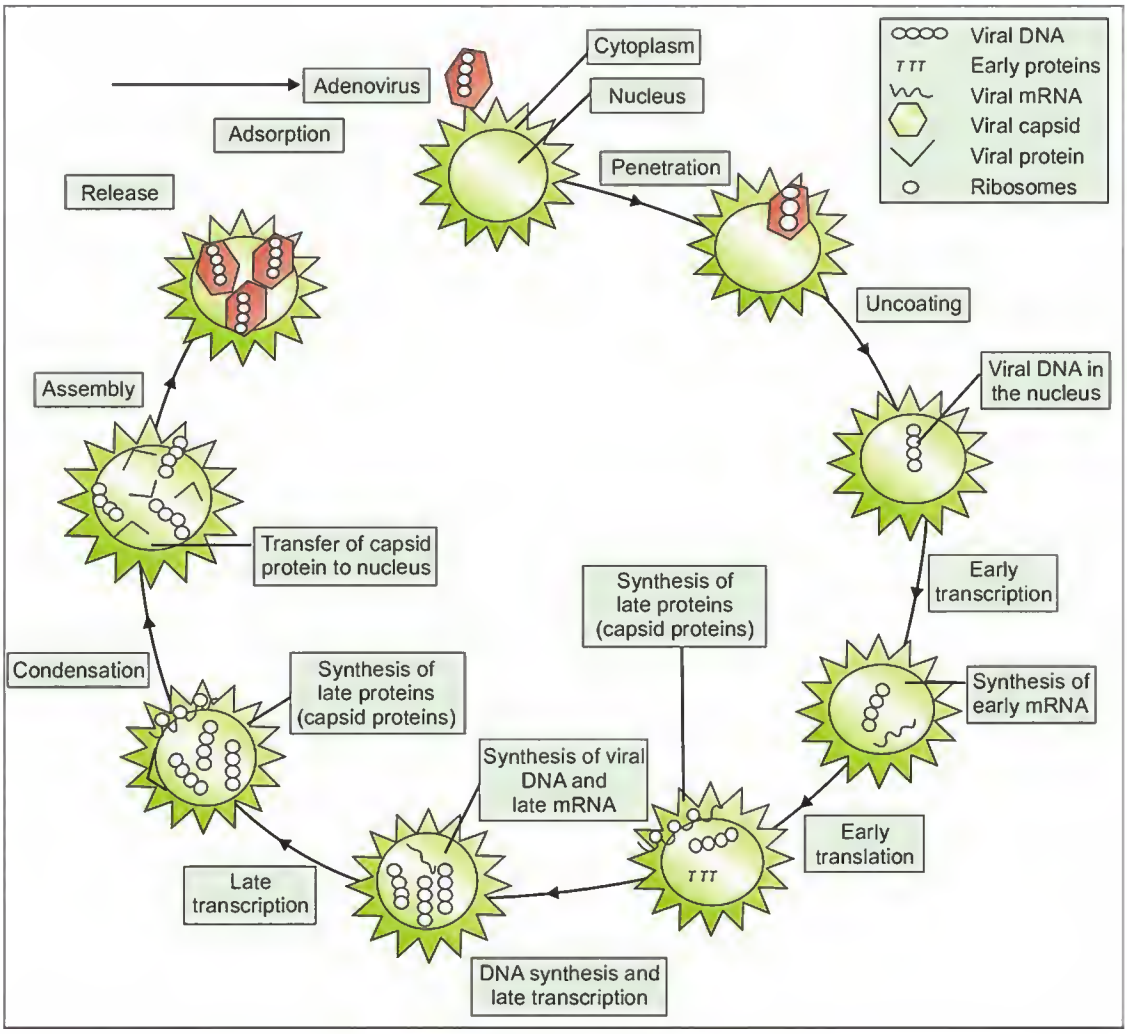

Figure 3: Virus replication cycle-DNA virus.

the host from infection in a non-specific manner. However, it does not confer long-lasting or protective immunity to the host.

RNA interference is an important innate defense against viruses. Many viruses have a replication strategy that involves double-stranded RNA (dsRNA). When such a virus infects a cell, it releases its RNA molecule or molecules, which immediately bind to a protein complex called dicer that cuts the RNA into smaller pieces. A biochemical pathway called the RNA-induced silencing complex (RISC) complex is activated, which degrades the viral mRNA and the cell survives the infection.

When the adaptive immune system encounters a virus, it produces specific antibodies that bind to the virus and render it non-infectious. This is called humoral immunity. Two types of antibodies are important. The first called IgM is highly effective at neutralising viruses but is only produced by the cells of the immune system for a few weeks. The second, called IgG, is produced indefinitely. The presence of IgM in the blood of the host is used to test for acute infection, whereas IgG indicates an infection sometime in the past. IgG antibody is measured when tests for immunity are carried out.

A second defense against viruses is called cell-mediated immunity and involves immune cells known as T cells. The body's cells constantly display short fragments of their proteins on the cell's surface, and if a T cell recognises a suspicious viral fragment there, the host cell is destroyed by killer T cells and the virus-specific T-cells proliferate. Cells such as the macrophage are specialists at this antigen presentation. The production of interferon is an important host defense mechanism. This is a hormone produced by the body when viruses are present. Its role in immunity is complex, but it eventually stops the viruses from reproducing by killing the infected cell and its close neighbours.

The immune response is not always protective. HIV evades the immune system by constantly changing the amino acid sequence of the proteins on the surface of the virion. These persistent viruses evade immune control by sequestration, blockade of antigen presentation, cytokine resistance, evasion of natural killer cell activities, escape from apoptosis, and antigenic shift. Neurotropic viruses are disseminated by neural spread where the immune system may be unable to reach them.

COMMON DISEASES PRODUCED BY VIRUSES IN HUMANS

Viruses produce a wide spectrum of diseases in humans ranging from mild infections like common colds, influenza, chickenpox and cold sores to many serious diseases, such as Ebola virus fever, Lhasa fever, AIDS, Avian influenza (H5N1), Swine influenza (H1N1) hepatits and severe acute respiratory syndrome (SARS) to malignancies like cervical cancers (human Papilloma virus) and leukaemias (HTLV I and HTLV II), etc.

Some viruses can cause life-long or chronic infections, where the viruses continue to replicate in the body despite the host's defense mechanisms. This is common in HIV, hepatitis B virus and hepatitis C virus infections. People chronically infected are known as carriers, as they serve as reservoirs of infectious virus. In contrast to acute lytic viral infections this persistence implies compatible interactions with the human host. Some viruses produce acute infection followed by long latency and recurrences time and again (HSV 1 and HSV 2). Viruses that infect the humans are listed in the **Table 1**.

SYMPTOMS OF VIRAL DISEASES

Symptoms of viral infection vary depending on the type of viral infection, the area of the body that is infected, the age and health history of the patient and other factors. The symptoms of viral infection can also resemble symptoms of other diseases, such as bacterial infections.

Symptoms may affect almost any area of the body or body system and include fever, chills, headache, stiff neck, irritability, enlarged glands, diarrhoea, nausea, vomiting, rash, abdominal pain, sore throat, ear pain, cough, weight loss, fatigue, body aches, and other flu-like symptoms.

In infants, signs of viral infection can include excessive crying, excessive sleepiness, difficulty with feeding, and a bulging of the soft spot on the top of the head.

Many viral infections, such as upper respiratory infection and seasonal influenza, are self limiting. People who are generally healthy are often able to survive these infections without developing serious complications. However, even young and healthy people may develop serious complications to some viral infections. For example, women infected with certain strains of human papillomavirus (HPV) are at risk for developing cervical cancer.

Certain risk factors make it more likely that a person will develop serious, even lethal, complications from a viral infection. People who are generally at risk for developing complications include those who have a compromised immune system due to such diseases as HIV/AIDS or combined immunodeficiencies. People who take certain medications, such as corticosteroids, which suppress the body's natural immune response, are also at risk. Other risk factors include malnutrition, high stress levels and being very young or very old.

Complications of a viral infection can include a secondary bacterial infection, pneumonia, dehydration, shock, the development of some forms of cancer and coma.

The viral infection HIV leads to the critical and eventually fatal complication of AIDS in all people who contract the infection in absence of anti-retroviral treatment (ART).

TREATMENT

Viruses are obligate intra-cellular parasites, so the anti-viral drugs which are going to kill the virus will also damage the host cell, thus limiting the benefits of treatment. The development of new, effective anti-viral drugs is limited due to the requirement that the agent should selectively stop viral replication and not affect the host cell functions. This is not possible to achieve all the time. So, the repertoire of anti-viral agents, available currently is limited. Anti-viral drugs are not available for all the human viral infections. Another problem is that by the time the viral infection is diagnosed the virus has already seeded most organs, caused the damage so drug treatment is not effective. Due to rapid replication of viruses and genetic diversity the viruses become resistant to available agents as seen in cases of anti-retroviral treatment of HIV/AIDS cases.

However, antiviral drugs that selectively interfere with viral replication have been and are used for treatment of cases and are used as chemoprophylaxis during outbreaks of viral diseases.

Treatment of viral illnesses varies greatly depending upon the infecting virus and the underlying health status of the patient.

Treatment

- Symptomatic management—many viral infections require only treatment of their symptoms and will self-resolve.
- Supportive care—some patients may require hospitalisation and care such as IV fluids and oxygen, especially the very young and the elderly.
- Anti-viral therapy—indicated in some viral illness, such as herpes zoster, H1N1 influenza and HIV.

Most children with viral infections get better without treatment but some of the measures taken include:

- Anti-viral drugs
- Palliative treatment

PREVENTION (VIRAL VACCINES)

Prevention of viral infections is the most effective medical approach to control viral diseases. Vaccinations provide immunity to infection, and are used under the universal immunisation programme of the country. Vaccines are administered by different routes—oral, subcutaneous or scarification and/or intra-muscular.

VIRAL VACCINES

There are three basic types of viral vaccines.

Inactivated/Killed Viral Vaccines

The virus is grown in appropriate tissue/culture cell lines and inactivated/killed by various methods (exposure to denaturing agents-heat, formaldehyde, beta-propiolactone) which results in loss of infectivity of virus without loss of antigenicity. Killed vaccines are not available for all the viruses, do not induce mucosal immunity and immunity induced may be for limited period. However, these vaccines are stable and there is no danger of reversion to the virulent form.

Live Viral Vaccines

These vaccines are prepared from live attenuated viruses which have reduced pathogenicity, have retained antigenicity and so provide immune response without causing disease. Such attenuated viruses may be naturally occurring (e.g. Jenner, cowpox, 1776 (variolation) or artificially attenuated (oral poliovirus vaccine). These vaccines are good immunogens and induce long-lived, appropriate immunity. Disadvantage is that these vaccines are unstable: biochemically (live virus) and genetically (reversion to virulence); contamination with other viruses from cell culture can happen and these vaccines have limited use in immunocompromised hosts, and rubella if administered to a pregnant woman may lead to disease in foetus. The yellow fever virus vaccine, a live-attenuated strain called 17D, is probably the safest and most effective vaccine ever generated.

Table 1: Viruses that Infect Humans

Nucleic acid	Capsid symmetry	Enveloped or naked	Physical type-nucleic acid	Virus family
DNA	Icosahedral	Naked	ss	Parvoviridae
			ds circular	Polyomaviridae
			ds circular	Papillomaviridae
			ds	Adenoviridae
		Enveloped	ds circular	Herpesviridae
			ds	Hepadnaviridae
Complex	Complex coats	ds	Poxviridae	
RNA	Icosahedral	Naked	ss	Picornaviridae
			ss	Astroviridae
			ss	Caliciviridae
			ds segmented	Reoviridae
		Enveloped	ss	Togaviridae
	Unknown or complex	Enveloped	ss	Flaviviridae
			ss segmented	Arenaviridae
			ss	Coronaviridae
			ss diploid	Retroviridae
	Helical	Enveloped	ss segmented	Orthomyxoviridae
			ss segmented	Bunyaviridae
			ss	Bornaviridae
			ss	Rhabdoviridae
			ss	Paramyxoviridae
			ss	Filoviridae

Live vaccines can be dangerous when given to people with a weak immunity, (immunocompromised), because in these people, the weakened virus can cause the original disease.

Sub Unit Vaccines

These are newer vaccines; are completely safe, except for rare adverse reactions. Problem is the relatively poor antigenicity (especially short peptides). Biotechnology and genetic engineering techniques are used to produce subunit vaccines. These vaccines use only the capsid proteins of the virus. Hepatitis B vaccine is an example of this type of vaccine. Subunit vaccines are safe for immunocompromised patients because they cannot cause the disease. These can be *synthetic vaccines, recombinant vaccines* (HBV produced in yeast), *Virus Vectors* which carry genes coding for the viral antigens which induce immune response (vaccinia virus-HIV genes).

Use of viral vaccines has resulted in a dramatic decline in morbidity (illness) and mortality (death) associated with viral infections, such as polio, measles, mumps, rubella, HBV, influenza. Smallpox infections have been eradicated through successful immunisation.

Human anti-viral vaccines currently in use include Hepatitis A, Hepatitis B, influenza, Japanese B encephalitis, measles, mumps, rubella (MMR), poliovirus, rabies, smallpox, varicella-zoster, yellow fever, HPV and tick-borne encephalitis.

Problems Faced with Viral Vaccines

- Complications after immunisation can occur in rare cases. These include sensitisation to proteins present in the vaccine, reversion back to virulent form and disease (e.g. polio).
- Attenuated vaccines preferably should not be given to pregnant or immunocompromised.
- Developing effective vaccines to some viruses is proving very difficult, e.g. influenza, common cold viruses, HIV-1, herpes, papilloma and more. Common problems include the existence of many serotypes, antigenic drift and shift.

Success Stories

Smallpox

WHO declared smallpox *'Eradicated'* from the world in 1980. Next targets for eradication are polio and measles through immunisation.

Polio: can it be eliminated by vaccination?

Intensified *Pulse Polio* Programme started in India in 1994 officially, but it was spread throughout the country in 1995 with the main aim of eradicating polio by 2000 AD by vaccinating annually all children under age five against poliovirus. According to it there is no need of giving oral polio vaccine to the children after 2000 AD. The campaign had limited success and the incidence of poliomyelitis in India has decreased dramatically: India recorded 4,791 cases of polio in 1994; 2,489 in 1997; 1,600 in 2002; 225 in 2003; and 135 in 2004. But this was not completely successful and so the programme was extended up to 2005 with a vision of declaring India a polio free state by 2005. But this also failed. According to National Plan of Action 2005 developed by Department of Women and Child Development 2007 the objective under child survival was to certify by 2007 the eradication of polio, which is not possible under present conditions with almost 1000 cases of polio being reported from different states of India. Now it is 2011, the Pulse Polio programme is still on and maybe this will be another success story in a couple of years.

17.39 Herpes Virus Infections

Aditya Prakash Misra

INTRODUCTION

Herpes has been known for at least 2000 years. Emperor Tiberius banned kissing in Rome for a time due to so many people having cold sores. In 16th century Romeo and Juliet, it is mentioned that there are blisters over ladies lips.

Exact data from the Indian population are not known, but its incidence is rapidly increasing over last four decades. In the United States 16.2% of people, aged 14 to 49 years have genital herpes simplex virus-2 (HSV-2) infection. Many people infected with HSV-2 display no physical symptoms and are described as asymptomatic or having sub-clinical herpes.

Herpes virus infections primarily include infections caused by HSV-1 and HSV-2, these viruses are also known as human herpes virus 1 and 2 (HHV-1 and HHV-2). These viruses belong to the family of *herpesviridae*. Both HSV-1 and HSV-2 are ubiquitous and contagious. They can spread when an infected person is producing and shedding the virus by inoculation, kissing and sexual intercourse.

VIRUS AND TRANSMISSION

Virus consists of a large double stranded, linear deoxyribonucleic acid (DNA) genome, encased within an icosahedral protein cage called capsid, which is wrapped in a lipid bilayer called the envelope. This complete particle is known as the virion. Both HSV-1 and HSV-2 contain at least 74 genes or open reading frames (ORF). These viruses contain two unique regions called the long unique region (UL) and the short unique region (US).

Entry of HSV into the host cell involves interaction of several glycoproteins on the surface of the enveloped virus, with receptors on the surface of the host cell. After binding the virus fuses with the host cell membrane and creates an opening or pore through which the virus enters the host cell. From the cellular cytoplasm, viral capsid enters the cell nucleus by creating a nuclear entry pore. HSV evades the immune system through interference with MHC class I presentation of antigen on the cell surface.

HSV-1 and HSV-2 are transmitted both horizontally and vertically. Horizontal transmission occurs during close contact with an infected person who is shedding virus from the skin, often in saliva or in secretion from the genitals. Transmission is most likely when sores are present, through viral shedding and transmission can occur in the absence of visible sores and most HSV-2 infection results from asymptomatic shedding. HSV-2 is primarily a sexually transmitted disease whereas HSV-1 is usually acquired orally during childhood. Both viruses may be transmitted from mother-to-child before or during child birth. The risk of the infection is highest if the mother becomes infected at around the time of delivery (transmission risk 30% to 60%); the risk fall to 3% if it is a recurrent infection and is less than 1% if there are no visible lesions.

As with most sexually transmitted disease (STD), women are more susceptible to acquiring genital HSV-2 than man. Risk of transmission of infection without the use of anti-virals or condoms from infected male to female is approximately 8% to 10%. Risk of transmission of infection from infected female to male is approximately 4% to 5% annually.

Following a primary infection, the virus enters the nerve at the site of primary infection, migrates to the cell body of the neuron and becomes latent in ganglion. As a result of primary infection, body produces antibodies to the particular type of HSV involved, preventing a subsequent infection of that type at a different site, for example, if a patient gets HSV-1 oral infection, then after recovery, he would not get additional HSV-1 infections, e.g. whitlow, genital herpes and keratitis. Prior HSV-1 seroconversion seems to reduce the symptoms of a later HSV-2 infection although HSV-2 can still be contracted. There are some indications that a prior HSV-2 infection confers partial immunity against subsequent HSV-1 infection.

CLINICAL FEATURES

HSV infections cause several distinct medical disorders. Most common is muco-cutaneous infection which may affect the face and mouth (orofacial herpes, **Figure 1**), genitalia (genital herpes, **Figure 2**) or hands (herpes whitlow). More serious disorders occur when the virus infect and damages the eye (herpes keratitis), on invades the central nervous system (CNS), damaging the brain (herpes encephalitis). It may also affect the newborn (neonatal herpes) which is a life-threatening condition.

Figure 1: Herpes labialis—vesicular eruption at angles of mouth.

After initial or primary infection some infected people experience sporadic episodes of viral reactivation or outbreaks. In an outbreak, the virus in a nerve cell becomes active and is transported via the nerve's axon to the skin, where virus replication and shedding occurs and causes new sores.

Figure 2: Herpes genitalis (on penis).

Mucocutaneous Infections

Lesions may appear anywhere on the skin or mucosa, but are most frequent around or in the mouth or on the lips, conjunctiva, cornea, and genitalia. After a prodromal period of tangling discomfort or itching, the clusters of small, tense vesicles appear on an erythematous base. Clusters vary in size from 0.5 to1.5 cm but may coalesce. Lesions on nose, ears, eyes, fingers or genitalia may be particularly painful. Vesicles typically persist for a few days, then rupture and dry forming a thin yellowish crust. Healing generally occur 8 to 12 days after the onset. Lesions usually heel completely but recurrent lesions at the same site may cause atrophy and scarring. Skin lesions can develop secondary bacterial infection. Localised infections can disseminate in immunocompromised patients.

Herpes Labialis

It usually occurs as a secondary outbreak of HSV. It develops as ulcers (cold sores) on the vermilion border of the lip.

Acute Herpetic Gingivostomatitis

This usually results from primary infection with HSV-1, typically in children. Occasionally through oral-genital contact, the HSV-2 can also lead to gingivostomatitis. Intra-oral and gingival vesicles rupture, usually within several hours to 1 or 2 days. Fever and pain are often present, at times there may be difficultly in eating and drinking.

Herpetic Whitlow

It is a painful swollen lesion of the distal phalanx of finger or thumb. It results from inoculation of HSV through the skin and is most common among health care workers. Occasionally infection occurs on the toes or on the nail cuticle.

Herpes Gladiatorum

Individuals that participate in contact sports, such as wrestling, rugby, or soccer, sometimes acquire this condition caused by HSV-1. It presents as skin ulceration on face, ears and neck, accompanied by fever, headache, sore throat and swollen glands. It occasionally affects the eyes or eyelids.

Herpetic Keratoconjunctivitis

Primary infection typically presents as swelling of the conjunctiva and eyelids (blepharoconjunctivitis). Infection of the corneal epithelium causes pain, tears, photophobia and corneal ulcers, that often have a branching pattern.

Genital Herpes

Genital herpes is the most common ulcerative STD in the developed countries. It is usually caused by HSV-2 although 10% to 30% of cases involve HSV-1. Genital HSV-2 is more common in women. In US approximately 1 of 5 women aged 14 to 49 years and about 1 of 9 men to 14 to 49 years suffer from genital herpes. Primary lesions develop within 4 to 7 days after contact. The vesicles usually erode to form ulcer that may coalesce. Lesions may occur on prepuce, glans penis and penile shafts in men and on the labia, clitoris, vagina, perineum and cervix in women. These may occur around the anus and in the rectum in men or women who engage in receptive anal intercourse. Genital HSV infection may cause urinary hesitancy, dysuria, urinary infection in counterparts. In some cases severe sacral neuralgia may occur. Scarring may follow healing and re-currences occur in 80% with HSV-2 and in 50% with HSV-1 cases. Primary genital lesions are usually more painful, prolonged and widespread and are more likely to be bilateral and involve regional lymphadenopathy and constitutional symptoms than recurrent genital lesions. Recurrent lesions may have severe prodromal symptoms and may involve the buttocks, groin or thigh. Some individuals with HSV-2 infection never have sores, or they may have very mild sign that they do not even notice. People diagnosed with a first episode of genital herpes can expect to have several (typically four or five) symptomatic recurrences within a year. Over the time these recurrences usually decrease in frequency. It is possible that a person becomes aware of the first episode years after the infection is acquired.

HSV Encephalitis

It is the commonest form of sporadic viral encephalitis. Cases are seen throughout the year and the age distribution is biphasic with peaks at 5 to 30 years and above 50 years of age. HSV-1 causes more than 95% of cases of HSV encephalitis. The pathogenesis of HSV encephalitis varies. In children and young adults, the primary HSV infection may result in encephalitis, presumably exogenously. Acquired virus enters the CNS by neurotropic spread from the periphery via olfactory bulb. However, most adults with HSV encephalitis have clinical or serological evidence of HSV-1 infection prior to the onset of CNS symptoms. Reactivation of the latent HSV-1 infection may be another mechanism for the development of HSV encephalitis.

Patient may present with headache, seizures, confusion, stupor or coma. In some patients these manifestations are preceded by symptoms and finding that betray the propensity of this disease to involve inferomedial portion of the frontal and temporal lobes. Late manifestations include olfactory or gustatory hallucinations, anosmia, temporal lobe seizures, aphasia, hemiparesis and abnormalities in behaviour. Rarely an affliction of memory may be present, but this becomes evident only later in the convalescent states of illness, as the patient awakens from stupor or coma. Swelling and herniation of one or both temporal lobes through tentorium may occur, leading to deep coma and respiratory arrest during the first three days. Early diagnosis and treatment can limit the sequlae. Even on the slightest suspicion one should start anti-HSV therapy, since this is the only encephalitis which is treatable.

Herpes Viral Meningitis

HSV-2 is the most common cause of Mollaret's meningitis, a type of recurrent viral meningitis.

Besides the above-mentioned disorders, HSV has been associated with various neuronal disorders, like Bell's palsy and Alzheimer's disease. The presence of HSV-1/DNA in saliva at a higher frequency in patients with Bell's palsy relative to those without the condition, has supported that reactivation of latent HSV-1 inside the geniculate ganglia may cause it. In the presence of certain gene variation (APOE-epsilon 4 carriers), HSV-1 increases one's risk of developing Alzheimer's disease.

DIAGNOSIS

Diagnosis is clinical, based on the characteristic lesions. Laboratory confirmation can be helpful, especially if infection is severe, the patient is immunocompromised, pregnant or if the lesions are atypical. It is important to determine whether the genital herpes infection is caused by HSV-1 or HSV-2 as the prognosis and treatment may differ. Virologic and serologic tests can be used to confirm herpes infection.

Virologic Tests

Viral culture tests are made by taking a fluid sample or culture from the lesions as early as possible, ideally within three days. Usually it takes 1 to 10 days, but in severe infection it may yield result in 24 hours. Viral culture is very accurate if the lesions are in early stage but not for older ulcerated sores, recurrent lesions or latency. Polymerase chain reaction (PCR) tests are much more accurate than viral culture but more expensive. Center for Disease Control and Prevention of United States (CDC) recommends PCR for detecting herpes in cerebrospinal fluids for diagnosing HSV encephalitis. An older test, Tzanck smear test using scrapping from the lesion is quick but accurate only in 50% to 70% of the cases. It cannot distinguish between virus types or between herpes simplex and herpes zoster and is not recommended.

Serologic Tests

Serologic tests can identify antibodies that are specific to the virus and its type. These tests are most accurate when done 12 to 16 weeks after exposure. Newer 'type-specific' arrays test for antibodies to two different proteins, associated with herpes virus. Glycoproteins gG-1 is associated with HSV-1, and glycoprotein gG-2 is associated with HSV-2. Various recommended tests include:

1. Herpe-Select: Includes enzyme-linked immunosorbent assay on immunoblot, results take larger time.
2. Biokit HSV-2: Detects only HSV-2, less expensive, results are provided in less than 10 minutes.
3. Western-Blot: This is gold standard, expensive and not widely available.

Serologic tests are recommended for patients with recurrent genital symptoms but negative viral cultures, confirming infection in genital herpes, to determine whether partner of someone diagnosed with genital herpes has acquired infection and people who have multiple sex partners. Serologic tests are not recommended for screening of HSV-1 or HSV-2 in general population.

Electroencephalography (EEG), computed tomography and magnetic resonance imaging may be useful in diagnosing.

TREATMENT

There is no medical cure that can eradicate HSV from body, but antiviral medication can reduce the frequency, duration and severity of the outbreaks. Antiviral drugs work by interfering with viral replication. They effectively slow the replication rate of virus and provide a greater opportunity for immune system to intervene. Various antivirals for controlling HSV are: acyclovir, valacyclovir, famciclovir and penciclovir (**Table 1**).

Acyclovir is the only approved drug for use during last trimester of pregnancy. Some reports suggest that famciclovir, when used during first herpes episode, reduces further outbreak by 5-fold as compared to acyclovir.

Topical treatment using docosanol has not shown any proven benefits, though it is sold as over the counter product in USA and Canada.

The virulite (1072 nm wavelength light) has proven to be effective against the cold sores and also reduces the outbreaks.

PREVENTION

Condoms offer moderate protection against HSV-2 in both man and women. Condom does not prevent skin or bodily fluid contact with scrotum, anus, buttocks, upper thighs or area immediately surrounding the penis, all of which are susceptible for transmission of virus. Wearing undergarments such as boxer shorts along with condoms should offer added protection. Long-term mutually monogamous relationship with a partner who has been tested and found to be uninfected can prevent genital HSV-2 to a greater extent. Persons with herpes should abstain from sexual activity with uninfected partners.

National Institutes of Health (NIH) in United States are conducting phase 3 trials of Herpevac, a vaccine against HSV-2.

Table 1: Treatment Strategies for HSV Presentations

Clinical Presentation	Drug Therapy
Keratitis	Topical idoxuridine or trifluridine Antibiotics if superinfection
Gingivostomatitis	Topical anaesthetics – 0.5% Benzocaine* – 5% Lidocaine as mouth rinse in large areas Severe cases oral: acyclovir valacyclovir, famciclovir
Herpes labialis	Topical acyclovir 1% q 2 hourly for 4 days Oral acyclovir 200 mg 5 times a day Famciclovir 1500 mg single dose Valacyclovir 2 g q 12 hourly for 1 day
Genital herpes	Acyclovir** 200 mg 5 times a day for 10 days Valacyclovir 1g q12 hourly for 10 days Famciclovir 250 mg q 8 hourly for 7 to 10 days
Recurrence	Acyclovir 200 mg q 4 hourly for 5 days Valacyclovir 500 mg q 12 hourly for 3 days Famciclovir 1 g q 12 hourly for 1 day
Herpes encephalitis/ meningitis	Acyclovir 10 mg/Kg IV q 8 hourly for 21 days
Neonatal herpes simplex	Acyclovir 20 mg/Kg IV q 8 hourly for 14 to 21 days

**Must not be swallowed as anaesthetises oropharynx, hypopharynx, etc. especially in children.*

***Doses should be adjusted in renal insufficiency.*

17.40 Human Papilloma Virus and Parvovirus Infections

Neerja Bhatla, Biswa B Dash

HUMAN PAPILLOMA VIRUS INFECTION

Introduction

Human papillomavirus (HPV) is a double stranded DNA virus that belongs to the family *Papovaviridae* and causes asymptomatic slow growing epithelial proliferation of skin and mucosa. Clinically three types of HPV are described based on the similarities of the genomic sequences: anogenital and/or mucosal, nongenital cutaneous and epidermodysplasia verruciformis (EV).

Epidemiology of HPV Disease

Warts occur at any age and in both sexes. An incidence of 10% has been estimated for children and young adults. It is low in early childhood, peaks between 12 and 16 years of age, then declines sharply by the age of 20. Warts are contagious. Impairment of cell mediated immunity increases the susceptibility to HPV infection. Anogenital warts have shown increased incidence in recent years and are regarded as a sexually transmitted condition. They are uncommon in children and when seen may be sexually transmitted as a consequence of sexual abuse.

Cervical cancer is the most important public health problem caused by HPV with a huge disease burden. It is the second most common cancer among women worldwide and the commonest cancer among women in India. Factors that increase the risk of progression include early age at sexual debut, multiple partners of self or partner, multiparity, smoking, prolonged oral contraceptive use, infection with other sexually transmitted diseases (STDs) such as herpes simplex, *Chlamydia* or gonorrhoea, poor nutrition and hygiene.

Aetiological Agent

The papillomavirus is a small 52 to 55 nm diameter DNA virus. Papillomaviruses are highly host and species-specific; thus HPV only infects humans. The virus lacks an envelope and its replication depends on differentiation of the epidermis. It is resistant to inactivation, freezing or desiccation. Till date more than 100 types of HPV have been detected and the genomes of more than 80 types have been completely sequenced.

Mode of Transmission

Transmission of HPV to uninfected persons occurs by close contact with infected individuals. Desquamated keratinocytes may also transmit the virus. In fully keratinised skin, a breach in the epithelial barrier function by trauma, maceration or both increase the predisposition to inoculation of virus. When these basal cells divide the viral genome is also replicated and transported within the daughter cells as they migrate upwards to form the differentiating epithelium. The greatest concentration of the virus is found in the granular layer. Warts are often distributed on hands, feet and knees. Plantar warts are acquired from swimming pool and hand warts spread widely around and beneath the nail in those who bite the nails. Autoinoculation results in local spread of warts.

Genital warts have high infectivity. The thinner mucosal surface is more susceptible to inoculation of virus than is thicker keratinised skin. Anogenital HPV infection is an STD. Females with multiple sexual partners or a single male partner who in turn has multiple female partners are more prone to genital HPV infection and genital cancers (cervical, vaginal and vulvar).

Pathology

The cytological changes of HPV were first recognised by Koss and Durfee in 1956 and given the term 'koilocytosis'. The characteristic histologic feature of viral warts is vacuolisation in cells, in and below the granular layer with basophilic inclusion bodies, composed of viral particles and eosinophilic inclusions representing abnormal keratohyaline granules, with hyperplasia of all layers of epidermis. Koilocytes are more often seen in benign than in malignant infection. Benign giant condylomas may be difficult to differentiate from malignant condylomas and repeated biopsies may be required to reveal malignant transformation. The final diagnosis in the case of cervical lesions rests on histopathology. Cervical intra-epithelial neoplasia (CIN) is divided into three grades. Based on the presence of abnormal cells up to the lower, middle or upper one-third of the epithelium, CIN is graded as CIN 1, 2 or 3. Full thickness abnormality is carcinoma *in situ* and disruption of the basement membrane is invasive cancer.

Clinical Manifestations of HPV Infections

The commonest presentation is benign proliferative lesions of the cutaneous epithelium, referred to as warts, and that of non-keratinising squamous epithelium of the mucosae known as condylomas or papillomas. HPVs have tropism for stratified squamous epithelial cells but vary in their specificity for different anatomical sites. For example HPV-1 replicates heavily in palms and soles, whereas HPV-11 replicates in genital and laryngeal epithelium. **Table 1** outlines characteristics of different types of warts.

The incubation period varies from a few weeks to more than a year in the case of common and plantar warts and from 3 weeks to 8 months in the case of genital warts.

Benign HPV infection can manifest as two types of clinical lesions—cutaneous and extra-cutaneous.

Table 1: Types of Warts, Location and Characteristics

Cutaneous Warts	HPV Types	Characteristics
Common warts (verruca vulgaris)	2, 57, 1 and 4	Can occur anywhere on skin, common on dorsal aspects of hands and fingers and on knees in children. Rough, keratotic firm papules, single/ multiple, discrete/ confluent, 1 mm to 1 cm size (**Figure 1**)
Plantar warts (myrmecia and mosaic)	1, 2, 4 and 57	Sharply defined, rounded lesions with a rough keratotic surface surrounded by smooth collar of thickened horn
Flat warts (verruca plana)	3 and 10	Smooth, flat, slightly elevated, skin colour to greyish brown; round or polygonal; 1 mm to 5 mm in diameter. Face, back of the hands and shins are common sites (**Figure 2**)
Anogenital warts	6 and 11	Classical protuberant type, commonly termed '*Condylomata acuminata*' (**Figures 3 and 4**) and may be confused with '*Condylomata lata*' of syphilis
Butcher's warts	2 and 7	Seen on skin of occupational handlers of meat, poultry or fish following prolonged contact with animal flesh, usually on hands. Lesions are papillomatous and/ or dome-shaped
Extracutaneous (along orificial mucous membranes)	6 and 11	Oral common warts, Oral *Condyloma acuminata*, Nasal and conjunctival papillomas, Laryngeal papillomatosis

Figure 1: Common warts.

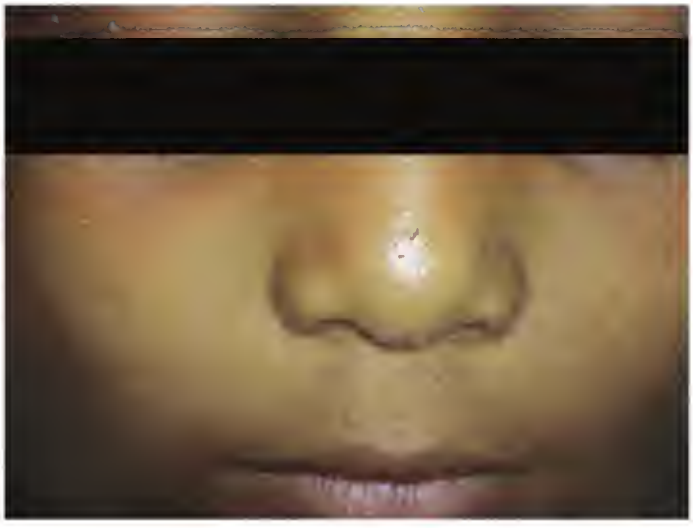

Figure 2: Verruca plana with Koebner's phenomenon.

Cervical Intraepithelial Neoplasia and Cervical Cancer (HPV 16, 18, 31, 33, 35, 39, 45, 51, 52, 56 and 58)

Many studies have revealed that 70% of genital HPV infection may be subclinical or latent and, therefore, asymptomatic. The infection goes unnoticed as there are no morphological changes but it can be detected by full clinical examination, cytology and histology. Usually the infection does not persist and clears in 9 to 15 months.

CIN lesions are acetowhite, iodine negative lesions. Benign lesions are usually located away from the squamocolumnar junction, while premalignant and malignant lesions are found abutting the squamocolumnar junction.

Patients with high grade CIN or invasive cancer may complain of vaginal bleeding between periods or after sexual intercourse, postmenopausal bleeding, persistent foul smelling vaginal discharge, dyspareunia and fullness in the pelvis. Speculum examination may reveal a frank cauliflower or ulcerative growth that is necrotic and bleeds on touch, easily detectable with the naked eye.

HPV Infection in Immunocompromised Patients

The lesions are refractory to treatment, persist and may undergo malignant transformation with development of squamous cell

Figure 3: Condyloma acuminata on penis.

Figure 4: Condyloma acuminata on labia.

carcinoma. The transition time to invasive cancer is typically shorter in these cases.

Diagnosis

Clinical diagnosis of warts is often sufficient; but atypical subclinical dysplastic lesions may need laboratory confirmation of HPV infection. Various diagnostic methods include histology, detection of viral particles by electron microscopy, immunohistochemistry, DNA hybridisation on tissue extracts and polymerase chain reaction (PCR). For routine clinical use, the vinegar test, application of 5% acetic acid may suffice to identify genital lesions.

Cervical and vaginal infections are detected on *Papanicolaou* smear and are broadly speaking reported as either normal, inflammatory smear, low-grade squamous intra-epithelial lesion or high-grade squamous intra-epithelial lesion according to the Bethesda classification. Pap smear has an overall sensitivity of only about 50% but has the advantage of high specificity of about 95%. Further examination after application of 3% to 5% acetic acid and colposcopy show characteristic acetowhite changes and abnormal blood vessel patterns indicative of HPV-triggered dysplasia. However, final diagnosis is based on histopathology. Obvious lesions can be biopsied with a punch biopsy forceps. Otherwise a colposcope is used to visualise the cervix under magnification and take a directed biopsy.

HPV DNA testing is a more sensitive method of cervical cancer screening than cytology. It is postulated that a negative HPV test can offer protection against CIN2+ for 5 to 8 years. The newer liquid based cytology has the same accuracy in detecting cervical cytology abnormality as the conventional Pap but has the additional advantage that HPV testing and typing can be done from the same sample. HPV DNA detection from the sample is possible by various methods such as hybrid capture method, PCR, etc. In the future, affordable HPV tests like *care*HPV™ may change the paradigm of cervical cancer screening.

Treatment

Warts can be expected to resolve spontaneously. Treatment failures and recurrences are common. Choice of treatment depends on the location, size, number and type of warts. The most commonly used treatments involve destruction of the infected area of the epidermis using topical preparations or surgical modalities. Other therapies are aimed at modifying the growth of the epidermis or stimulating an immune response.

Topical agents

Strong (40%) salicylic acid plaster or salicylic and lactic acid in a flexible collodion base is very effective in common warts on the hand and plantar warts. 5-Fluorouracil (5-FU) and topical podophyllin resin are common and effective treatments for anogenital warts. Podophyllin is contraindicated in pregnancy. Canthardin is a vesiccant which can be used for periungual warts. Trichloroacetic acid (50%), silver nitrate, formalin (37%) and glutaraldehyde (2%) also can be used.

Imidazoquinoline (5%) cream is especially useful for genital and perianal warts, especially in HIV positive patients. It stimulates peripheral monocytes and macrophages to release interferons and interleukins in HPV-infected cells when applied topically. Cidifovir, an antiviral purine nucleotide, applied topically is extremely effective in plantar, anogenital and laryngeal warts.

Systemic agents

Oral retinoids: Etretinate (1 mg/kg/dL) and acitretin are useful in common warts, epidermodysplasia verruciformis and laryngeal papillomatosis. Systemic interferons (IFN-α) can be tried in genital warts. Bleomycin is a cytostatic drug used intralesionally in plantar verrucae and recalcitrant periungual warts.

Surgical and physical methods

Liquid nitrogen and carbon dioxide ice is effective in various types of warts. Curettage and cautery/electrodessication/electrocoagulation usually in combination may be used for painful, persistent or resistant warts. Use of carbon dioxide laser assures high cure rates in periungual and plantar verrucae. Cryotherapy is a useful method for treatment of low grade CIN also. High grade CIN lesions may require excision with a loop electrosurgical excision procedure. These methods are effective in treating more than 95% of precancerous lesions of the cervix by simple outpatient procedures.

Immunotherapy

Immunotherapy in the form of introduction of allergic contact dermatitis with dinitrochlorobenzene (DNCB) allows localisation of inflammation to warts on which allergen is painted and stimulates local immunity.

Prevention

Secondary prevention has already been discussed.

Primary prevention—vaccination

The prophylactic HPV vaccine could lead to potential reduction in the incidence of HPV related diseases. It contains virus like particles that give immunity against infection with the specific vaccine type, with some degree of cross-protection against related types.

The bivalent vaccine (Cervarix™, GlaxoSmithKline) contains HPV types 16 and 18. It has been shown to have an efficacy of 98% for cervical intra-epithelial neoplasia caused by the vaccine types. There is also evidence of cross-protection against some related types including HPV 31, 33 and 45. The quadrivalent vaccine (Gardasil®, Merck and Co.) contains HPV 6 and 11 in addition to HPV 16 and 18. It gives protection against 99% of cervical intra-epithelial neoplasia and 100% against benign genital warts caused by the vaccine types. Screening for cervical cancer is to be recommended even after vaccination to detect cases caused by other types.

PARVOVIRUS INFECTION

Aetiological Agent

Parvovirus is a linear, non-segmented single-stranded DNA virus, with an average genome size of 5000 nucleotides. Parvoviruses are some of the smallest viruses found in nature. The B19 virus, generally referred to as parvovirus B19 or sometimes erythrovirus B19 was the first known human virus in the family of parvoviruses, genus erythrovirus. Parvovirus infection is a common and highly contagious childhood ailment, sometimes called slapped-cheek disease because of the distinctive face rash that develops. Parvovirus infection also has been known

as fifth disease because, historically, it was one of five common childhood illnesses characterised by a rash.

Epidemiology

A significant increase in the number of cases is seen every 3 to 4 years; the last epidemic year was 1998. Outbreaks can arise especially in nurseries and schools. One infection gives life-long immunity. Parvovirus B19 causes an infection in humans only. Cat and dog parvoviruses do not infect humans. There is no vaccine available for human parvovirus B19. However, there is a vaccine available for parvovirus that infects small mammals.

Transmission

The virus is primarily spread by infected respiratory droplets; blood-borne transmission, however, has been reported. The secondary attack risk for exposed household persons is about 50%, and about half of that for classroom contacts.

Infectivity

Symptoms begin some 6 days after exposure and last about a week. Infected patients with normal immune systems are contagious before becoming symptomatic, but probably not after then. Individuals with B19 IgG antibodies are generally considered immune to recurrent infection, but reinfection is possible in a minority of cases. About half of adults are B19-immune due to a past infection.

Manifestation of the Infection

Fifth disease

Fifth disease or erythema infectiosum is only one of several expressions of parvovirus B19. Any age may be affected, although common in children aged 6 to 10 years.

Patients usually develop the illness after an incubation period of 4 to 14 days. The disease commences with fever and malaise while the virus is most abundant in the bloodstream, and patients are usually no longer infectious once the characteristic rash of this disease has appeared.

Teenagers or young adults tend to develop the so called 'Papular Purpuric Gloves and Socks Syndrome'. Unlike young children, these patients may be infectious with this rash. The 'slapped cheek' appearance typical of fifth disease is erythema across the cheeks and sparing the nasolabial folds, forehead, and mouth. These rashes can last for up to 5 weeks and are worse after sun exposure, exercise, or hot baths.

Arthritis

In adults (and perhaps some children), parvovirus B19 can lead to a sero-negative arthritis which is usually easily controlled with analgesics. Women are approximately twice as likely as men to experience arthritis after parvovirus infection. Possibly up to 15% of all new cases of arthritis are due to parvovirus, and a history of recent contact with a patient and positive serology generally confirms the diagnosis. This arthritis does not progress to other forms of arthritis. Typically joint symptoms last 1 to 3 weeks, but in 10% to 20% of those affected, it may last weeks to months.

Aplastic crisis

Although most patients have an arrest of erythropoiesis [production of red blood cells (RBCs)] during parvovirus infection, it is most dangerous in patients who have sickle cell anaemia or hereditary spherocytosis, and are therefore heavily dependent on erythropoeisis due to the reduced lifespan of the red cells. This is termed 'aplastic crisis' (also called reticulocytopaenia). It is treated with blood transfusion.

Hydrops foetalis

Parvovirus infection in pregnant women is associated with miscarriage and hydrops foetalis sometimes leading to stillbirth. The virus has an affinity for the RBCs precursors in the bone marrow and causes destruction of these cells leading to anaemia. Adult RBCs are not usually affected for which the bilirubin level in the amniotic fluid remains unaffected. Foetal blood sampling (by cordocentesis) is an effective method to evaluate foetal anaemia. Foetal middle cerebral artery peak systolic velocity (MCA-PSV) on ultrasonographic colour Doppler is an indirect method of evaluation of foetal anaemia. The MCA-PSV is usually high (>1.5 MOM) in anaemic foetuses.

The risk of foetal loss is about 10% if infection occurs before pregnancy week 20 (especially between weeks 14-20), but minimal after then. The risk to the foetus will be reduced with correct diagnosis of the anaemia (by ultrasound scans) and treatment (by blood transfusions). There is some evidence that intrauterine parvovirus B19 infection leads to developmental abnormalities in childhood.

AIDS Patients

Parvovirus B19 is a cause of chronic anaemia in individuals who have acquired immunodeficiency syndrome (AIDS). It is frequently overlooked. Treatment with erythropoietin or intravenous immunoglobulin has been helpful in some patients. The parvovirus infection may trigger an inflammatory reaction in AIDS patients who have just begun anti-retroviral therapy.

Diagnosis

In acute phase, the virus can be detected in the serum by electron microscopy or DNA hybridisation and after rash appears specific IgM antibodies to human parvovirus. Foetal infection may be recognised by hydrops foetalis and presence of B19 DNA in amniotic fluid or foetal blood in association with maternal IgM antibodies to B19.

Treatment

Acute parvovirus infection requires no treatment and same is true for arthropathy. Transient aplastic crisis is usually treated with erythrocyte transfusion. Immunodeficient anaemic patients are treated by intravenous immunoglobulin.

17.41 Bird Flu and Swine Flu

Sandhya Kamath

Three influenza pandemics have occurred in recent years, each of these being caused by the appearance of a new strain of the influenza virus in human beings. An avian strain named H5N1 caused the 'Bird Flu'. In April 2009, a novel flu strain evolved that combined genes from human, pig, and bird flu, initially dubbed 'swine flu' and also known as 'Influenza A/H1N1' or '2009 H1N1 flu'. WHO officially declared the outbreak to be a pandemic on June 11, 2009. WHO's declaration of a pandemic level 6 was an indication of spread, not severity. The strain actually has a lower mortality rate than common flu outbreaks. On August 10, 2010, WHO declared the H1N1 influenza pandemic to be over, saying worldwide flu activity had returned to typical seasonal pattern.

BIRD FLU

Bird flu is an infection caused by avian influenza viruses. These flu viruses occur naturally among birds. Wild birds worldwide carry the viruses in their intestines, but usually do not get sick from them. However, bird flu is very contagious among birds and serious, fatal infection may occur in domesticated birds, including chickens, ducks, and turkeys.

Bird flu viruses do not usually infect humans, but more than 100 confirmed cases of human infection with bird flu viruses have occurred since 1997.

Epidemics of 'Bird Flu' in India

The first reports of bird flu in India came from the village of Nawapur in the Nandurbar district of Maharashtra on 19 February 2006. Villagers reported a large number of bird deaths in the village. Laboratory analysis proved that the poultry was affected with the H5N1 virus. Avian flu also occurred in July 2007 in Manipur, in the North Eastern part.

On January 11, 2008, unusual mortality of birds was reported from state poultry farm in Dakshin Dinajpur district and in some areas of Birbhum district in West Bengal. In January 2010, once again India reported the return of 'bird flu'. West Bengal's Murshidabad district tested positive for H5N1 infection.

Avian influenza infection (H5N1) in humans was noted in south-east Asia in 2003-2004 in Vietnam, Cambodia, Thailand, Indonesia. The expanding geographic distribution of this infection, with recent outbreaks in Kazakhstan, Mongolia, and Russia, indicates that more human populations are at risk. However, H5N1 case in humans has not been reported from India.

Bird Flu Virus

There are many different subtypes of type A influenza viruses. They do not usually infect humans, even though it now has been seen that they can. There are only three known influenza A virus subtypes of human flu viruses (H1N1, H1N2, and H3N2). Influenza A viruses are constantly mutating, and they might adapt over time to infect and spread among humans.

Influenza A (H5N1) virus—also called H5N1 virus—is influenza A virus subtype that occurs mainly in birds. Like all bird flu viruses, H5N1 virus circulates among birds worldwide, is very contagious among birds, and can be deadly. A variant of the H5N1 virus has been implicated as the causative agent of bird flu in humans. Infected birds shed flu virus in their saliva, nasal secretions, and faeces. Susceptible birds become infected when they have contact with contaminated excretions or surfaces that are contaminated with excretions. It is believed that most cases of bird flu infection in humans have resulted from contact with infected poultry or contaminated surfaces. The spread of avian influenza viruses from one ill person to another has been reported very rarely, and transmission has not been observed to continue beyond one person.

Transmission

The risk from bird flu is generally low to most people because the viruses occur mainly among birds and do not usually infect humans. However, during an outbreak of bird flu among poultry (domesticated chicken, ducks, turkeys), there is a possible risk to people who have contact with infected birds or surfaces that have been contaminated with excretions from infected birds. The recent outbreak of avian influenza A (H5N1) among poultry in Asia and Europe is an example of a bird flu outbreak that has caused human infections and deaths. In such situations, people should avoid contact with infected birds or contaminated surfaces, and should be careful when handling and cooking poultry. In rare instances, limited human-to-human spread of H5N1 virus has occurred, and transmission has not been observed to continue beyond one person.

Because all influenza viruses have the ability to change, scientists are concerned that the H5N1 virus one day could be able to infect humans and spread easily from one person to another. Since these viruses do not commonly infect humans, there is little or no immune protection against them in the human population. If the H5N1 virus were able to infect humans and spread easily from person-to-person, an influenza pandemic (worldwide outbreak of disease) could begin.

Clinical Features of Bird Flu

Symptoms of bird flu in humans range from typical flu-like symptoms (fever, cough, sore throat and muscle aches) to eye infections, pneumonia, severe respiratory diseases (such as acute respiratory distress), and other severe and life-threatening complications. The symptoms of bird flu may depend on which virus caused the infection.

Fever may be high, cough and shortness may develop early in the course of illness. X-ray chest may be non-specific and include diffuse multifocal and patchy infiltrates and segmental or lobular consolidation with air bronchogram. The illness can rapidly progress to ARDS and subsequently respiratory failure within 1 week of onset of symptoms. Mortality is high in such cases.

Laboratory Findings

Laboratory diagnosis depends upon demonstration of the virus and/or rising antibody titre. Available tests include virus culture, RT-PCR, immunofluorescence using monoclonal antibody to H5N1 and ELISA for detection of antibodies.

Treatment

The H5N1 virus currently infecting birds in Asia that has caused human illness and death is resistant to amantadine and rimantadine, two antiviral medications commonly used for influenza. Two other anti-viral medications, oseltamivir and zanamivir, would probably work to treat flu caused by the H5N1 virus. These have fewer side-effects and resistance to these is not common.

SWINE FLU

Influenza A H1N1 virus is a subtype of influenza A virus and was the most common cause of human influenza (flu) in 2009. Some strains of H1N1 are endemic in humans and cause a small fraction of all influenza-like illness and a small fraction of all seasonal influenza. Other strains of H1N1 are endemic in pigs (swine influenza) and in birds (avian influenza).

Transmission

Flu viruses are spread mainly from person to person through coughing or sneezing by people with influenza. Sometimes people may become infected by touching something—such as a surface or object—with flu viruses on it and then touching their face.

Epidemic of 'Swine Flu' in India

The 2009 flu pandemic in India was the outbreak of swine flu. This was the first epidemic attributed to this infection in India. Soon after the outbreak of H1N1 virus in the United States and Mexico in March 2009, the Government of India started screening people coming from the affected countries for swine flu symptoms at airports. The first case of the swine flu in India was found at Hyderabad airport on 13 May 2009, when a man travelling from US to India was found H1N1 positive. Subsequently, more confirmed cases were reported and the rate of transmission of the flu increased in the beginning of August 2009 till November 2009, after which there was a reduction in the number of cases. The 2009 swine flu outbreak in India had affected mostly its main cities.

Symptoms and Signs

The symptoms of H1N1 flu are similar to other influenzas, and include fever, dry cough, running nose, sore throat, headache, muscle pain, joint pain, chills, and fatigue. Diarrhoea, vomiting, and neurological problems have also been reported in some cases.

People at higher risk of serious complications include elderly age group, children less than 5 years of age, children with neurodevelopmental anomalies, pregnant women (especially during the third trimester), and those of any age with underlying medical conditions, such as asthma, diabetes, obesity, heart disease, or those who are immunosuppressed.

Symptoms in Severe Cases

WHO reported that the clinical picture in severe cases is strikingly different from the disease pattern seen during epidemics of seasonal influenza. While people with certain underlying medical conditions are known to be at increased risk, many severe cases occur in previously healthy people. In these patients, predisposing factors that increase the risk of severe illness are not presently understood, though research is under way. In severe cases, patients generally begin to deteriorate around three to five days after the onset of symptoms. Deterioration is rapid, with many patients progressing to respiratory failure within 24 hours. Most patients need immediate ICU admission and respiratory support with mechanical ventilation.

CDC recommends immediate medical attention should be sought if a person experiences any one of the following 'emergency warning signs':

- In adults they include difficulty in breathing or shortness of breath, pain or pressure in the chest or abdomen, sudden dizziness, confusion, severe or persistent vomiting and low temperature.
- In children they include fast breathing or working hard to breathe, bluish skin colour, not drinking enough fluids, not waking up or not interacting, being so irritable that the child does not want to be held, flu-like symptoms that improve but then return with fever and worse cough, fever with a rash, not eating, having no tears when crying.

Complications

Most complications have occurred among previously healthy individuals, with obesity and prior respiratory disease as the strongest risk factors. Pulmonary complications are common. Primary influenza pneumonia occurs most commonly in adults and may progress rapidly to acute lung injury requiring mechanical ventilation. Secondary bacterial infection is more common in children. Staphylococcus aureus, including MRSA, is an important cause of secondary bacterial pneumonia with a high mortality rate. Neuromuscular and cardiac complications are unusual but may occur. Fulminant myocarditis and pulmonary emboli were other complications detected.

Diagnosis

To confirm the diagnosis, testing of a nasopharyngeal, nasal, or oropharyngeal tissue swab from the patient is required. Real-time (RT) PCR is the recommended test as others are unable to differentiate between pandemic H1N1 and regular seasonal flu. However, most people with flu symptoms do not need a test for pandemic H1N1 flu specifically, because the test results usually do not affect the course of treatment. CDC recommends testing only for people who are hospitalised with suspected flu, pregnant women, and people with weakened immune systems. For the mere diagnosis of influenza and not pandemic H1N1 flu specifically, more widely available tests include rapid influenza diagnostic tests (RIDT), which yield results in about 30 minutes, and direct and indirect immunofluorescence assays (DFA and IFA), which take 2 to 4 hours. Due to the high rate of RIDT false negatives, CDC advises that patients with illnesses compatible with novel influenza A (H1N1) virus infection but with negative RIDT results should be treated empirically based on the level of clinical suspicion, underlying medical conditions, severity of illness, and risk for complications, and if a more definitive determination of infection with influenza virus is required, testing with RT-PCR or virus isolation should be performed.

A new test called the 'CDC Influenza 2009 A (H1N1) pdm Real-Time RT-PCR Panel (IVD)' has been launched. It uses a molecular biology technique to detect influenza A viruses and specifically the 2009 H1N1 virus. The new test will replace the previous RT-PCR diagnostic test used during the 2009 H1N1 pandemic, which received an emergency use authorisation by the FDA in April 2009. Test results are available in four hours and are 96% accurate.

Treatment

Adequate fluid intake and rest have been recommended to help ease symptoms. Pain medications, such as acetaminophen and ibuprofen are useful to reduce symptoms. Aspirin and other salicylate products should not be used by people under 19 years with any flu-type symptoms because of the risk of developing Reye's syndrome.

If the fever is mild and there are no other complications, fever medication is not recommended. Most people recover without medical attention, although those with pre-existing or underlying medical conditions are more prone to complications and may benefit from further treatments.

People in at-risk groups should be treated with antivirals (oseltamivir or zanamivir) as soon as possible when they first experience flu symptoms. The dose of oseltamivir is 75 mg twice a day for 5 days. The at-risk group includes pregnant and post partum women, children under two years old, and people with underlying conditions, such as respiratory problems. People who are not from the at-risk group who have persistent or rapidly worsening symptoms should also be treated with antivirals. These symptoms include difficulty in breathing and a high fever that lasts beyond three days. People who have developed pneumonia should be given both anti-virals and antibiotics, as in many severe cases of H1N1-caused illness, bacterial infection develops. Antivirals are most useful if given within 48 hours of the start of symptoms and may improve outcomes in hospitalised patients. In those beyond 48 hours who are moderately or severely ill, antivirals may still be beneficial. If oseltamivir is unavailable or cannot be used, zanamivir is recommended as a substitute. Peramivir is an experimental anti-viral drug approved for hospitalised patients in cases where the other available methods of treatment are ineffective or unavailable. Both medications have known side effects, including lightheadedness, chills, nausea, vomiting, loss of appetite, and troubled breathing. Children were reported to be at increased risk of self-injury and confusion after taking oseltamivir.

Infection Control

Reasonably effective ways to reduce the transmission of influenza include good personal health and hygiene habits such as: not touching your eyes, nose or mouth; frequent hand washing (with soap and water, or with alcohol-based hand rubs); covering coughs and sneezes; avoiding close contact with sick people; and staying home yourself if you are sick. Avoiding spitting is also recommended. Although face masks might help prevent transmission when caring for the sick, there is mixed evidence on beneficial effects in the community. Prophylaxis with anti-viral drug is recommended for high risk population in contact with confirmed cases. Oseltamivir is given in the dose of 75 mg once daily for 10 days.

Vaccines

Vaccines that have been developed to protect against the pandemic H1N1/09 virus either contain inactivated (killed) influenza virus, or live attenuated virus. The killed vaccine is injected, while the live vaccine is given as a nasal spray. In studies, the vaccine appears both effective and safe, providing a strong protective immune response and having similar safety profile to the normal seasonal influenza vaccine. Killed vaccine is used in pregnant women and immunocompromised persons.

17.42 Dengue

ME Yeolekar

DEFINITION AND EPIDEMIOLOGY

Dengue, the most common arboviral disease worldwide is usually endemic but several epidemics have been recorded. The causative agent, dengue virus belongs to genus Flavivirus. It has a single-stranded ribonucleic acid genome surrounded by an icosahedra nucleocapsid covered by lipid envelope. Dengue fever (DF) and dengue haemorrhagic fever (DHF) are caused by four antigenically related dengue viruses 1, 2, 3 and 4. Infection with one serotype provides life-long immunity to that virus but not to the others. Dengue viruses are maintained in an urban transmission cycle in tropical and sub-tropical areas by the mosquito vector closely associated with human habitation, *Aedes aegypti*.

In Southeast Asia, epidemic DHF first appeared in the 1950s. By 1975 it had become a leading cause of hospitalisation and death among children in many countries. In the 1980s, DHF began a second expansion into Asia. Different serotypes have been observed in 1996 (DEN-2) and 2003 (DEN-2 and 3) outbreaks in north India. Rapid urbanisation, inadequate supply of piped water, increased movement of human population within and between countries, and further development and spread of insecticide-resistance in the mosquito vector population, are some of the reasons for the increase of dengue transmission in recent years (**Table 1**).

Table 1: Criteria for Diagnosis of DHF and DSS

Criteria for dengue haemorrhgic fever (all 4 criteria required)

- Fever or history of fever lasting 2 to 7 days.
- Haemorrhagic tendencies indicated by at least one of the following:
  - A positive tourniquet test
  - Petechiae, ecchymoses, purpura
  - Bleeding per mucosa, GIT, other
  - Haematemesis, melaena.
- Thrombocytopenia <100,000/mm³
- Plasma leakage evidenced by at least one of the following:
  - Rise in haematocrit >20%
  - Fall in haematocrit >20% after intravenous fluids
  - Pleural effusion, ascites, hypoalbuminaemia.
- Tourniquet test is performed by inflating the sphygmomanometer cuff on the upper arm to midway between systolic and diastolic pressure for 5 minutes. A positive test is identified by appearance of more than 20 petechiae per 2.5 cm.

Criteria for DSS

- DSS require all DHF criteria and in addition a circulating failure manifested by:
  - Rapid and weak pulse
  - Narrow pulse pressure (<20 mm Hg)
  - Hypotension for age ≤5 yr <80 mm Hg and for age ≥5 year ≤90 mm Hg
  - Cold dry skin, restlessness.

AETIOPATHOGENESIS

Macrophage/monocyte infection is central to the pathogenesis of DF and to the origin of DHF/dengue shock syndrome (DSS). Previous infection with a heterologous dengue-virus serotype may result in the production of non-protective anti-viral antibodies. Subneutralising levels of dengue antibodies enhance the infectivity of the virus. The major pathophysiological change that determines the severity of disease in DHF and differentiates it from DF is the leakage of plasma. Extravasations occur through endothelial gaps, without necrosis or inflammation of the capillary endothelium. Complement activation and release of cytokines and other mediators cause capillary leakage and coagulopathy, so characteristic of DHF. Vascular instability, decreased vascular integrity, increased permeability, decreased platelet function individually and in sequential combination can cause abnormalities in control of local circulation manifested clinically by cutaneous flushing, conjunctival suffusion, and with widespread vascular damage the clinical haemorrhagic manifestations/bleeding and/or loss of blood volume leading to shock. In severely ill patients even disseminated intravascular coagulation may occur.

CLINICAL FEATURES

Classic Dengue ('Break-Bone Fever') (Table 1)

The incubation period is usually 4 to 6 days (range 3 to 14 days) followed by abrupt onset of fever, chills, headache, retro-orbital pain, conjunctival suffusion and backache that is quite often severe. The fever is typically of 39 to 40°C and is occasionally followed by remission lasting few hours to 2 days followed by a second febrile phase for 1 to 2 days (biphasic curve or saddleback pattern). Fever lasts for 5 to 7 days. A transient generalised erythematous rash may be present during the first 24 to 48 hours. The typical morbiliform rash appears on the trunk and spreads centripetally to face, trunk and limbs and spares palms and soles, lasts for 1 to 5 days, and sometimes resolves with desquamation. Generalised myalgia, arthralgia and constitutional symptoms like anorexia, nausea, vomiting, and dysgeusia can also be present. The physical examination may reveal relative bradycardia and lymphadenopathy. Marked leucopaenia and neutropaenia are typical, and thrombocytopaenia may occur between 3rd to 8th day. Thrombocytopaenia results from impaired megakaryocytic production and increased platelet destruction. Platelet function abnormalities also contribute to bleeding. In some epidemics DF has been associated with haemorrhagic phenomena, particularly petechial haemorrhages and epistaxis, gastrointestinal bleed, haematuria, menorrhagia, but in the absence of signs of plasma leakage, a diagnosis of DHF is unwarranted. South-east Asian serotype 2 strains have more potential to cause DHF/DSS than others.

Dengue Haemorrhagic Fever

DHF is primarily a disease of older children and young adults. DHF is defined as an acute febrile illness with minor or major bleeding, thrombocytopaenia (platelet count $<10^5/mm^3$) and evidence of plasma leakage documented by haemoconcentration (haematocrit increased by at least one-fifth) and pleural and other effusions (serositis). Susceptibility to DHF/DSS drops considerably after 12 years of age. Type 2 is more dangerous than other serotypes. DHF commonly begins with a sudden rise in temperature and other symptoms resembling DF. The temperature is typically high (38-40°C) and continues for 2 to 7 days. DHF and dengue shock usually develop around the 3rd to 7th day of illness. The most common haemorrhagic feature is a positive tourniquet test. Petechiae, easily bruised skin and subcutaneous bleeding at venepuncture sites are present in most cases. Transudate due to excessive capillary permeability collects at the pleural and abdominal cavities. The development of DHF provides warning of an increased probability of shock. A progressively decreasing platelet count and a rising haematocrit (signalling abnormal capillary permeability) indicates increased probability of impending shock.

Dengue Shock Syndrome

DSS is defined as DHF (Grade III/IV) with signs of circulatory failure, including narrow pulse pressure (30 mm Hg), hypotension or frank shock. The four warning signs for impending shock are intense, sustained abdominal pain, persistent vomiting, restlessness or lethargy and a sudden change from fever to hypothermia with sweating and prostration. Blotchy skin, cyanosis, tachypnoea, hepatomegaly, pleural effusion, oedema and oliguria are other physical findings. The patient may recover rapidly after volume replacement but shock may recur during the period of excessive capillary permeability. The prognosis in DHF/DSS depends on prevention or early recognition and treatment of shock.

DIAGNOSIS

Microbiology

The virus should be sought from serum obtained during febrile phase of illness. Serum is the specimen of choice for both virological and serological studies. Circulating virus remains detectable in the blood during the febrile period (for an average of 5 days after onset of symptoms), and is then rapidly cleared with the appearance of specific antibody. Serologic diagnosis is achieved by demonstrating a rise in haemagglutination inhibition, complement fixation, or neutralising antibody titres in appropriately timed paired sera drawn 7 to 14 days apart. The IgM antibody capture ELISA is especially useful in the diagnosis of recent infection. IgM antibodies are relatively specific for dengue, but do not distinguish between various serotypes. Rising titre of IgM antibodies is much more specific. Newer diagnostic techniques like reverse-transcriptase polymerase chain reaction (RT-PCR) are very sensitive and specific for detection of viral RNA. Hybridisation probe identify viral nucleic acids. Modified RT-PCR using fluorescent labeled oligonucleotide probe and nucleic acid sequence based amplification are recent research developments.

Blood Chemistry

Thrombocytopaenia and haemoconcentration are constant findings in DHF. A drop in platelet count below $100,000/mm^3$ is usually found between 3rd and 8th day of illness. Haemoconcentration with an increase in the haematocrit of 20% or more is considered to be definitive evidence of increased vascular permeability and plasma leakage. However, it should be noted that the haematocrit level may be affected by volume replacement or bleeding. A drop in total white blood cell count with reduction in number of neutrophils is observed near the end of febrile phase of illness. A relative lymphocytosis with more than 15% atypical lymphocytes is also common at early shock stage. Deranged hepatic and renal function tests and prolonged prothrombin time are observed in severe cases of DHF. The above haematological parameters have to be performed on a repetitive basis during the early stages as well as for monitoring/prognostic purpose, more often when patient is in intensive care unit (ICU) set-up.

Differential Diagnosis

Dengue should be differentiated from malaria, leptospirosis, infectious hepatitis, chikungunya, sepsis, meningococcaemia, rubella, influenza and other haemorrhagic fevers. Presence of haemoconcentration along with thrombocytopaenia differentiates DHF from other diseases. Normal erythrocyte sedimentation rate differentiates DHF from septic shock and bacterial infection. Case definitions of dengue are summarised in **Table 2**.

Table 2: WHO Case Definitions of Dengue Fever

Probable Case

An acute febrile illness with two or more of following:
- Headache
- Retro-orbital pain
- Myalgia and arthralgia
- Nausea and vomiting
- Skin rash
- Haemorrhagic manifestations

AND

Supportive serology

OR

Occurrence at the same location and time as other confirmed cases of dengue fever

Confirmed Case

Confirmation of dengue fever is based on laboratory criteria:

Virus isolation from serum or tissue samples

OR

Demonstration of four-fold or more rise in IgG and IgM antibody titres to dengue antigens in paired serum samples

OR

Demonstration of dengue antigen in tissue CSF by immunocytochemistry or detection of genomic sequence by PCR

WHO = Warld Health Organisatian; Ig = Immunaglabulin; CSF = Cerebrospinal fluid; PCR = Palymerase chain reactian.

TREATMENT

Treatment of DF is symptomatic with paracetamol (aspirin and NSAIDs are avoided due to risk of bleeding), rest, and oral rehydration therapy. Patient can be managed at home in absence of signs of dehydration or bleeding. Patient should be alerted for danger signs, like abdominal pain, melena, bleeding and cold skin. In DHF, careful and repeated estimation of volume status and fluid replacement are the cornerstones of management. This should include measuring vital signs,

urine output, haematocrit, and serum protein concentration. Insufficient volume replacement will allow worsening of shock, acidosis, and disseminated intravascular coagulation, while fluid overload will produce massive effusions, respiratory compromise, and congestive heart failure. Because patients have loss of plasma (through increased vascular permeability into serous spaces) they must be given isotonic solution or plasma expanders. Initial fluid challenge is given with 6 mL/kg/hour and up to 10 to 20 mL/kg/hour, if no improvement occurs. Drop in haematocrit to approximately 40% and improvement of urine output indicates adequate hydration.

DSS requires close monitoring, oxygen administration, much more aggressive fluid replacement therapy, sometimes colloid infusion, ionotropic support and ICU care. Platelets are replaced in case of profound thrombocytopaenia (platelet count <10,000/mm^3) or clinical bleeding. Patients with DF should preferably receive single donor aphaeresis platelets as compared to random donor platelets to lower the risk of alloimmunisation. There is no role of steroids in the management of DHF. Correction of metabolic acidosis, electrolyte imbalance and hypoglycaemia are essential.

Complications

Overt bleeding (haematemesis, melena and severe ecchymoses) is the main complication. Other complications include acute respiratory distress syndrome, renal failure, hepatic failure and encephalopathy. DSS in association with haemorrhagic signs is a serious complication.

PROGNOSIS AND PREVENTION

Classic DF is rarely fatal. However, general weakness and depression may persist for several weeks following the acute illness in adults. Although DF is a self-limiting disease, timely intervention is required to prevent complications and fatal outcome in patients with DHF/DSS. At its worse, the case fatality rate in patients with DSS can be up to 44% where patient is hospitalised late and developed multiple complications.

The key to control of DF/DHF/DSS is the control of mosquitoes that live and breed in stagnant water in and around the house. Vector control includes simple measures, like eliminating larva habitats, using repellents/indoor space-spray insecticides and mosquito-nets while sleeping. Control efforts have been handicapped by the presence of non-degradable tyres and long-lasting plastic containers in trash repositories, insecticide resistance, urban dwelling and poverty. As there is no cross protection between the 4 dengue serotypes and because of fear of immune enhancement by heterotypic antibodies, only a tetravalent vaccine will be acceptable. Tetravalent live attenuated vaccine is presently going through Phase II trials. In view of emerging outbreaks of DF in various states of India, it becomes imperative for primary care physicians to be aware of the management guidelines.

17.43 Ebola and Marburg Infections

Partha Pratim Chakraborty

A haemorrhagic fever is an acute febrile illness clinically manifested at times by severe muco-cutaneous bleeding. The term originates from the Greek '*Haima*' meaning blood and '*rhegnynai*' meaning to burst forth. Viral haemorrhagic fevers (VHFs) are caused by viruses from four distinct families (Arenaviridae, Bunyaviridae, Filoviridae, Flaviviridae) and vary in severity from relatively mild to life-threatening complications. Filoviruses ('thread' viruses) are causative agents of such a haemorrhagic fever in man. They are enveloped, non-segmented negative-stranded RNA viruses and are separated into 2 types, Marburg and Ebola, which can be serologically, biochemically and genetically distinguished. Both of them share the same morphology, characterised by a filamentous structure. They can appear like a 'U', a '6', or spiralled like a snail; and can sometimes be branched. Filoviruses are prime examples for emerging pathogens.

EPIDEMIOLOGY

Ebola virus infection was first recognised in 1976 with almost simultaneous outbreaks in Sudan and Zaire (now the Democratic Republic of Congo). It was named after a river in the Democratic Republic of Congo. The Ebola virus has four subtypes: Zaire, Sudan, Reston, and Ivory Coast.

Marburg is named after the German town where some of the first identified cases were described. Endemic areas appear to be Central and East Africa. Another fertile area is the Mt. Elgon region on the border of Kenya and Uganda. It also has a natural reservoir in Zimbabwe.

Although the natural host and the route of transmission are uncertain, bats may be the possible candidates for spread of Marburg disease (MD). The viruses appear to be spread mainly by close and prolonged contact with infected persons or by inoculation from syringes and needles contaminated with blood or body fluids.

Factors involved in the emergence of these viruses are international commerce and travel, limited experience in diagnosis and therapy, import of non-human primates, and their potential for rapid evolution.

AETIOPATHOGENESIS

Development of new technologies and extensive studies on animal models has substantially expanded the knowledge on the pathogenic mechanisms of these diseases. Two major factors postulated in pathogenesis of Ebola disease (ED) are immune dysregulation and vascular endothelial dysfunction.

As with Ebola, the exact mechanism of MD is also unknown. It is presumed that virion surface spikes made of large glycoprotein bind to receptors on the host cell and mediate entry into susceptible cells. Viral replication takes place in the cytoplasm and then it involves the liver, lymphoid organs, and kidneys.

CLINICAL FEATURES

Incubation period of ED is 4 to 16 days and that of MD is 3 to 10 days. Clinical pictures are indistinguishable.

Although all begin with constitutional symptoms, some may develop more serious manifestations, including severe internal and external bleeding with widespread tissue necrosis and shock. Early signs and symptoms mimic any of the viral illnesses and include: fever, severe headache, joint and muscle aches, chills, sore throat and prostration. Over time, symptoms become increasingly severe and may include: nausea and vomiting, diarrhoea (may be bloody), red eyes, maculopapular rash, chest pain and cough, epigastric pain, confusion, irritability or aggression and massive haemorrhage from many sites, including nose, mouth, rectum, eyes, ears and solid organs.

The fever typically lasts for around 7 days. On the 5th day of fever, a maculopapular petechial rash appears, and bleeding begins. In survivors, the skin will eventually begin to shed or peel.

Renal, cardiac and adrenal failures are common. Some patients may become jaundiced. Unusual symptoms may include inflammation of the eyelid, polyserositis and pulmonary interstitial oedema. Patients finally experience coma and convulsions, followed by death. Death from shock usually occurs 6 to 9 days after clinical onset of symptoms.

Within 7 to 10 days, patients who will survive begin to recover. Recrudescence occurs by 12th day and can be complicated with secondary bacterial infections. Recovery can take 5 weeks or more, and is marked by prostration, weight loss, and amnesia for the period of acute illness. Complications during convalescence can include recurrent hepatitis, as well as inflammation of the spinal cord, bone marrow, eyes, testes, and parotid gland.

For patients presenting with filovirus symptoms, initial possible diagnoses can include malaria, dengue, chikungunya, leptospirosis and typhoid fever. Other differentials are rickettsial diseases and different VHFs.

DIAGNOSIS

Laboratory findings are non-specific and include lymphopaenia, neutrophilia and thrombocytopaenia. Transaminase levels are elevated (AST>ALT). Alkaline phosphatase and bilirubin levels are usually normal or only mildly elevated.

Diagnosis is confirmed by IgG ELISA (high or rising titres), although IgM ELISA can be used to distinguish acute infections from old infections. IFA results can be misleading. Electron microscopy is useful, but does not distinguish MD from ED. Other modalities are immunohistochemistry of skin biopsies, virus isolation, or PCR of blood or tissue specimens.

TREATMENT

There are no drugs that work against these diseases. Supportive therapy and control of complications is the rule. Therapy involving blood plasma from convalescent patients, anticoagulants and interferon has been used with limited success. Another emerging option is recombinant nematode anticoagulant protein with therapeutic antibodies. However, the effectiveness of these still remains controversial.

PROGNOSIS AND PREVENTION

ED can have up to 90% mortality. It has been placed in the category A list of potential biothreat agents by World Health Organisation.

The case fatality rate in MD is approximately 25%. The virus is classified as a biosafety level 4 agent because of its extreme pathogenicity and the lack of a vaccine or anti-viral drug.

Till date no effective vaccines are available and exposure to filoviruses does not confer subsequent immunity. The antibody response in convalescent patients does not neutralise or protect against subsequent infection by the same virus. Until additional vaccines are developed, the best approach is prevention.

The most effective way to reduce or prevent transmission in an outbreak is through the proper use of barrier protection for doctors and nurses. This includes the use of gloves and masks, with gloves being changed after every patient. Another important aspect is proper sterilisation of equipments. The virus is sensitive to lipid solvents, detergents, commercial hypochlorite disinfectants, and phenolic disinfectants. The virus can also be destroyed by ultraviolet and gamma radiation.

17.44 Japanese Encephalitis

UK Misra, J Kalita

INTRODUCTION

Japanese encephalitis (JE) is the commonest human endemic encephalitis in the world and is prevalent throughout the Eastern and Southern Asia. JE was recognised in horses and humans as early as 1871. The term Japanese B encephalitis was used to distinguish it from summer epidemics of von Economo's lethargica known as type A encephalitis. Later the term type B was dropped and it is known as Japanese encephalitis instead.

EPIDEMIOLOGY

Japanese encephalitis virus (JEV) is a single stranded RNA virus which belongs to the family Flaviviridae. Most members of the Flavivirus genus are arthropod borne (arbo) viruses, a term that emphasises the need of a blood sucking arthropod to complete the life cycle. JE virus is transmitted through zoonotic cycle between mosquitoes, pigs and water birds. Humans are accidentally infected when bitten by an infected mosquito (**Figure 1**).

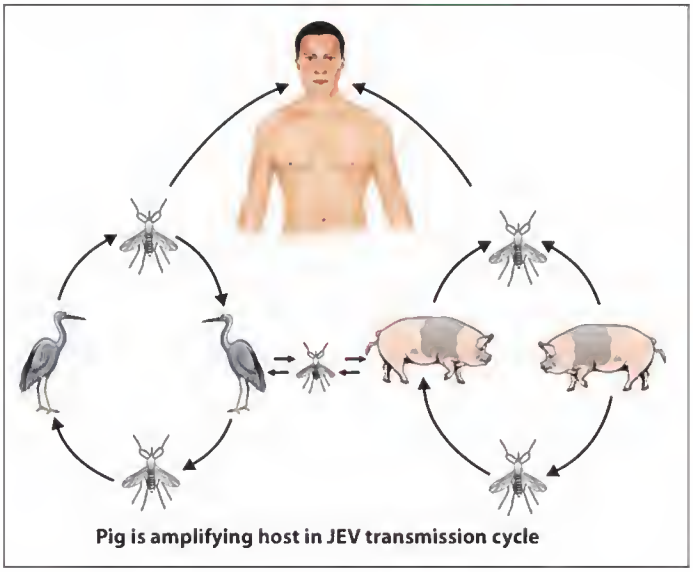

Figure 1: Life cycle of Japanese encephalitis virus. Humans are the accidental dead-end host.

Vector

Culex tritaeniorhynchus is the most important vector for JEV transmission which is present in stagnant water in large numbers shortly after the rainy season and prefer pigs and birds over humans for blood meal but bite humans with high enough frequency to transmit JEV.

Host

Pigs and ardeid birds are the most important host for maintenance, amplification and spread of JEV. Pigs are the most important natural host for transmission of JEV to humans because they are often kept close to human habitat, have prolonged and high viraemia and produce many offspring, resulting in a continuous supply of new hosts. JEV infected animals generally remain asymptomatic, however, fatal encephalitis occurs in horses and foetal wastage occurs in cows.

Human Infection

Humans develop JEV infection coincidentally when living or travelling in close proximity to the enzootic cycle to JEV (**Figure 1**). JE is a rural disease but is also found in the suburban areas due to pigs and mosquito breeding. Most human infections, however, are asymptomatic or result in a nonspecific flu like illness. The ratio of symptomatic to asymptomatic infection varies from 1 in 25 to 1 in 1000. In the endemic areas, JE affects mainly the children whereas in non-endemic or newly affected areas both adults and children are affected. The highest age specific attack rates of JE are between 3-6 years of age which is due to high outside exposure especially playing in the evening with high risk of mosquito bites to poorly clothed village children. Age specific attack rates decline after 14 years of age and are attributed to high levels of antibodies due to natural exposure to JEV (subclinical infection).

Environment

JEV transmission occurs throughout the year in the tropics, but seasonal epidemics occur during the rainy season when the mosquito density is maximum. Two epidemiological patterns of JE are recognised: in the northern region, the epidemics of JE occur during the summer months whereas in the southern region JE tends to be endemic and the cases occur throughout the year with the peak incidence during the rainy season. This difference has been attributed to temperature rather than rainfall.

PATHOGENESIS

The incubation period of JE is 6-16 days. Local replication of virus occurs at the site of mosquito bite followed by lymphatic or haematogenous spread. Replication of JEV beyond the primary site results in secondary viraemia which can result in central nervous system (CNS) involvement. In most patients, primary viraemia is terminated by a macrophage response and subsequently by the development of antibodies. JEV infects the endothelial cells of the capillaries of the brain and crosses the blood brain barrier. JEV spreads to both extracellular and intracellular spaces and results in inflammatory response leading to formation of characteristic glial nodules (foci of degenerating neurons surrounded by inflammatory cells). Both humoral and cellular immune responses occur following JEV infection. A rapid and potent IgM response occurs in the serum and CSF following primary JEV infection. By day 7, most patients have raised IgM titres. Antibodies to JEV prevent viral replication and also limit damage by neutralising extracellular virus and facilitating lysis of infected cells by antibody dependent cytotoxicity.

On autopsy, leptomeninges are normal or hazy and the brain parenchyma is congested with petechiae or focal haemorrhages.

Thalamus, basal ganglia, midbrain, cerebral cortex, cerebellum and anterior horn cells are commonly affected. In some patients, the grey matter of the spinal cord is confluently discoloured as in poliomyelitis.

CLINICAL FEATURES

Following 2 to 4 days of nonspecific illness, the patients develop headache, fever, rigours, flu-like symptoms or gastrointestinal symptoms which improve in a few days. The encephalitis syndrome is characterised by behavioural abnormality; altered sensorium, seizures and focal neurological deficits in the form of hemiplegia, quadriplegia or cerebellar signs. Neck stiffness and Kernig's sign may also be present. Severely affected patients may have decerebrate or decorticate posturing. Cranial nerve palsy is rare although visual blurring, diplopia and blindness have been reported. Tremulous eye movements subside as fever abates. In some patients, particularly older children and adults, abnormal behaviour may be the only presentation, which may be confused with a psychiatric illness.

Seizure

During the acute stage of JE, seizures have been reported in 6.7% to 67.2% patients. The seizures may be focal or generalised and rarely may progress to status epilepticus. The seizures are commoner in children compared to adults. In children, subtle seizures manifest with twitching of digits and facial muscles, nystagmus, ocular deviation, irregular respiration or excessive salivation. Occurrence of seizures in JE may also be contributed by co-infection with cysticercosis which may either suggest the role of neurocysticercosis in the predisposition of JE or co-existence of both the diseases because of common pig reservoir.

Acute Flaccid Paralysis

Japanese encephalitis is actually an encephalomyelitis. Patients with encephalitis may manifest with variable focal lower motor neuron signs, which may be as subtle as focal reflex loss or as severe as flaccid quadriparesis followed by wasting and muscle atrophy (**Figure 2**). Acute flaccid paralysis in JE has been reported in 5% to 20% patients. Majority of these patients have features of encephalitis.

Movement Disorders

The movement disorders in JE have been reported in 20-80% patients as the patient recovers from deep coma. Three major groups of movement disorders in JE are:

1. *Parkinsonian features*: Parkinsonian features in JE are characterised by mask facies, paucity of blinking, abulia, akinesia and rigidity with or without tremor.
2. *Dystonia*: In JE, wide varieties of dystonia, such as orofacial, limb and axial are described (**Figure 3**). These are fixed dystonia with varying severity and are usually superimposed on parkinsonian features.
3. *Miscellaneous movement disorders:* Other movement disorders, such as chorea, athetosis and myoclonus are also rarely observed in JE. Sometimes dystonia in JE patients may be very severe, simulating status dystonicus which is difficult to treat and refractory to various drugs, such as anticholinergic, tetrabenazine, haloperidol, diazepam, clonazepam and baclofen in various combinations. Most of the patients, however, improve to variable extent over months to years.

Figure 2: Photograph of a Japanese encephalitis patient shows severe wasting of both the legs.

DIAGNOSIS

Currently IgM capture ELISA is the most reliable method. Presence of IgM antibodies in the CSF has a reported sensitivity and specificity of 90% for the diagnosis of JE. Rapid IgM capture ELISA (JEV Chex) has been reported as robust and user friendly, with similar sensitivity as conventional ELISA. On CT scan or MRI, involvement of thalamus, basal ganglia and brainstem is highly suggestive of JE (**Figure 4**) especially in post monsoon period in the endemic area.

MANAGEMENT

There is no specific antivira l therapy against JE, therefore, the treatment is symptomatic and supportive. Fever and convulsions are managed symptomatically. Seriously ill patients may require artificial ventilation. Dexamethasone and IFNα have not been found to be beneficial in JE. Management of nutrition and electrolytes and prevention of aspiration pneumonia, bed sores and urinary tract infection are important.

PREVENTION

The application of larvicide to the rice field and insecticide spray in the community have been tried to combat JEV infection. Inactivated and live attenuated JEV vaccines have been used

Figure 3: Photograph shows marked axial and limb dystonia.

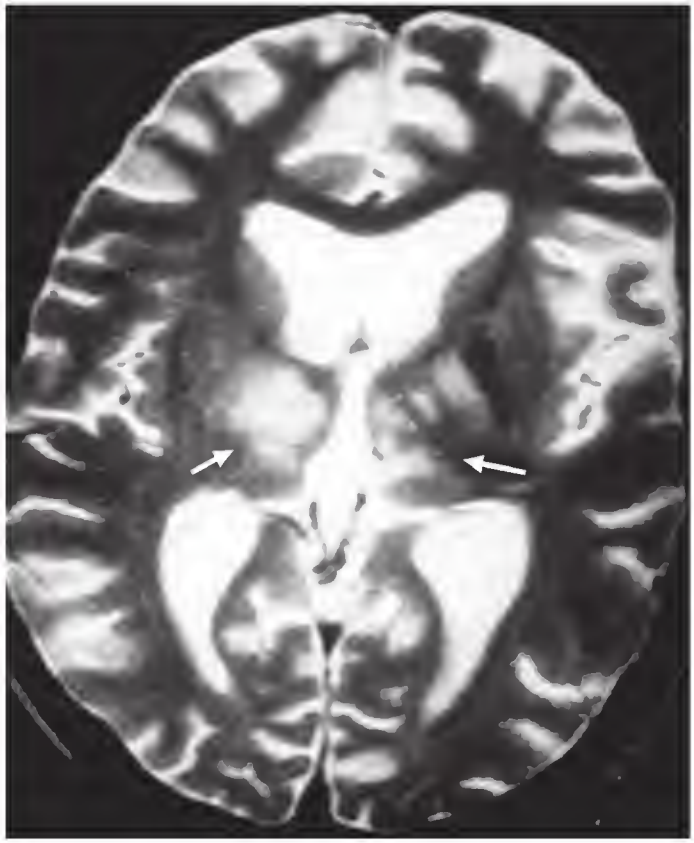

Figure 4: Characteristic cranial MRI changes on T2 sequence in Japanese encephalitis. Bilateral thalamic lesions are demonstrated (white arrows).

to protect the swine against JEV infection but is not feasible in developing countries. The residents and travellers to JE endemic areas should take personal precaution to avoid mosquito bite by minimising outdoor exposure at dusk and dawn, wearing clothing that leaves a minimum of exposed skin, using insect repellents and sleeping under bed-nets. The above mentioned measures though are possible for short term travellers but are not practical for permanent residents.

Immunisation

Immunisation is the only effective measure for long term protection against JEV infection. There are two types of JEV vaccines—formalin inactivated vaccine and live attenuated vaccine.

Purified formalin inactivated JEV vaccine: Formalin inactivated Nakayama BIKEN vaccine is produced by Osaka University and is available under the BIKEN label from 1968. Similar vaccines are prepared by various Asian countries, such as Thailand, India, Korea, China and Vietnam. Two doses may be sufficient (0.5-1 ml subcutaneously 1 to 4 weeks apart) and booster dose is recommended after 1 to 3 years. In travellers from Western countries, vaccine is recommended at 0, 7 and 30 days and a booster dose at 1 year. The protective antibodies after 3 doses are reported in 80% to 100% of recipients. Formalin inactivated JE vaccine is associated with moderate frequency of local and systemic side effects. Local tenderness, redness and swelling occur in about 20% and fever, malaise and dull headache in 10% of recipients. The neurological complications implicated due to mouse myelin basic protein in the vaccine have not been universally seen; however, encephalitis, encephalopathy, seizures and peripheral neuropathy have been reported in 1 to 2.3/million recipients.

PROGNOSIS

Approximately 20% to 40% patients with JE die during acute stage. About 50% of survivors have severe neurological sequelae. Seizures may persist in 20% and focal weakness in 30% patients. The poor prognostic predictors include extremes of age, high fever, CSF pleocytosis, deep coma, hypotonia, features of raised intracranial pressure and low level of IgG and IgM antibodies against JEV.

17.45 Rabies

Tarun Kumar Dutta, Ashish Kumar Panigrahi

INTRODUCTION

Rabies is a fatal disease of nearly worldwide distribution caused by a filterable neurotropic virus, which is present in the saliva of infected animals and transmitted to man through their infected saliva.

Urban rabies is propagated chiefly by unimmunised domestic or street dogs and cats. Street virus is the natural virus present in rabid animals. Wild-life or sylvatic type rabies is propagated by wolves, foxes, raccoons, skunks, jackals and other wild-life carriers, which are the main reservoir and transmitters of rabies. These animals maintain a cycle amongst themselves and transmit the disease to dogs and domestic animals. Man may contract rabies by intrusion into the wild-life cycle of rabies. Bat rabies occurs in certain Latin American countries where the vampire bat serves as an important host and vector for rabies. In USA, at present, insectivorous bats and wild animals are the most important vectors.

The source of infection in man is the saliva of rabid animals. Domestic dog is the cause of more than 90% of human rabies in India. Dogs also infect cats and other domestic species.

Rabies-free countries are Australia, New Zealand, Japan, Taiwan, Hong Kong, Singapore, Fiji, UK, Ireland, Norway, Sweden, Jamaica and Barbados. In India, the islands of Andaman and Lakshadweep are rabies-free.

EPIDEMIOLOGY

The true incidence is unknown due to lack of published figures. In India, the estimated mortality is 25,000 to 50,000 deaths per year. Recent figures in China showed less than 1000 cases per year. In Bangladesh, about 2000 deaths and in Nepal, about 200 deaths occur per year. Only 0.01% cases of human rabies occur in the temperate zones. On an average, two persons die of rabies, every year in USA.

AETIOPATHOGENESIS

Rabies virus is the prototype of the genus *Lyssavirus* of the large family of Rhabdoviridae. It is a bullet-shaped virus containing a single-strand of ribonucleic acid (RNA) combined with nucleoprotein, that forms a helical coil. The virus is rapidly inactivated by heat. At 56°C, half-life is less than one minute. The lipid coat is disrupted by 1% soap solution.

Humans are infected by inoculation of virus-laden saliva by the bite of a rabid dog or animal. Licking on abraded skin or mucous membrane may also result in infection. Scratching by claws can also cause infection. The virus cannot enter through intact skin. However, there are other modes of transmission also.

The rabies virus travels in the nerves and is carried centripetally by the flow of axoplasm to the dorsal root ganglion. It multiplies further in the dorsal root ganglion and causes characteristic prodromal symptoms and paraesthesiae at the site of inoculation. From there it travels to the brain, where massive viral replication occurs. Then the virus migrates along the efferent nerves to almost every organ such as adrenal medulla, cornea, pancreas, nerve twiglet of the hair follicle and salivary gland, and this leads to virus shedding in the saliva. Virus may also be shed in milk and urine.

At autopsy, widespread infection is usually found in the brain particularly in the brainstem, hippocampus and basal ganglia. Congestion of blood vessels of central nervous system (CNS) and petechial haemorrhages of the pia-arachnoid are found. Histological examination shows perivascular cellular infiltration of lymph spaces. Negri bodies can be detected within the cytoplasm of nerve cells as round or oval eosinophilic inclusion bodies, particularly in the hippocampus and Purkinje cells of the cerebellum. Negri bodies in the brain are also found in more than 95% of rabid animals.

CLINICAL FEATURES

Incubation period is usually 4 to 8 weeks but may vary from 5 days to 7 years. Face, neck and head bites which are close to the CNS have a shorter incubation period.

It may be of two types:

- Encephalitic type (Furious rabies)—observed in the majority of cases
- Paralytic type (Dumb rabies)—observed in about 20% of cases

Encephalitic Type (Furious Rabies)

The onset is usually sudden. But prodromal symptoms are noted for 2 to 3 days before the hydrophobic syndrome appears. Only a proportion of people bitten by a rabid animal develop the disease, but once manifest, the disease is almost invariably fatal. Specific prodromal features include pain, paraesthesiae and itching over the healed bite wound scar. Other features are fever, headache, tachycardia, anxiety, insomnia, restlessness and myalgias. After 2 to 3 days, the stage of excitement supervenes. There is mental excitement, restlessness, hyperaesthesia and hydrophobia. Hyodrophobia consists of sudden spasm of muscles of the mouth, pharynx, larynx and whole of the respiratory musculature, particularly the diaphragm and muscles of inspiration. The attack can be induced by offering water to patients. As the glass of water approaches the mouth, typical spasmodic jerks with violent contraction of diaphragm and other inspiratory muscles occurs and water is ejected from the mouth. Afterwards the sight and even the sound of water may provoke the distressing spasm. In the later stage a wide number of stimuli like sudden sound, strong lights and even the suggestion of water may induce the attack. Cold air or blowing of air due to fan may also induce an attack (aerophobia). The mind remains clear during the intervals. Hallucinations, delusions accompanied by biting, mania and spitting may develop later. There is malfunction of brain stem, limbic system and higher centres.

Death occurs within a week after the onset of symptoms.

Paralytic Type (Dumb Rabies)

It is characteristic of bat-transmitted rabies. It also occurs in partially vaccinated persons. Patient presents with flaccid paralysis. It resembles Guillain-Barre syndrome. The stage of excitement is absent. In a few days, paralysis may ascend to involve the respiratory muscles. There is fever and profuse sweating.

The patient has a comparatively longer survival.

Rabies in Dogs

There is no hydrophobic syndrome like man. There is change of temperament and the animal runs amok, biting wildly anything and everything in its way. There is profuse frothing and its bark is altered. The jaw drops, and general paralysis ensues.

Death occurs within five days.

DIAGNOSIS

Diagnosis is confirmed by virus isolation, identification of antigen and detection of antibodies. Virus culture is positive in the first week from saliva, throat swab, eye swab and cerebrospinal fluid (CSF).

Antigen Detection

Direct fluorescent antibody test is used to identify antigen in skin biopsies taken from the nape of the neck, where hair follicles are highly innervated. It is a sensitive test and positive results are found in 60% to 100% cases. The corneal smear test is not so sensitive and false-positive results occur.

Antibody Detection

Seroconversion occurs during the second week of illness in unvaccinated patients. Antirabies antibody detection in serum and CSF confirms the diagnosis.

Negri Body Detection

The offending animal is captured (if possible) and humanely killed for demonstration of Negri bodies in the brain. Fluorescent antigen can also be detected in the animal's brain, and confirms the diagnosis of rabies.

DIFFERENTIAL DIAGNOSIS

This includes other causes of encephalitis or bulbar paralysis (including post-vaccinial encephalomyelitis or ADEM—acute disseminated encephalomyelitis), Guillain-Barre syndrome and hysterical pseudorabies.

TREATMENT

Once symptoms develop, only palliative treatment is possible. Seizures should be controlled by heavy sedation. Diazepam 10 mg, six hourly supplemented by chlorpromazine 50 mg, if necessary can be used to control seizures. Fluid balance and nutrition must be maintained by IV route. Airway and oxygenation should be maintained. On rare occasions, partially immunised patients survive due to extensive intensive care. To date, there are six survivors of rabies including one six year old girl from India, the majority with some neurological sequelae.

PROPHYLAXIS

Rabies vaccine can be used for pre-exposure, as well as post-exposure prophylaxis. The commonly used regimen of intramuscular administration (1 mL) of vaccine is being superseded by intradermal vaccination, which requires lesser quantity of vaccine (0.1mL) and is equally effective.

Post-Exposure Prophylaxis

Post-exposure prophylaxis (PEP) is indicated for persons possibly exposed to a rabid animal. Possible exposure include animal bites or mucous membrane contamination with an infectious secretion, such as saliva. PEP should begin immediately after an exposure. Before initiating anti-rabies treatment one should establish the category of the animal bite (**Table 1**). This categorisation helps in deciding the future course of action. **Figure 1** gives an algorithmic guide for the management of rabies exposure. In addition, tetanus toxoid and proper antibiotics should be used.

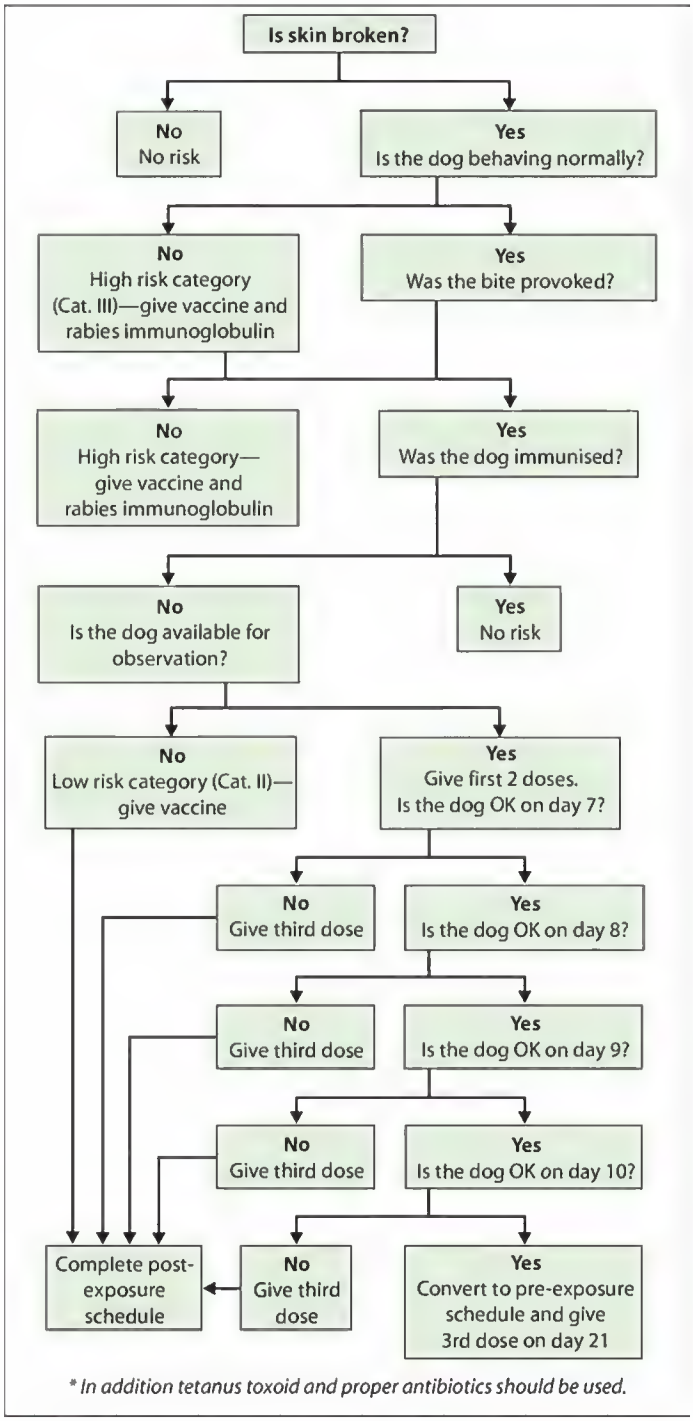

Figure 1: Management of rabies exposure.

Table 1: WHO Classification of Wound

Recommended post-exposure prophylaxis category	Type of contact with a suspect or confirmed rabid domestic or wild[a] animal, or animal unavailable for testing	Type of exposure	Recommended post-exposure prophylaxis
I	Touching or feeding of animals Licks on intact skin	None	None, if reliable case history is available
II	Nibbling of uncovered skin Minor scratches or abrasions without bleeding	Minor	Administer vaccine immediately[b] Stop treatment if animal remains healthy throughout an observation period of 10 days[c] or if animal is proven to be negative for rabies by a reliable laboratory using appropriate diagnostic techniques
III	Single or multiple transdermal bites or scratches, licks on broken skin, contamination of mucous membrane with saliva (i.e. licks), exposures to bats[d]	Severe	Administer rabies immunoglobulin and vaccine immediately. Stop treatment if animal remains healthy throughout an observation period of 10 days or if animal is found to be negative for rabies by a reliable laboratory using appropriate diagnostic techniques

[a] Exposure to rodents, rabbits and hares seldom, if ever, requires specific anti-rabies post-exposure prophylaxis.

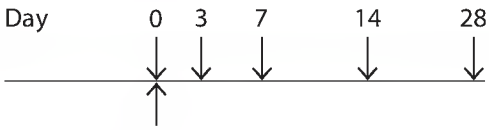
[b] If on apparently healthy dog or cat in or from a low-risk area is placed under observation, the situation may warrant delaying initiation of treatment.

[c] This observation period applies only to dogs and cats. Except in the case of threatened or endangered species, other domestic and wild animals suspected as rabid should be humanely killed and their tissues examined for the presence of rabies antigen using appropriate laboratory techniques.

[d] Post-exposure prophylaxis should be considered when contact between a human and a bat has occurred unless the exposed person can rule out a bite or scratch, or exposure to a mucous membrane.

PEP consists of a regimen of one dose of immunoglobulin (passive immunisation) and five doses of rabies vaccine over a period of 28 days. Vaccines should be given intramuscularly. Alternatively, vaccine can be given intradermally also. Human rabies immunoglobulin 20 IU/kg should be infiltrated around the wound and any remaining volume should be administered intramuscularly at an anatomical site distant from the site of vaccine administration, preferably in the gluteal region. Rabies immunoglobulin (RIG) should not be administered in the same syringe as that of the vaccine. Alternatively, equine immunoglobulin 40 IU/kg may be administered. Equine immunoglobulin is cheaper, but the incidence of serum reactions is more.

Intramuscular (IM) Regimen



There are currently four types of vaccines available, and the regimen most commonly used in India for IM administration is described below:

Vaccines:

1. Tissue Culture Vaccines
   i. Human diploid cell vaccine (HDCV): One dose—1 mL (IM)
   ii. Purified chick embryo cell vaccine (PCEC): One dose—1 mL (IM)
   iii. Purified vero cell rabies vaccine (PVRV): One dose—0.5 mL (IM)
2. Purified duck embryo vaccine (Vaxirab): One dose—1 mL (IM)

Regimen: Essen schedule (Standard WHO five dose intramuscular regimen)—the course for post-exposure prophylaxis should consist of intramuscular administration of five injections on days 0, 3, 7, 14 and 28.

Dose: one IM dose into deltoid

The sixth injection (D90) should be considered as optional and should be given to those individuals who are immunologically deficient, are at the extremes of age or on steroid therapy. Day 0 indicates date of first injection.

Site of inoculation: The deltoid region is ideal for the inoculation of these vaccines. Gluteal region is not recommended because the fat present in this region retards the absorption of antigen and hence impairs the generation of optimal immune response. In case of infants and young children, the antero-lateral part of the thigh is the preferred site.

Vaccination in special situations

Any of the cell culture vaccines is safe in pregnancy. Same dose of the vaccine, as mentioned above, is used in pregnancy, neonates and old age.

In case of re-exposure, only two doses of vaccine are required to be given, i.e. on days 0 and 3.

Previously used nerve tissue vaccine has been abandoned totally due to its serious neuro-paralytic side-effects. Its manufacture in India has been stopped since 2004.

Intradermal (ID) Regimen

Intradermal recommendation by WHO is a newer attempt to have effective antibody titres against rabies with a lower total

requirement of vaccine. The principle that allows intra-dermal vaccination to be effective at lower dose is the better response to an equal volume of antigen when placed in contact with Langerhans cells of the epidermis and use of multiple sites of vaccination at a time to obtain maximum drainage of antigen-presenting cells to lymph nodes. The intradermal regimens have had remarkable success in Thailand. However, some expertise is necessary for correct intradermal administration.

Regimen: Considering the recommendations on intra-dermal administration of rabies vaccine by WHO and reports of safety, efficacy and feasibility trials conducted in India, the Drug Controller General of India (DCGI) approved the use of reduced dose, economical intra-dermal vaccination regimen in 2006 for post-exposure prophylaxis of rabies.

The following vaccines are currently approved by DCGI for use by intradermal route:

Vaccines:

PVRV – Verorab, Aventis Pasteur (Sanofi Pasteur) India Pvt. Ltd.

PCECV – Rabipur, Chiron Behring Vaccines Pvt. Ltd.

PVRV – Pasteur Institute of India, Coonoor

PVRV – Abhayrab, Human Biologicals Institute.

DCGI has recommended the updated Thai Red Cross 2-2-2-0-2 schedule of ID vaccination, which is as follows:

Dose: one ID dose 0.1 mL

Day	0	3	7		28
ID Sites	X2	X2	X2		X2

Rabies Immunoglobulin

This involves injection of only 0.1ml of reconstituted vaccine per ID site and the vaccination has to be given at two different sites on a single visit (one on each deltoid area, an inch above the insertion of deltoid muscle) on days 0, 3, 7 and 28, using 1 ml insulin syringe. A bleb formed after injection is a sign of successful ID administration (**Figure 2**). It is best used in anti-rabies clinics for group vaccinations (minimum 10 persons at a time), because contents of a broken ampoule of 1 ml have to be used within eight hours and single person requirement on a single visit will be just 0.2 ml and rest will thus go waste.

Intra-dermal vaccination is contra-indicated in patients with immuno-compromised states or those on immunosuppressants like chloroquine or prednisolone. They should take full dose of IM injections.

Wound Treatment

Wound treatment is the most important part of treatment and should begin immediately. It minimises viral load. Thorough cleaning of all wounds with soap and water should be done immediately. A viricidal agent, such as povidone iodine 1% solution or 70% alcohol should be used to irrigate the wound. Suturing of the wound is to be avoided. Bites of rats, mice, rabbits, guinea pigs do not require anti-rabies PEP.

Figure 2: Bleb raised after intradermal inoculation.

Pre-Exposure Prophylaxis

Pre-exposure prophylaxis is recommended for persons in high risk groups, such as veterinarians, animal handlers and certain laboratory workers. Other persons whose activities bring them into frequent contact with the rabies virus or potentially rabid bats, dogs, cats, skunks and raccoons should also be considered for pre-exposure prophylaxis. Pre-exposure prophylaxis consists of three doses of rabies vaccine either intramuscularly (1 mL or 0.5 mL according to vaccine used) or intra-dermally on day 0, 7 and 21.

PROGNOSIS

The prognosis of rabies encephalomyelitis is grave. At the time of the bite, before the virus has invaded the nervous system, correct and prompt cleansing of the wound and use of proper post-exposure immunisation reduces the risk of development of rabies from 30% to 50% in untreated cases to less than 5%. The risk varies with the biting species and the site and severity of the bite. It is highest following head bites by rabid wolves. Interposition of clothing, extent of tissue laceration and immediate local treatment modify the prognosis.

17.46 Viral Gastroenteritis

Prabhash Chandra Bhattacharyya, Rupjyoti Talukdar

DEFINITION AND EPIDEMIOLOGY

Viral gastroenteritis (VGE) constitutes up to 40% of all cases of infectious diarrhoea worldwide. It is the most common disease associated with diarrhoea and vomiting in children. Four major groups of viruses are associated with VGE: rotavirus, enteric adenovirus, calcivirus (including genus norovirus and sapovirus) and astrovirus. Except for adenovirus, which contains double stranded DNA, all others are RNA viruses. Rotavirus is an enveloped virus, while the other three groups are non-enveloped. Other viruses that are infrequently associated with VGE include parvovirus B19, torovirus, coronavirus, enterovirus and picornavirus.

Rotavirus is the leading cause of VGE worldwide, particularly in children occurring in the first 2 years of life and contributes to 40% of severe gastroenteritis in children in India. Norovirus, rotavirus, astrovirus, enteric adenovirus and sapovirus infections are all endemic, although norovirus can also cause epidemics. VGE does not have a clear-cut geographic distribution, but does have a seasonal distribution. In North India, rotavirus associated diarrhoea occurs predominantly in winter while in South India it occurs all the year round. Astrovirus associated VGE is more prevalent during winters in Western India.

PATHOGENESIS

Rotavirus, norovirus, astroviruses and possibly adenovirus are transmitted by close contact via faeco-oral route. However, norovirus can also spread through contaminated food and water.

After oral inoculation, viruses infect cells of the small intestinal villi. Infection of the mature villous enterocytes of the small intestine, which have digestive and absorptive functions, lead to cell death and sloughing of the villous cells leading to villous blunting. Diarrhoea due to rotavirus infection is both osmotic and secretory due to loss of absorptive surface and opening up of calcium channels, respectively. Following infection, viruses are shed in the stool in large quantity during acute illness. Rotavirus, norovirus and astrovirus can be shed for 1 or 2 days prior to the illness and for several days after resolution. Asymptomatic infection is also common and may be the source of infection. Partial immunity due to infection in childhood is possible.

CLINICAL MANIFESTATIONS

Severity of the disease ranges from subclinical infection to mild, moderate or severe illness. The incubation period is short and the disease begins with vomiting followed by frequent watery diarrhoea without blood or mucous. Fever is seen in 50% of patients, which along with vomiting cease within 1 to 2 days; while diarrhoea often persists. Additional symptoms include malaise and abdominal cramps. The clinical profile of various types of viral gastroenteritis causing viruses and fever are presented in **Table 1**.

DIAGNOSIS

There are no diagnostic clinical features for VGE. For rotavirus, stool for enzyme immunoassay (EIA) or latex particle agglutination (LPA) are available. For adenovirus, only EIA is available and for norovirus and sapovirus, RT-PCR can be employed.

COMPLICATIONS

Dehydration, electrolyte disturbance and malabsorption can occur as complications. Rare complications, like encephalitis, myositis, polio like paralysis and sudden infant death syndrome have been reported with rotavirus infection.

TREATMENT AND PREVENTION

No definite treatment is available for VGE. After rapid assessment, fluid and electrolyte disturbance should be corrected and nutrition should be maintained. Oral rehydration with glucose and electrolyte containing solutions is usually sufficient. However, in severe cases with vomiting, dehydration and shock, intravenous rehydration may be required. Both infants and older children should be given their usual diet, including breastfeeds. Breastfeeding confers some protection against rotavirus infection. Two live attenuated oral vaccines against rotavirus have been licensed globally so far.

Table 1: Summary of Viral Gastroenteritis Caused by the Common Organisms

Feature	Rotavirus	Astrovirus	Adenovirus	Norovirus	Sapovirus
Age of illness	<5 years	<2 years	<2 years	All ages	<5 years
Incubation period	1-3 days	1-4 days	1-4 days	12-48 hours	12-48 hours
Duration of illness	2-8 days	1-5 days	3-10 days	1-5 days	1-4 days
Mode of transmission	Faeco-oral	Faeco-oral	Faeco-oral; food	Faeco-oral	Faeco-oral
Diarrhoea	Up to 10 episodes per day	Mild	Mild, prolonged	Mild	Mild
Vomiting	~ 90%	Mild	Mild	>50%	Mild
Fever	Common	Mild	Mild	Mild	Mild

17.47 Mumps

Falguni S Parikh

DEFINITION

Mumps is an acute generalised viral infection caused by mumps virus which is a paramyxovirus. The virus has a strong predilection for glandular and nervous tissue. It is characterised by non-suppurative swelling and tenderness of one or both parotid glands. The infection is readily transmissible.

EPIDEMIOLOGY

With introduction of mumps vaccine since 1967, the incidence is on the decline. Most cases occur in young adults. The infection is common in late winter and early spring. Males are more affected as compared to females. Infection in pregnancy especially in the first trimester is associated with adverse foetal outcome.

AETIOPATHOGENESIS

Mumps virus spreads from infected persons via direct contact, droplet nuclei, fomites or secretions. The transmission is greatest from before 48 hours up to 9 days of parotid swelling. Incubation period is 14 to 18 days. Virus replicates in the upper respiratory tract epithelium leading to viraemia which is followed by infection of glandular tissues and/or central nervous system.

Approximately 20% to 40% of mumps infection goes unrecognised due to subclinical infection which does not produce parotitis.

Single attack confers life-long immunity. Antibodies to mumps virus are transferred across the placenta and persist during first 2 to 3 months of life.

CLINICAL FEATURES

Although parotid involvement has been emphasised, mumps can occur without parotid swelling.

Prodromal period is characterised by low grade fever, malaise, headache and anorexia. After 1 to 2 days, parotid swelling and tenderness is often the first sign to appear. The swelling is unilateral or bilateral and persists for 4 to 5 days before decreasing. Slight redness of the orifice of Stenson's and Wharton's duct may be diagnostic.

Pre-sternal oedema may be present due to pressure on the lymphatics. Patient may experience pain whilst chewing. Sub-maxillary and sublingual glands are involved less often.

Central nervous system involvement is not uncommon and may occur 1 week before or 2 weeks after the onset of parotitis. Meningitis, encephalitis, transverse myelitis, cerebellar ataxia, Guillian-Barre syndrome (GBS) and cranial nerve involvement have been described.

Epididymo-orchitis is the most common extra-salivary gland complication of mumps. It occurs in 38% of post-pubertal men with mumps. It may be the only manifestation of mumps. Two thirds of cases develop it during first week of parotitis. Presentation is in the form of severe pain, swelling and tenderness of testes and scrotal erythema. Sterility is rare.

Pancreatitis, oophoritis, arthritis, myocarditis, hepatitis, thyroiditis and dacryocystitis are some of the rare complications of mumps.

DIAGNOSIS

History of exposure, constitutional symptoms, and parotid tenderness in presence of serologic confirmation or isolation of mumps virus is diagnostic of mumps.

Influenza, parainfluenza, coxsackie, HIV and cytomegalovirus infections can cause parotid enlargement. Tumours, sarcoidosis, Mikulicz syndrome and stone in the Stenson's duct are some of the non-infectious causes of parotid enlargement. Mumps virus can be isolated from throat swabs and cerebrospinal fluid. Infection can be confirmed by rising antibody titres in paired sera by complement fixation, haemagglutination inhibition or ELISA test. Serum amylase levels are elevated in mumps parotitis and pancreatitis.

TREATMENT AND PROGNOSIS

Supportive treatment in the form of adequate hydration, nutrition, analgesics and anti-pyretics is advocated. Bitter and acidic foods are best avoided. Most patients recover completely. Deafness and sterility are rare complications.

PREVENTION

Attenuated live mumps vaccine is given in combination with Measles and Rubella as MMR Vaccine at 12 to 15 months and 4 to 6 years of age. Seroconversion rate is 98% to 100%.

It is contraindicated in pregnant women and immuno-suppressed individuals. Patients with asymptomatic HIV infection without immunosuppresion can receive MMR vaccine.

The second dose of MMR vaccine is to protect children failing to seroconvert against primarily mumps and less commonly against rubella.

Vaccination with two doses of the vaccine should be given to all those not previously immunised (with no upward age limit) and especially to health care workers, adolescent girls and students travelling for studies overseas.

The burden of mumps has been reduced in developed countries following the use of MMR vaccine. Outbreaks have been noted in previously vaccinated populations and hence two doses are needed for durable protection. There is no causal relationship between MMR vaccine and autism, inflammatory bowel disease and Guillain-Barre syndrome.

17.48 Measles (Rubeola)

RK Goyal, Prashant Mathur

DEFINITION

Measles (Rubeola) is a highly contagious, acute respiratory viral disease with a characteristic clinical picture, rash and a pathognomonic enanthem Koplik's spot.

Measles is uncommon in most developed countries where measles vaccine is used, but contributes to significant childhood morbidity and mortality in developing countries.

EPIDEMIOLOGY

Measles has a worldwide distribution. Human beings are the only natural hosts. Before availability of live attenuated measles vaccine, the epidemics were common. It is transmitted by direct contact with respiratory secretions, mainly through exposure to aerosols and infectious droplets. Patients are contagious from 1 or 2 days before onset of symptoms (3 to 5 days before onset of rash) and up to 4 days after the rash appears. The infectivity is maximum during the prodromal phase. The mean intervals from infection to onset of symptoms and appearance of rash are about 10 and 14 days respectively.

The mortality rates are highest among children below 2 years of age. Approximately 3,50,000 childhood death occur due to measles; out of these 80,000 are accounted by India. In adults with impaired cell mediated immunity (immunocompromised patients), mortality is high.

AETIOPATHOGENESIS

Measles virus is a RNA virus which belongs to the genus *Morbillivirus* of *Paramyxoviridae* family. The viruses are pleomorphic spheres with a diameter of 100 to 250 nm having inner capsid and outer envelope.

Measles virus invades the respiratory epithelium and spreads via the blood stream (viraemia) to the reticuloendothelial system and white blood cells, especially monocytes.

The respiratory and lymphoid tissues have pathognomonic multinucleated giant cells with inclusion bodies in the nucleus and cytoplasm (Warthin-Finkeldey cells). There is transient depression of cellular immunity with direct invasion of T lymphocytes and increased levels of suppressive cytokines (e.g. interleukin-4) which accounts for high-risk for severe measles in some patients. Infection of the entire respiratory tract produces generalised damage with loss of cilia and predisposition to secondary bacterial infection with characteristic cough, coryza, bronchiolitis and pneumonia.

The immune reaction of measles virus in the endothelial cells of cutaneous capillaries accounts for pathognomonic Koplik's spots and cutaneous rash. Pathologic changes in measles encephalitis include focal haemorrhage, congestion and perivascular demyelination.

CLINICAL FEATURES

The prodromal phase (2 to 4 days) is most infectious. The catarrhal stage with upper respiratory symptoms like cough, coryza, conjunctivitis with lacrimation, nasal discharge, increasing high grade fever is present before appearance of rash.

The pathognomonic enanthem Koplik's spots appear as 1-2 mm blue-white spots on a bright red background, typically located on the internal buccal mucosa alongside second molar. Koplik's spots may spread to involve lips, hard palate and gingiva. They may also occur in conjunctival folds and in the vaginal mucosa. The spots usually disappear after onset of rash.

The characteristic maculopapular, erythematous rash begins at the hairline on forehead and behind the ears, spreading down to trunk and limbs including soles and palms. By the fourth day, fever and rash begin to fade with desquamation and brownish discolouration of skin. The other features include diarrhoea, vomiting, splenomegaly and generalised lymphadenopathy due to involvement of reticuloendothelial cells. The entire illness usually lasts for about 10 days.

Milder forms of the illness with less intense symptoms and milder rash termed as modified measles may occur in individuals with pre-existing partial immunity induced by active or passive vaccination or in infants less than one year of age having passively acquired maternal antibodies.

Children who had received the original formalin inactivated measles vaccine at times develop a more severe form of disease called atypical measles with high fever and headache followed by appearance of a maculopapular rash on the extremities that become petechial and purpuric and progress in a centripetal direction. The illness is frequently complicated by pneumonia and pleural effusion. The cause of atypical measles may be formation of immune complexes due to an abnormal immune response to vaccine.

COMPLICATIONS

Respiratory

The manifestations are due to generalised involvement of respiratory tract and include laryngitis, croup, otitis media, bronchitis, bronchiolitis, bronchopneumonia (giant cell pneumonia) and secondary bacterial infections.

Central Nervous System

Acute measles encephalitis-mild to severe/fatal may present with fever, headache, drowsiness, coma and/or seizures resulting from an immune mediated response to myelin proteins (post-infectious encephalomyelitis). Rarely transverse myelitis follows measles. Subacute sclerosing panencephalitis (SSPE) results from a persistent infection with an altered measles virus that is

harboured intra-cellularly in the central nervous system for several years. It begins insidiously 7 to 13 years after primary measles infection with permanent sequelae (mental retardation, progressive dementia and seizures). Prognosis is usually fatal.

Gastrointestinal System

Gastroenteritis, hepatitis, appendicitis, ileocolitis and mesenteric adenitis.

Rare Complications

Myocarditis, glomerulonephritis, post-infectious thrombocytopenic purpura and exacerbation of pre-existing tuberculosis. In immunocompromised patients with decreased cell mediated immunity, e.g. patients with congenital cellular immune defects, recipients of immunosuppressive therapy, malignancy, infection with HIV, may have severe protracted and fatal measles.

Measles in Adults

Measles is a disease of childhood and like many other viral infections, it is more severe in adults than children. Primary viral pneumonia with severe bronchospasm, confluent rashes, hepatitis with bacterial superinfection are the predominant features of measles in adults.

LABORATORY FINDINGS

Lymphopaenia and neutropaenia are common which may be due to invasion of leucocytes by the virus with subsequent cell death. Presence of leucocytosis heralds bacterial superinfection.

DIAGNOSIS

It is primarily clinical. A specific diagnosis can be made by staining a smear of respiratory secretions. Measles virus can be demonstrated by culture or detected by polymerase chain reaction (PCR). Specific IgM antibodies are detectable within 1 to 2 days after onset of rash and the titre of IgG antibodies rises significantly after 10 days.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of measles includes other exanthematous fevers, scarlet fever, infectious mononucleosis, drug eruption, pneumonias and Kawasaki syndrome.

MANAGEMENT

It is largely supportive and symptomatic, like tepid sponging and antipyretics. Antibiotic therapy should be given only for complications like pneumonia, otitis media, etc. No specific antiviral treatment is available. WHO recommends high dose of vitamin A to all children with measles in developing countries, especially with malnutrition. The doses are 50,000 IU for infants 1 to 6 months, 100,000 IU for infants 7 to 12 months and 200,000 IU for children over one year.

PREVENTION

Measles is rapidly transmitted in large families, crowded and urban slums. Proper hygiene of mouth, eyes and skin prevents infection. Without immunisation, every child is prone to get measles. Two types of vaccines are available: (a) measles vaccine, (b) MMR vaccine.

Measles Vaccine

It is a live attenuated vaccine. Indian vaccines are usually formulated from the Edmonston-Zagreb strain grown on human diploid cells or purified chick embryo cells. The dose is 0.5 mL sub cutaneously or intra-muscularly preferably over upper arm or anterolateral aspect of thigh. Appropriate age for vaccination is completed nine months of age. Administration of vaccine within two days of exposure protects or modifies the severity of clinical illness. The vaccine may be given along with all vaccines except BCG vaccine.

The adverse effects reported are local pain and tenderness, mild measles like illness (7 to 12 days after vaccination), thrombocytopaenic purpura, etc.

Measles vaccine is contraindicated in severely immunocompromised, in those with history of severe allergic reactions and in pregnancy. It may be safely given to those with history of egg allergy.

MMR (Measles, Mumps, Rubella) Vaccine

Two doses are recommended: one at the age of 12 to 15 months and second at school entry (4 to 6 years) or at any time 4 to 8 weeks after the first dose.

Post-Exposure Prophylaxis

Susceptible children and adults who are exposed to the disease should receive post-exposure prophylaxis with immune globulin (0.25 mL/kg for healthy persons and 0.5 mL/kg for immunocompromised patients) given intra-muscularly.

RECOMMENDED READINGS

17.49 Smallpox

Ramesh Balwant Pandit

HISTORY

In 1796, Edward Jenner developed smallpox vaccine from material of cowpox lesion (same family as Variola). Current formulation of smallpox vaccine is a live virus preparation of infectious vaccinia virus. Routine childhood vaccination was discontinued in USA in 1972 and in most European countries in 1970. Vaccination is now primarily recommended for laboratory workers and for army personnel. In December 1979, WHO certified that smallpox is eradicated globally. Smallpox is the only human infectious disease eradicated and certified so by WHO.

AETIOPATHOGENESIS

Smallpox is caused by variola virus (Genus: *Orthopox virus*). Two types, variola major and variola minor are responsible. Infection is man to man, through droplet. Virus enters respiratory tract causing viraemia in 10 to 12 days, lesions localise in small blood vessels of skin, mouth, throat, etc. Incubation period is around 12 days. There are 4 types of variola major infection based on Rao's classification. Infections with variola minor are milder in nature.

CLINICAL FEATURES

Prodromal phase is with fever and malaise like in any other viral fever lasting 4 to 5 days. By 12 to 15 days rash develops on the skin and mucous membrane (macules on skin). Rashes are mainly on face, trunk and proximal portions of extremities and lastly on distal portion of extremities including palms. Rash develops within 24 to 36 hours. Ordinary type of infection is the most common seen in unvaccinated persons. The skin rash becomes papules and later on by 3rd or 4th day it becomes umbilicated postules filled with tissue debris. By 2nd week pustules deflate and scabbing occurs causing scars. Other types of smallpox are modified, haemorrhagic and malignant variety.

DIAGNOSIS

Light microscopy and electron microscopy demonstrate viral particles in vesicular fluid. Cytoplasmic inclusions known as Guarnieri bodies are identified in skin lesions.

DIFFERENTIAL DIAGNOSIS

The typical centrifugal distribution of umbilicated eruptions at one time with severe toxic illness helps to distinguish smallpox from chickenpox. Palms are spared from rash in chickenpox (**Figure 1**).

COMPLICATIONS

Commonly seen complications are secondary infections, toxaemia, eye complications due to corneal ulceration, bronchopneumonia, post-infective encephalitis and osteomyelitis.

PREVENTION

Primary vaccination confers full immunity to smallpox. If vaccinated within 4 days of exposure, smallpox can be prevented, or its severity reduced. Recently, syndrome of myopericarditis has been described in vaccinated persons. Post-vaccination encephalitis is rarely seen.

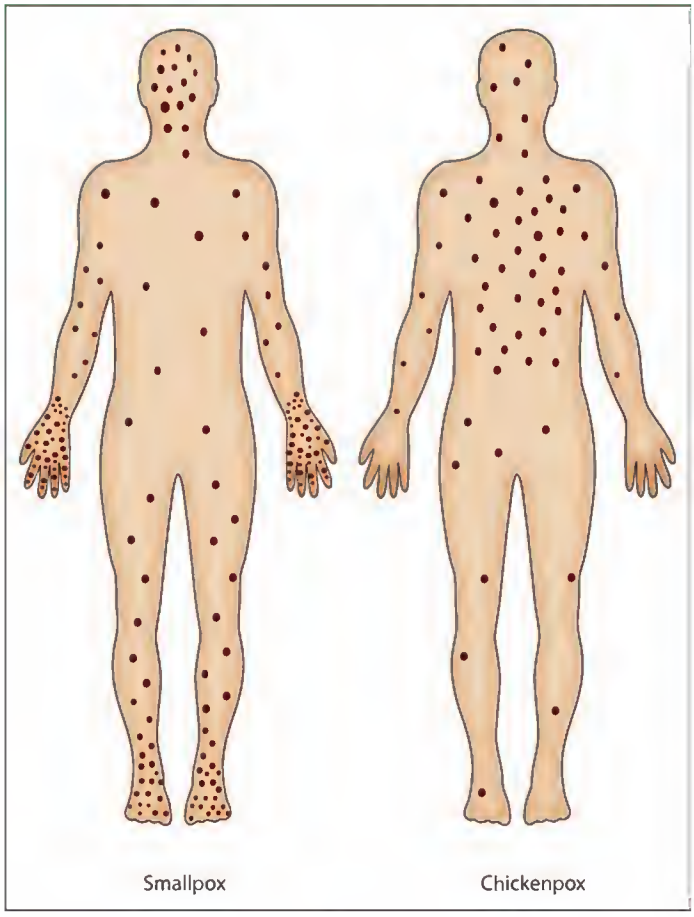

Figure 1: Distribution of skin rash in smallpox and chickenpox.

PROGNOSIS

The overall case fatality rate for ordinary type smallpox is about 30% but varies by pock distribution. Malignant and haemorrhagic types of smallpox are highly fatal.

TREATMENT

There is no specific treatment for smallpox. Suspected cases should be handled with strict isolation procedure. Treatment is mainly supportive (e.g. IV fluids, acetaminophen for fever and pain). Several anti-viral agents, including cidofovir, used in other viral fevers have *in vitro* activity against variola major. Vaccinia immune globulin has no benefit in patients with clinical smallpox cases.

RECOMMENDED READINGS

17.50 Lymphocytic Choriomeningitis and Other Arena Virus Infections

Deepti Vibha, Garima Shukla

INTRODUCTION

Lymphocytic choriomeningitis (LCM) is a rodent borne viral infectious disease that presents as aseptic meningitis, encephalitis or meningoencephalitis in Europe, the Americas, Australia and Japan. The causative agent is lymphocytic choriomeningitis virus (LCMV), which was the first of the arenavirus family isolated in 1933 during an epidemic of St Louis encephalitis. Other viruses of this family are Lassa virus (causing Lassa fever in Africa), Junin, Machupo, Guanirato and Sabia virus (all causing haemorrhagic fever in parts of South America). No case reports exist from India.

AETIOPATHOGENESIS

LCMV is transmitted from the common house mouse (*Mus musculus*) to humans by aerosols of excreta and secretions. It is maintained in the mouse mainly by vertical transmission from infected female mouse. The vertically infected mouse remains viremic for life, with high concentrations of virus in all tissues. Infected colonies of pet hamsters have also served as a link to humans. Individuals become infected with LCMV after exposure to fresh urine, droppings, saliva, or nesting materials. Transmission can also occur when these materials are directly introduced into broken skin, the nose, the eyes or the mouth or presumably, via the bite of an infected rodent. Person-to-person transmission has not been reported, with the exception of vertical transmission from infected mother to foetus. Recent investigations indicate that organ transplantation may also be a means of transmission. Patients with LCM may have a history of residence in rodent-infested housing or other exposure to rodents. An antibody prevalence of approximately 5-10% has been reported among adults from the United States, Argentina and endemic areas of Germany.

CLINICAL MANIFESTATIONS

LCM presents with gradual fever and myalgia. Other symptoms are orchitis, transient alopaecia, arthritis, pharyngitis, cough and maculopapular rash. Less than 25% patients experience a febrile phase of 3 to 6 days with transient remission followed by recurrence of fever with severe headache, nausea and vomiting, and meningeal signs lasting for approximately 1 week. These patients virtually always recover fully, as do the uncommon patients with clear-cut signs of encephalitis. Recovery may be delayed by transient hydrocephalus.

In pregnant women, LCM virus infection may lead to foetal invasion with consequent congenital hydrocephalus and chorioretinitis. Since the maternal infection may be mild, consisting of only a short febrile illness, antibodies to the virus should be sought in both the mother and the fetus in suspicious circumstances, particularly TORCH-negative neonatal hydrocephalus.

DIAGNOSIS

During the initial febrile phase, leucopaenia and thrombocytopaenia are common and virus can usually be isolated from blood. In cases of aseptic meningitis, any of the following should suggest a suspicion of LCM: well-marked febrile prodrome, adult age, autumn seasonality, low cerebrospinal fluid (CSF) glucose levels, or CSF mononuclear cell counts of >1000/L.

The IgM-capture ELISA of serum and CSF is usually positive; RT-PCR assays have been developed for application to CSF. Recent infections transmitted by organ transplantation did not include evidence of an immune response, followed a fulminant course, and required immunohistochemistry or RT-PCR for diagnosis.

COMPLICATIONS AND MORTALITY

No chronic infection has been described in humans. Nerve deafness and arthritis have been reported. Infection of the human foetus during the early stages of pregnancy may lead to developmental deficits that are permanent. Mortality is less than 1% except in transplant recipients where high mortality has been reported.

TREATMENT

The patients require hospitalisation and supportive care, based on the severity of symptoms. Although studies have shown that ribavirin, a drug used to treat several other viral diseases, is effective against LCMV *in vitro*, there is no established evidence to support its routine use for treatment of LCM in humans.

17.51 Prion Diseases

PK Maheshwari, A Pandey

DEFINITION

Prion diseases are a group of relentlessly progressive and fatal human and animal neuro-degenerative conditions associated with the deposition of abnormal prion protein (PrP) in the brain. The most common human form is Creutzfeldt-Jakob disease (CJD), a syndrome that can be manifested as a genetic, infectious (including 'variant'), or sporadic disorder.

EPIDEMIOLOGY

CJD is found throughout the world. The annual incidence of CJD is approximately one per million.

CLASSIFICATION

Human Prion Diseases

- Creutzfeldt-Jakob disease (CJD)
- Variant Creutzfeldt-Jakob disease (vCJD)
- Gerstmann-Straussler-Scheinker syndrome
- Fatal familial insomnia
- Kuru

PATHOGENESIS

The term 'prion' derives from proteinaceous infectious particle. Moreover, the hallmark of all prion diseases, whether sporadic, dominantly inherited, or acquired by infection, is that they involve the aberrant metabolism of PrP. In humans, the PrP gene is designated PRNP and is located on the short arm of chromosome 20.

CLINICAL MANIFESTATIONS

Subacute Spongiform Encephalopathy (Creutzfeldt-Jakob Disease) (See Also Neuropathy)

The classic diagnostic triad of sporadic CJD is rapidly progressive multi-domain dementia, myoclonus, and a characteristic periodic electroencephalogram (EEG). Diffuse myoclonic jerks are seen in 80% of cases. It is asymmetrical, arrhythmic, asynchronous, and sensitive to stimuli; and most frequently found in the limbs. Additional features include cerebellar ataxia, extra-pyramidal signs, pyramidal involvement, and cortical blindness.

DIAGNOSIS

Routine blood test results are usually normal. Cerebrospinal fluid (CSF) characteristically lacks a pleocytosis or fall in glucose, but an elevated protein level (only very rarely greater than 100 mg/dL) occurs in about 40% of cases.

The only specific diagnostic tests are measurement of PrPSc by conformation-dependent immunoassay (CDI). The CDI is extremely sensitive and quantitative and can be applied in both the post- and ante-mortem detection of prions.

EEG shows typical pattern of repetitive, high-voltage, triphasic, and polyphasic sharp discharges of less than 200 ms duration, occurring every 1 to 2 seconds, seen in 60% of cases.

CT head may be normal or show cortical atrophy. MRI is valuable. On FLAIR sequences and diffusion-weighted imaging, ~90% of patients show increased intensity in the basal ganglia and cortical ribboning.

Brain, tonsillar, and olfactory mucosal biopsy can demonstrate spongiform changes.

DIFFERENTIAL DIAGNOSIS

Many conditions may mimic CJD superficially.

1. Dementia with Lewy bodies: Absence of abnormalities on diffusion-weighted and FLAIR MRI distinguishes from CJD.
2. Hashimoto's encephalopathy is diagnosed by the finding of high titers of anti-thyroglobulin or anti-thyroid peroxidase antibodies in the blood and improves with glucocorticoid therapy.
3. Intracranial vasculitides: Prominent headache, absence of myoclonus, and focal white matter changes on MRI or angiographic abnormalities favour vasculitis.
4. Paraneoplastic conditions: Detection of the paraneoplastic antibodies is the only way to distinguish these from CJD.
5. Other conditions include neurosyphilis, AIDS dementia complex, progressive multifocal leucoencephalopathy, subacute sclerosing panencephalitis, progressive rubella panencephalitis, herpes simplex encephalitis, diffuse intracranial tumour, anoxic encephalopathy, dialysis dementia, uraemia, hepatic encephalopathy, and lithium or bismuth intoxication can simulate CJD.

TREATMENT

Currently there is no available treatment. All forms of prion diseases are ultimately fatal. Treatment approaches, directed to arrest or reverse the detrimentatal secondary structures of protein are under investigation. Another approach is immunological. The ultimate goal of these studies is to produce a vaccine or compound using peptidomimetic technology that would interact with the PrP^{sc} molecule to prevent its multiplication.

17.52 Malaria

AK Agarwal, Sarit Chatterjee

Malaria is the most important parasitic disease of humans and is caused by protozoa of the genus *Plasmodium*. The malarial parasite is transmitted by the mosquito vector of the *Anopheles* family. Although primarily a disease of the tropics, it is transmitted in 107 countries (eliminated from the United States, Canada, Europe, and Russia) causing 1 to 3 million deaths each year.

AETIOLOGY

More than 200 species of the genus *Plasmodium* are known. Only ten cause human infection. Five species cause nearly all malarial infections in humans. These are *P. falciparum*, *P. vivax*, *P. ovale*, *P. malariae* and *P. knowlesi*. Human infection begins when a female anopheline mosquito inoculates plasmodial sporozoites from its salivary gland during a blood meal. Rarely, malaria may be transmitted by a blood transfusion, needle sharing, organ transplant or vertically from mother to foetus.

EPIDEMIOLOGY

Malaria occurs mostly in the tropics. India harbours both *P. vivax* (50% to 55%) and *P. falciparum* (45% to 50%) and contributes 70% of malarial cases in the South East Asian region. *P. falciparum* predominates in Africa, New Guineas, and Haiti; *P. vivax* is more common in Central America. The prevalence of these two species is approximately equal in South America, the Indian subcontinent, Eastern Asia, and Oceania. *P. malariae* and *P. ovale* are unusual outside Africa. The true burden of malaria in India is difficult to ascertain. There are an estimated 70 to 100 million cases each year, but only 1.6 to 1.8 million cases are reported by the National Vector Borne Disease Control Programme (NVBDCP). The state-wise distribution of malaria in India is shown in **Figure 1**.

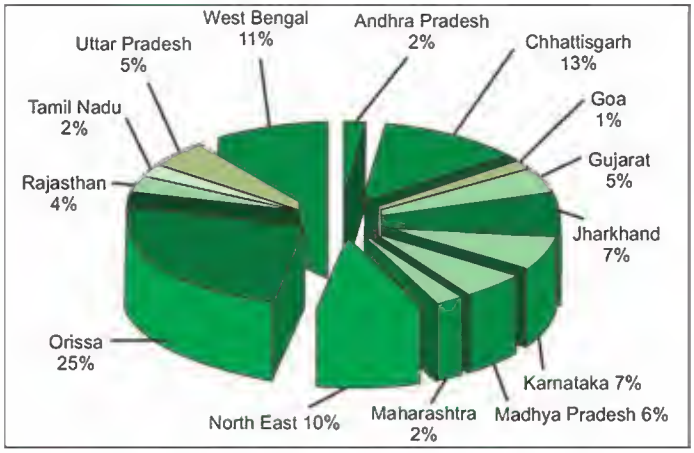

Figure 1: State-wise distribution of malaria cases in India.

Endemicity (parasitaemia rates or palpable-spleen rates in children 2 to 9 years of age) has been defined as hypoendemic (<10%), mesoendemic (11% to 50%), hyperendemic (51% to 75%), and holoendemic (>75%). With constant, frequent, year-round infection (stable transmission) adults develop immunity to severe disease. In hypoendemic areas, where transmission is low, full protective immunity is not acquired and symptomatic disease may occur at all ages (unstable transmission). In areas with unstable transmission, such as northern India, malaria behaves like an epidemic disease. To transmit malaria, the mosquito must survive for more than 7 days. In general, at altitudes above 1,000 meters and at temperatures below 16°-18°C transmission does not occur. A comparison between malaria endemicity in India in 1948 and 2004 is shown graphically in **Figure 2**.

PATHOGENESIS

The sporozoites, upon reaching the liver, begin asexual reproduction (pre-erythrocytic schizogony or merogony) and a single sporozoite produces 10,000 to >30,000 daughter merozoites. The swollen liver cell bursts and discharges merozoites into the bloodstream. These invade the red blood cells (RBCs) and multiply six- to twenty fold every 48 to 72 hour. The RBC then ruptures to release 6 to 30 daughter merozoites, each potentially capable of invading a new RBC and repeating the cycle. After a series of asexual cycles, some of the parasites develop into sexual forms (gametocytes) that can transmit malaria.

In *P. vivax* and *P. ovale* infections, a proportion of the intrahepatic sporozoites may remain dormant as hypnozoites for three weeks to a year and cause relapses.

Erythrocyte Changes in Malaria

Within the erythrocyte, haem is detoxified to haemozoin (malaria pigment). The RBC becomes more irregular in shape and less deformable.

Cytoadherence, rosetting, and agglutination leading to sequestration of RBCs are central to the pathogenesis of falciparum malaria. Membrane protuberances (knobs) appear which extrude an adhesive protein PfEMP1 (*P. falciparum*–specific, erythrocyte membrane protein 1) promoting cytoadherence. Moreover, these infected RBCs also adhere to uninfected RBCs (to form rosettes) and to other parasitised erythrocytes (agglutination). This results in the sequestration of RBCs containing mature forms of the parasite in vital organs (especially the brain), where they interfere with microcirculatory flow and metabolism. Therefore, only the younger ring forms are seen in the peripheral blood leading to under estimation of the true level of parasitaemia.

In other forms of malaria, sequestration does not occur and all stages are seen on peripheral smears. *P. vivax* and *P. ovale* show a marked predilection for young RBCs, while *P. malariae* prefer old cells. They produce a level of parasitaemia that is seldom more than 2%. *P. falciparum* invades erythrocytes of all ages and may be associated with very high levels of parasitaemia.

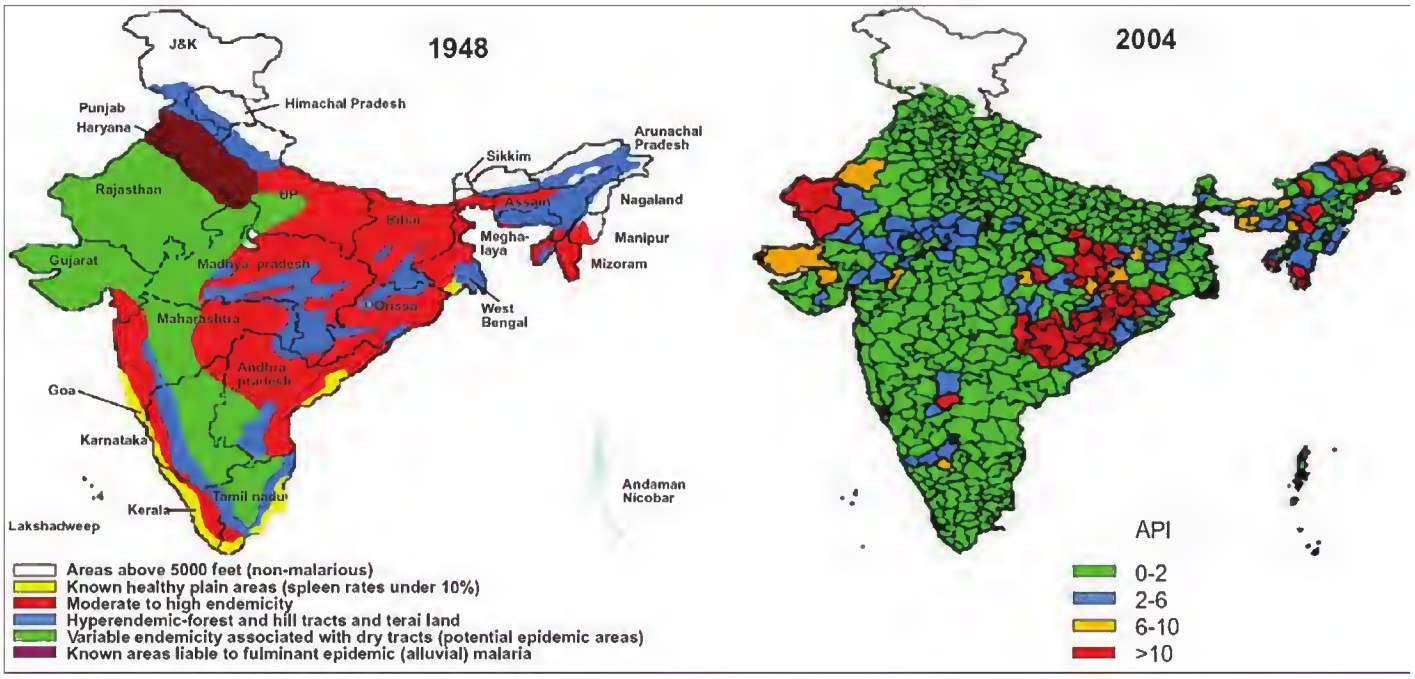

Figure 2: Malaria endemicity in India.

Source: World Health Organisation Regional Office for South-East Asia. Malaria situation in SEAR countries, India. Available at the URL: http://www.searo.who.int/Linkfiles/Malaria_in_the_SEAR_MalEndemicity_india.pdf.

API = Annual parasite incidence (a malariometric index to express malaria cases per thousand population).

Host Response

Splenic removal of both parasitised and uninfected erythrocytes is accelerated. The ruptured schizont releases cytokines causing fever. Synchronisation of the parasitic cycle eventually produces the regular fever spikes and rigors. These regular fever patterns (tertian, every two days; quartan, every three days) are seldom seen today in patients who receive prompt and effective antimalarial treatment.

Sickle cell disease, ovalocytosis, thalassaemia, haemoglobin C and glucose-6-phosphate dehydrogenase (G6PD) deficiency confer protection against death from falciparum malaria. West Africans lacking RBC Duffy antigen and individuals with haemoglobin E are refractory to infection by *P. vivax*.

Repeated exposure confers protection from disease, but not from infection. Immunity is both species and strain specific. Both humoral immunity and cellular immunity are necessary for protection.

CLINICAL FEATURES

Uncomplicated Malaria

Malaria begins with nonspecific symptoms like headache, fatigue, abdominal discomfort, and muscle aches followed by fever; but there is no neck stiffness or photophobia. Nausea, vomiting and orthostatic hypotension are common. The classic malarial paroxysms (fever spikes, chills, and rigors at regular intervals), are common in infection with *P. vivax* or *P. ovale*. The fever often rises above 40°C with tachycardia and delirium. Generalised seizures are specifically associated with falciparum malaria and may herald the onset of cerebral disease. Slight enlargement of the liver and a palpable spleen are common. Mild jaundice is common in patients with otherwise uncomplicated falciparum malaria and usually resolves over one to three weeks.

Severe Malaria

Severe malaria is a medical emergency. Unlike *P. falciparum*, *P. vivax* rarely causes severe disease in healthy travellers or in temperate endemic regions and has been regarded as readily treatable with chloroquine. However, in tropics recent reports have highlighted severe and fatal disease associated with *P. vivax* infection. Studies from Indonesia, Papua New Guinea, Thailand and India have shown that 21% to 27% of patients with severe malaria have *P. vivax* monoinfection. The clinical spectrum of these cases is broad with an overall mortality of 0.8% to 1.6%. Major manifestations include severe anaemia and respiratory distress with infants being particularly vulnerable. Other features observed were hepatic dysfunction and jaundice, renal failure, shock, cerebral malaria, thrombocytopaenia and hypoglycaemia. However, it has been observed that in the majority of cases where *P. vivax* was initially attributed as the cause of severe disease, concurrent mixed infection with *P. falciparum* was identified. A laborious search for *P. falciparum* even after an initial *P. vivax* positive report is of great value. A nested PCR when available can be very useful in detection of the causal species.

Clinical features of severe malaria are presented in **Table 1**. Poor prognostic features in severe falciparum malaria are shown in **Table 2**.

Cerebral Malaria

Cerebral malaria is characterised by a deep unarousable coma with a Glasgow coma scale (GCS) less than 7/15 with an onset which may be gradual or sudden following a convulsion. The eyes may remain open (coma vigil) (**Figure 3A**). It carries a mortality of >20%.

Table 1: Manifestations of Severe Falciparum Malaria

Signs	Manifestations
Cerebral malaria	Unarousable coma, coma persisting for >30 min after generalised convulsions
Jaundice	Serum bilirubin level of ≥3.0 mg/dL
Renal failure	Urine output <400 mL/24 hrs; serum creatinine >3.0 mg/dL
Acidosis	Arterial pH <7.25 or plasma bicarbonate level of <15 mmol/L
Severe anaemia	Haematocrit of <15% or haemoglobin level of <5 g/dL
Pulmonary oedema/ adult respiratory distress syndrome	Non-cardiogenic pulmonary oedema, often aggravated by overhydration
Hypoglycaemia	Plasma glucose level of <40 mg/dL
Hypotension/shock	Systolic blood pressure of <80 mm Hg in adults; core/skin temperature difference of >10°C; capillary refill >2 s
Bleeding/ disseminated intravascular coagulation	Significant bleeding and haemorrhage from the gums, nose, and gastrointestinal tract and/or evidence of disseminated intravascular coagulation
Convulsions	More than two generalised seizures in 24 hours
Haemoglobinuria	Macroscopic black, brown, or red urine (*should not be associated with G6PD deficiency*)
Hyperparasitaemia	Parasitaemia level of >5%

Table 2: Features Indicating a Poor Prognosis in Severe Falciparum Malaria

Clinical	Marked agitation, deep coma, absent corneal reflexes, decerebrate/decorticate rigidity, opisthotonus, papilloedema, respiratory distress (acidosis), hypothermia (<36.5°C), bleeding, repeated convulsions, anuria, shock.
Biochemistry	Hypoglycaemia (<40 mg/dL), acidosis (arterial pH <7.3, serum HCO_3 <15 mmol/L), serum creatinine (>3 mg/dL), total bilirubin (>3 mg/dL), elevated liver enzymes (AST/ALT>3 times the upper limit of normal), elevated muscle enzymes (CPK, myoglobin), high CSF lactate >6 mmol/L, low CSF glucose, venous lactate >5 mmol/L, elevated plasma 5'nucleotidase, low antithrombin III levels, very high plasma tumour necrosis factor (TNF).
Haematology	Leucocytosis (>12,000/µL), severe anaemia (PCV <15%, haemoglobin <5 g/dl), coagulopathy, decreased platelet count (<50,000/µL), prolonged prothrombin time (>3 s), prolonged partial thromboplastin time, decreased fibrinogen (<200 mg/dL).
Parasitology	Increased mortality at >100,000/µL, high mortality at >500,000/µL, >20% mature pigmented parasites, >5% of neutrophils with visible pigment.

It clinically manifests as a diffuse symmetric encephalopathy without focal neurological or meningeal signs. Retinal haemorrhages, papilloedema and cotton wool spots may be evident on ophthalmoscopy. Convulsions (usually generalised and multiple) are common. Patients surviving cerebral malaria (especially children) may have neurologic sequelae.

Figure 3A: Clinical photograph of a patient lying in coma due to severe complicated malaria. The eyes are open even though the patient is in unarousable coma suggestive of a vigil-like state. When a patient is in coma-vigil, assessment of the eye signs in the Glasgow coma scale becomes difficult.

Hypoglycaemia

Hypoglycaemia results from failure of hepatic gluconeogenesis and increased consumption of glucose by both the host and the malarial parasites. Moreover, quinine and quinidine are powerful insulin secretagogues and compound the problem. Hypoglycaemia can be a significant problem in children and pregnant women.

Acidosis

Lactic acidosis results from anaerobic glycolysis in tissues, hypovolaemia, lactate production by the parasites and a failure of hepatic and renal lactate clearance. In children, ketoacidosis may also be present. The prognosis of severe acidosis is poor.

Non-cardiogenic pulmonary oedema

The pathogenesis of non-cardiogenic pulmonary oedema is unclear. The mortality rate is more than 80%. This condition can be aggravated by over-vigorous administration of IV fluids.

Renal impairment

Renal impairment manifests as acute tubular necrosis and is the result of erythrocyte sequestration interfering with renal microcirculatory flow and metabolism. Early dialysis enhances the likelihood of a patient's survival.

Haematologic abnormalities

Anaemia results from accelerated RBC removal by the spleen, obligatory RBC destruction during parasite schizogony and ineffective erythropoiesis. Mild coagulation abnormalities and mild thrombocytopaenia are usual in falciparum malaria. Significant bleeding due to disseminated intravascular coagulation is uncommon.

Liver dysfunction

Mild haemolytic jaundice is common in malaria. Severe jaundice in severe falciparum malaria results from haemolysis, hepatocyte injury, and cholestasis and is usually associated with manifestations of acute renal failure (ARF). This association is a common clinical presentation of severe and complicated falciparum malaria.

Other complications

Sepsis, especially due to *Salmonella* bacteraemia has been specifically associated with *P. falciparum* infections. Aspiration pneumonia and catheter-induced urinary tract infections are not uncommon. Haemoglobinuria may occasionally be a manifestation of severe malaria in patients with massive intravascular haemolysis (**Figure 3B**).

Figure 3B: Cola coloured urine in a patient with severe malaria with haemoglobinuria.

Sequelae: Post-Malaria Neurological Syndrome (PMNS)

Rarely, adults (<3%) and children (>10%) suffer from a syndrome of neurological and psychiatric symptoms within two months after treatment of malaria (PMNS). Psychosis (paranoia, mania, hallucinations, and delusions) are the commonest sequelae. Hemiplegia, cerebral palsy, cortical blindness/deafness, impaired cognition and learning have been reported. Rare cases of Guillain-Barré syndrome (GBS) and cerebellar ataxia have also been observed.

Malaria in Pregnancy

Falciparum malaria is associated with low birth weight, foetal distress, premature labour, stillbirth and increased infant and childhood mortality. *P. vivax* malaria in pregnancy is also associated with a reduction in birth weight.

Malaria in Children

Convulsions, coma, hypoglycaemia, metabolic acidosis, and severe anaemia are relatively common among children with severe malaria. Deep jaundice, acute renal failure, and acute pulmonary oedema are unusual. Anti-malarial drugs are well tolerated.

Transfusion Malaria

Malaria can be transmitted by blood transfusion, needle-stick injury, sharing of needles and organ transplantation. The incubation period is short as there is no pre-erythrocytic stage. Radical chemotherapy with primaquine is not necessary for *P. vivax* infections.

Malaria and HIV

HIV infection increases the frequency of clinical malaria and parasite density. There is greater parasitaemia with advancing immunosuppression. Morbidity is more and chemoprophylaxis is less effective. Maternal HIV infection predisposes pregnant women to malaria.

CHRONIC COMPLICATIONS OF MALARIA

Tropical Splenomegaly (Hyperreactive Malarial Splenomegaly)

Chronic or repeated malarial infections stimulate reticulo-endothelial hyperplasia and clearance activity and eventually produce splenomegaly. Hyperreactive malarial splenomegaly (HMS) is characterised by massive splenomegaly, hepatomegaly, marked elevations in serum titres of IgM malarial antibody. Peripheral smears usually do not reveal malarial parasites. The patient usually presents with an abdominal mass or a dragging sensation in the abdomen and occasional sharp abdominal pains suggesting perisplenitis. Anaemia and some degree of pancytopaenia are usually evident. There is hepatic sinusoidal lymphocytosis. PCR can detect low levels of parasitaemia, but the cost and complexity preclude widespread use. Long-term antimalarial prophylaxis is required in endemic areas. Chloroquine, proguanil and pyrimethamine are the agents of choice.

In some cases of HMS, a malignant lymphoproliferative disorder may develop.

Quartan Malarial Nephropathy

Chronic or repeated infections, especially with *P. malariae,* cause immune-complex injury to the renal glomeruli, resulting in nephrotic syndrome. Some cases respond to cytotoxics, but antimalarials and corticosteroids do not prevent progression.

Burkitt's Lymphoma

There is a strong association between Burkitt's lymphoma and malaria. Progression of Epstein-Barr virus (EBV) infection in B lymphocytes is controlled by cytotoxic T cells. This response is decreased in malaria which may predispose to malignant transformation.

DIAGNOSIS

Demonstration of the Parasite

The diagnosis of malaria requires demonstration of asexual forms of the parasite. Both thin and thick blood smears should be examined. Giemsa at pH 7.2 is the preferred stain. While the thick film has the advantage of concentrating the parasites, the thin smear helps in identifying the species. Sequential blood smears should be obtained particularly for detection of *P. falciparum*, sexual as well as asexual forms. The appearance of malarial parasites on

peripheral blood smears are shown in **Figures 4A to D**. Antibody-based diagnostic stick or card tests that detect *P. falciparum*–specific, histidine-rich protein 2 (PfHRP2) or lactate dehydrogenase antigens are rapid, simple, sensitive and specific (**Figure 5**). Some of these tests allow falciparum malaria to be distinguished from the other forms of malaria. Microtube concentration methods with acridine orange staining are ideal for processing large numbers of samples rapidly and have sensitivity similar to or superior to that of thick films (**Figure 6**). PCR can detect as few as 5 parasites/μL and is the most sensitive and specific test. Availability of equipment and trained personnel and cost are the limiting factors.

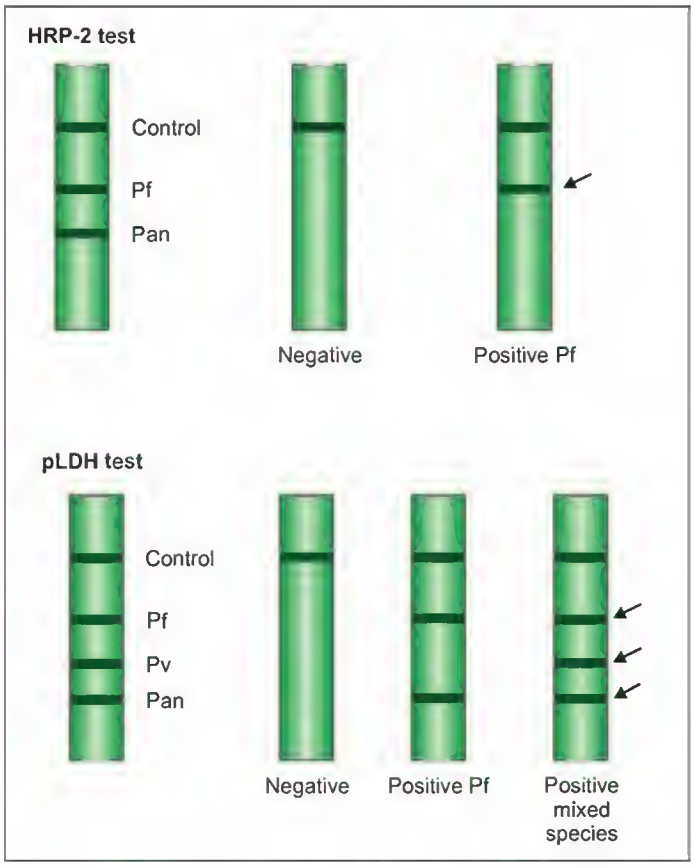

Figure 5: Antibody-based diagnostic stick / card tests that detect *P. falciparum*–specific, histidine-rich protein 2 (PfHRP2) or lactate dehydrogenase antigens.

Laboratory Findings

In uncomplicated malaria, normochromic, normocytic anaemia and a normal leucocyte count are usual. The erythrocyte sedimentation rate, plasma viscosity and levels of C-reactive protein are high. The platelet counts is usually reduced to <100,000/μL. At times, severe thrombocytopaenia may be associated with vivax malaria. Urinalysis generally gives normal results. Usually the CSF is normal.

Laboratory findings of severe malaria have been discussed earlier.

TREATMENT

Malaria cannot be diagnosed clinically. However, presumptive treatment may occasionally be given by experienced clinicians,

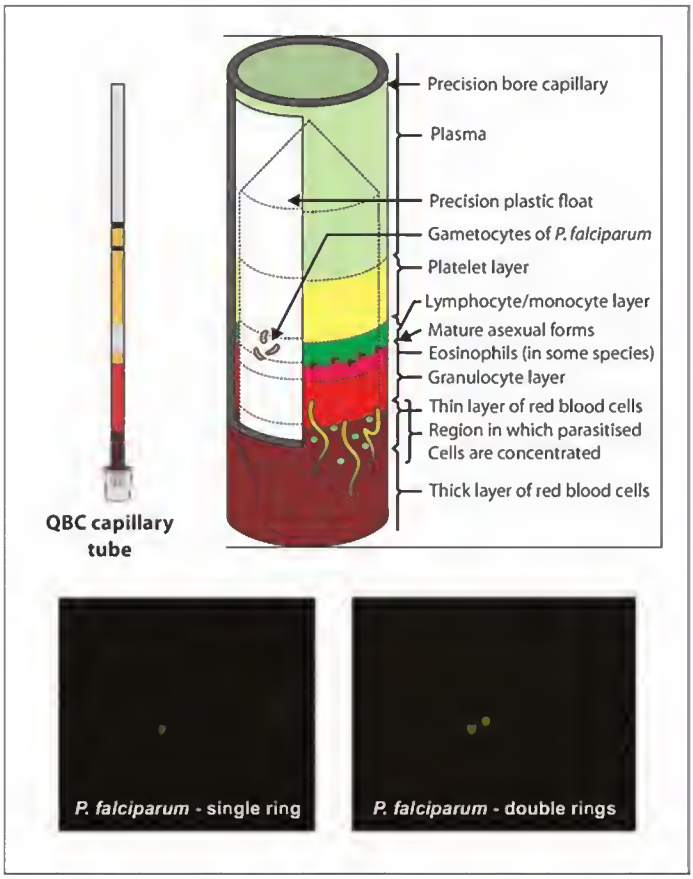

Figure 6: Quantitative buffy coat technique for identification of malarial parasites.

if the situation warrants such an approach. The treating physician should know the seasonal distribution and resistance pattern of malaria in his area. *P. vivax* cases tend to occur more during the monsoon season and *P. falciparum* cases in the post-monsoon season. When a patient presents with fever, thick and thin blood smears should be prepared and examined immediately. Alternatively, a rapid antigen detection card or stick test should be performed. Patients with severe malaria or those unable to take oral drugs should receive parenteral anti-malarial therapy. If in doubt, the parasitic agent should be considered resistant. The treatment of uncomplicated malaria is summarised in **Table 3**.

Chloroquine remains the drug of choice for uncomplicated vivax malaria. Artemisinin-based combination therapy (ACT) regimens now constitute first-line recommended treatment for falciparum malaria. In 117 districts in India, ACT (artesunate + sulphadoxine-pyrimethamine) has been used. In areas with multidrug-resistant falciparum malaria, either artemether-lumefantrine or artesunate-mefloquine should be used. Artesunate plus sulphadoxine-pyrimethamine combination may not be preferred due to emerging resistance to sulphadoxine-pyrimethamine. Furthermore, this combination is not recommended for *P. vivax* infection. These 3-day regimens are well tolerated, although mefloquine is associated with increased rates of vomiting and dizziness. Gametocidal therapy with primaquine is not required when ACT regimens have been used. ACT use is associated with minimal incidence of recrudescence and is designed to prevent or delay the emergence of resistance to artemisinins. The treatment of severe malaria is shown in **Table 4**.

Table 3: Treatment of Uncomplicated Malaria

Known chloroquine-sensitive strains:

1. Chloroquine (10 mg of base/kg body wt stat followed by 5 mg/kg body wt at 12, 24, and 36 hours or 10 mg of base/kg body wt stat followed by 10 mg/kg body wt at 24 hours and 5 mg/kg body wt at 48 hours)
2. Amodiaquine (10-12 mg of base/kg body wt OD for 3 days)

Nowadays, chloroquine-sensitive falciparum malaria occurs in only limited regions of India.

Radical treatment for P. vivax or P. ovale infection:

In addition to chloroquine or amodiaquine as detailed above, primaquine (0.25 mg of base/kg body wt OD) should be given for 14 days. Primaquine should not be given to patients with severe G6PD deficiency.

Uncomplicated P. falciparum malaria:

1. Artemether-lumefantrine (1.5/9 mg/kg body wt at hours 0 and 8 on day 1 and bid on day 2 and 3)
2. Artesunate (4 mg/kg body wt OD for 3 days) plus Mefloquine (25 mg of base/kg body wt – either 8 mg/kg body wt OD for 3 days or 15 mg/kg body wt on day 2 and then 10 mg/kg body wt on day 3)
3. Artesunate (4 mg/kg body wt od for 3 days) plus sulphadoxine (25 mg/kg body wt)/pyrimethamine (1.25 mg/kg body wt) as a single dose
4. Artesunate (4 mg/kg body wt od for 3 days) plus amodiaquine (10 mg of base/kg body wt OD for 3 days)

Note: All drugs are administered orally.

Table 4: Treatment of Severe Malaria

Chloroquine resistant:

1. Artesunate (2.4 mg/kg bw stat IV followed by 2.4 mg/kg body wt at 12 and 24 h and then daily)*

OR

2. Artemether (3.2 mg/kg body wt stat IM followed by 1.6 mg/kg body wt qd)*

OR

3. Quinine dihydrochloride (20 mg of salt/kg body wt infused over 4 hours, followed by 10 mg of salt/kg body wt infused over 2-8 hours q8h)#

OR

4. Quinidine (10 mg of base/kg body wt infused over 1-2 hours, followed by 1.2 mg of base/kg body wt per hour with electrocardiographic monitoring). (Not easily available in India)#

Chloroquine sensitive:

1. Chloroquine dihydrochloride 10 mg base /kg body wt in isotonic fluid IV over 8 hours followed by 15 mg/kg body wt over next 24 hours.

OR

2. Chloroquine dihydrochloride 5 mg base /kg body wt in isotonic fluid IV over 6 hours followed by 5 mg/kg body wt every 6 hours over next 30 hours.

OR

3. If IV infusion is not possible chloroquine dihydrochloride 3.5 mg base/kg body wt every 6 hours by intramuscular or subcutaneous route (contraindicated in children less than 7 years of age).

** Complete course of artemisinin-based combination therapy (ACT) should be administered to all cases following parenteral treatment as soon as oral treatment is feasible (Pregnancy being an exception).*

As soon as possible oral therapy (same drug) may be administered and a 7-10 day course completed. It is preferable to add doxycycline (3 mg/kg body wt qd for 3-7 days) or clindamycin (10 mg/kg body wt bid for 3-7 days).

GUIDELINES FOR PARENTERAL ADMINISTRATION OF ANTI-MALARIAL DRUGS IN SEVERE MALARIA

Treatment of severe and complicated malaria should be initiated without any delay, preferably with intravenous antimalarials. Artesunate is the drug of choice for severe and complicated falciparum malaria; intravenous quinine by infusion is an alternative.The data from large studies in Southeast Asia showed a 35% reduction in mortality rate compared to quinine. Artesunate is preferably given by the IV route, but can also be given by IM injection. Artemether and arteether (oil-based formulations given by IM injection) do not confer the same survival benefit as artesunate. The administration of quinidine must be closely monitored for dysrhythmias and hypotension. Total plasma levels >8 microg/ml, a QTc interval >0.6 sec or saline-unresponsive hypotension warrant treatment stoppage. Quinine is safer than quinidine; cardiovascular monitoring is not required except when the recipient has cardiac disease. All patients treated with IV quinine or quinidine should receive a continuous infusion of 5% or 10% dextrose. A loading dose of quinine should not be used if the patient has received quinine, quinidine or mefloquine in the preceding 12 to 24 hours. If the patient remains seriously ill or in acute renal failure after 48 hours of IV quinine therapy, the maintenance dose should be reduced by one-third to half. The initial dose of antimalarials should never be reduced in the presence of renal or hepatic dysfunction. In areas where IV artemisinins are unavailable, rectal preparations have been used. The possibility of developing resistance with artemisinin monotherapy is real and it should be avoided. All patients should receive the preferred form of ACT (for three days) as soon as they can take fluids. In case parenteral treatment needs to be continued, artemisinins and quinine are to be continued for five days and seven days respectively.

Ancillary drugs, such as high-dose glucocorticoids, urea, heparin, dextran, desferrioxamine, antibody to tumour necrosis factor, and high-dose phenobarbital (20 mg/kg) have proven to be either ineffective or harmful and should not be used. Recombinant human erythropoietin has shown promise in the management of cerebral malaria. In ARF or severe metabolic acidosis, haemofiltration or haemodialysis should be started as early as possible. Exchange blood transfusions can be lifesaving in severely ill patients with very high levels of parasitaemia, but conclusive evidence regarding their efficacy is yet to be established.

Whole blood (preferably fresh) or packed cells should be transfused if the hematocrit falls to <20%. Renal function should be checked daily. Central venous pressure should be measured and maintained in the low-normal range.

Malaria in Pregnancy

The expert group on chemotherapy of malaria, NVBDCP has recommended a combination of quinine plus clindamycin for the treatment of falciparum malaria in all trimesters of pregnancy. Use of ACT, though safe in 2nd and 3rd trimesters, is under evaluation in an ongoing trial by National Institute of Malaria Research (NIMR). Anti-malarial activity and toxicity of drugs are listed in **Table 5**.

Table 5: Characteristics of Anti-Malarial Drugs

Drug(s)	Anti-malarial Activity	Toxicity
Quinine, quinidine	Trophozoites, gametocytes of *P. vivax*, *P. ovale*, and *P. malariae*	Hypoglycaemia, hypotension, blindness, deafness, cardiac arrhythmias, thrombocytopaenia, haemolysis, haemolytic-uraemic syndrome, vasculitis, cholestatic hepatitis, neuromuscular paralysis, 'Cinchonism'; postural hypotension; QTc interval prolongation, diarrhoea, visual disturbance, rashes, very bitter taste
Chloroquine	As for quinine	Bitter taste, hypotensive shock (parenteral), cardiac arrhythmias, neuropsychiatric reactions, retinopathy, myopathy, nausea, dysphoria, pruritus, postural hypotension
Amodiaquine	As for quinine	Nausea, agranulocytosis; hepatitis (mainly with prophylactic use)
Mefloquine	As for quinine	Neuropsychiatric reactions, convulsions, encephalopathy, nausea, dysphoria, sleeplessness, nightmares
Halofantrine	As for quinine	Atrioventricular block; QTc interval prolongation, ventricular tachyarrhythmias, diarrhoea, abdominal pain, cough, rash
Artemisinin derivatives (artemether, artesunate)	Kills all but fully mature gametocytes of *P. falciparum*, no action on liver stages	Anaphylaxis, urticaria, fever, reduction in reticulocyte count (but not anaemia)
Pyrimethamine	For blood stages	Megaloblastic anaemia, pancytopaenia, pulmonary infiltration, methaemoglobinaemia
Proguanil (chloroguanide)	Primary tissue stages; not used alone for treatment	Megaloblastic anaemia, renal failure, mouth ulcers, alopaecia
Primaquine	Radical cure; eradicates hepatic forms of *P. vivax* and *P. ovale*; kills all stages of gametocyte development of *P. falciparum*	Massive haemolysis in subjects with severe G6PD deficiency, nausea, vomiting, diarrhoea, abdominal pain, haemolysis, methaemoglobinaemia
Atovaquone	Acts mainly on trophozoite blood stage	Needs to be taken with food, contraindicated in renal compromise, pregnancy, lactating mothers and children <5 years
Lumefantrine	As for quinine	None identified

Table 6: Chemoprophylaxis in Malaria

Drug	Usage	Dose	Comments
Atovaquone/ proguanil	Prophylaxis only in areas with chloroquine or mefloquine-resistant *P. falciparum*	250 mg of atovaquone and 100 mg of proguanil hydrochloride OD	Begin 1-2 days before and for 7 days after leaving such areas
Chloroquine phosphate	Prophylaxis only in areas with chloroquine-sensitive *P. falciparum*	300 mg of base (500 mg of salt) PO once weekly	Begin 1-2 weeks before and for 4 weeks after leaving such areas
Doxycycline	Prophylaxis in areas with chloroquine or mefloquine-resistant *P. falciparum*	100 mg PO OD	Begin 1-2 days before travel and for 4 weeks after leaving such areas
Mefloquine	Prophylaxis in areas with chloroquine-resistant *P. falciparum*	228 mg of base (250 mg of salt) PO once weekly	Begin 1-2 weeks before travel and for 4 weeks after leaving such areas

PREVENTION

Vector Control

Vector control measures include spraying of insecticides and biological methods. These have not been very successful due to resistance and changing breeding habits of vectors.

Personal Protection

These measures include the avoidance of exposure to mosquitoes at their peak feeding times, the use of insect repellants, suitable clothing, and insecticide-impregnated bed nets.

Containment

Malaria may be contained by judicious use of insecticides to kill the mosquito vector, rapid diagnosis, appropriate patient management, and chemoprophylaxis.

Malaria Vaccine

Currently, several antigen and adjuvant combination vaccines are in clinical trials.

Chemoprophylaxis

Recommendations for prophylaxis (**Table 6**) depend on knowledge of local patterns of plasmodial drug sensitivity and the likelihood of acquiring malarial infection. When there is uncertainty, drugs effective against resistant *P. falciparum* should be used.

Atovaquone/proguanil is contraindicated in persons with severe renal impairment (creatinine clearance rate <30 ml/min). Atovaquone/proguanil is not recommended for children weighing <5 kg, pregnant women, or women breastfeeding infants weighing <5 kg. It should be taken with food or a milky drink.

Mefloquine is the only prophylactic drug advised for pregnant women. This drug is generally considered safe in the second and third trimesters of pregnancy. For pregnant women residing in endemic regions (Pf% >30) IPTp (Intermittent Preventive Therapy in pregnant women) with sulphadoxine-pyrimethamine is recommended.

Children born to nonimmune mothers in endemic areas should receive prophylaxis from birth.

17.53 Amoebiasis and Giardiasis

MP Sharma, Vaibhav Gupta

GIARDIASIS

Giardiasis (beaver fever) is a parasitic infection caused by a single celled organism called *Giardia lamblia*. Leeuwenhoek is credited with discovering it; however, its current name was given by an American parasitologist, Charles Wardell Stiles, to commemorate the work done on *Giardia* by Dr Giard and Dr Lambl.

Epidemiology

There are six species of Giardia, namely *G. lamblia* (mammals), *G. agilis* (amphibians), *G. muris* (rodents), *G. ardeae* and *G. psittaci* (Birds) and *G. microti* (Muskrats). Only *G. lamblia* is responsible for clinical disease in humans.

G. lamblia is seen throughout the world with a prevalence ranging between 20% and 30% in the developing world and 2% to 5% in the developed world. It commonly infects individuals who drink unclean/unfiltered water directly from taps, ponds, rivers, etc., campers, swimmers, hikers, international travelers and child care workers.

Life Cycle

Giardia has no vector. Humans, aquatic and semi-aquatic mammals, rodents, etc., serve as important reservoirs.

Giardiasis is caused by ingestion of infective cysts (10 to 25 cysts) which are transmitted through water-borne, person-to-person and venereal routes. Cysts are non-motile, egg shaped, measure 8 to 14 µm by 7 to 10 µm and encased by a smooth colourless, thick refractile wall. Upon ingestion, they survive the acidic environment of the stomach, reach the small intestine and upon excystation give rise to two binuclear trophozoites which are actively motile owing to the presence of four pairs of flagellae. They attach themselves to the intestinal mucosa and divide by binary fission. They do not cause invasive disease. As trophozoites migrate towards the lower intestine, they retreat into the cyst form which are excreted in the faeces, and are responsible for spread of infection. Cysts are resistant to routine chlorination but not to heating and drying.

Clinical Features

Majority of patients remain asymptomatic. Acute symptoms include crampy abdominal pain, watery diarrhoea, vomiting and fever which may last for few days. In the chronic stage, patients will have bloating, nausea, abdominal fullness, epigastric or substernal burning, malaise, fatigue, etc. A few patients may also develop malabsorption syndrome.

Diagnosis

Diagnosis can be made by stool examination and looking for cysts and trophozoites. Trophozoites are visible only in fresh watery stools. Usually three stool samples are taken and the trichrome stain is used.

Trophozoites can also be seen in a duodenal aspirate, which is more specific and sensitive than stool examination, but is more cumbersome and technically demanding.

Immunofluorescent antibody (IFA) assay or a capture enzyme linked immunosorbent assay (ELISA) against cyst or trophozoite antigens are available commercially. They have a sensitivity of 85% to 98% and specificity of 90% to 100%. Stool antibody tests are not readily available.

Differential Diagnosis

Other causes of acute diarrhoea should be considered like amoebiasis, viral infection, helminths, salmonellosis, etc., while making a diagnosis of giardiasis.

Treatment and Prevention

Treatment includes antibiotics like metronidazole (400 mg PO tid x 5d), albendazole (400 mg PO od x 3d), tinidazole (2 gm PO once), furazolidone and nitazoxanide.

Cyst excretion stops after 2 to 3 days of initiation of antibiotics. Paromomycin is the drug of choice for pregnant woman, as it is poorly absorbed and excreted almost 100% in faeces.

Prevention is of utmost importance and includes maintenance of personal hygiene like washing hands properly with soap, drinking clean boiled water, avoiding eating from unhygienic open places where food is washed in contaminated water.

An important step in prevention of infection is an effective and good excreta disposal system and regular cleaning of swimming pools, wells and other water sources.

AMOEBIASIS

Entamoeba histolytica is one of the most prevalent intestinal protozoa in developing countries.

E. histolytica exists in either trophozoite or cyst form. Trophozoite is the motile form of *Entamoeba*. Actively motile amoebae are elongated whereas resting trophozoites tend to be spherical. The cysts are round or oval hyaline bodies, surrounded by a refractile wall composed of fibrillar material. There are two separate species—*E. histolytica* and *E. dispar*, morphologically indistinguishable from one another.

E. dispar also colonises the human gut but has no pathogenic potential.

Life Cycle of *E. histolytica* (Figure 1)

A human acquires infection by ingestion of the cyst form which is resistant to the acidic pH of the stomach. Excystation occurs in the small bowel, with division of the mature quadrinucleated cyst into four, and then eight trophozoites by nuclear and cytoplasmic division. The trophozoites move to, and colonise in, the large bowel, where they feed on bacteria and cellular

debris. If luminal conditions are unfavourable, the trophozoites may encyst. The cysts are excreted and remain viable for weeks or months. Trophozoites excreted during episodes of acute colitis rapidly degenerate and do not transmit infection. Infection results from ingestion of cysts in contaminated food or water.

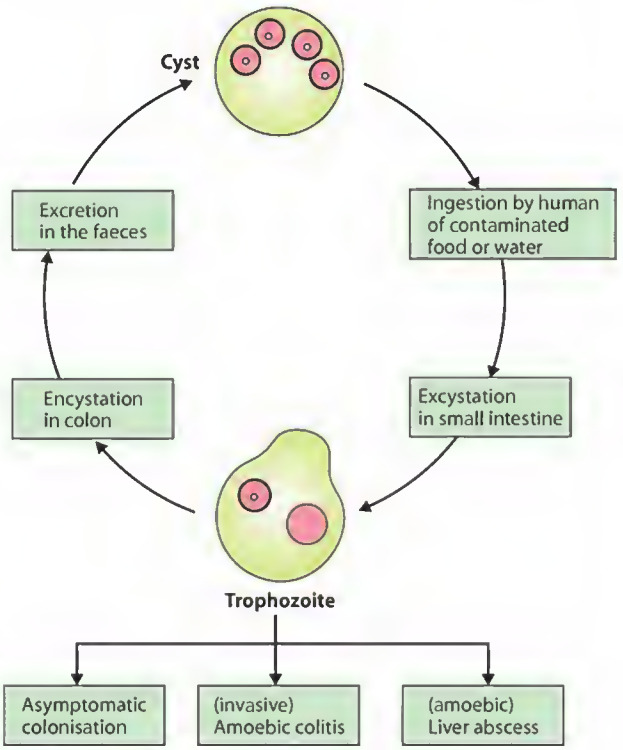

Figure 1: Life-cycle of *Entamoeba histolytica* and the clinical manifestations of infection in humans.

Epidemiology

The main reservoirs of *E. histolytica* are humans. It is estimated that 10% of the world's population is infected by *E. dispar* or *E. histolytica*. *E. dispar* infection is approximately 10-fold more common than *E. histolytica* infection. Symptomatic invasive amoebiasis develops in 10% of individuals with *E. histolytica* infection.

High rates of amoebic infection are seen in the Indian subcontinent, in Southern and Western Africa, in the Far East and in areas of South and Central America.

Patients with a high mortality from invasive amoebiasis, though not necessarily at increased risk of infection, include malnourished individuals, children younger than one year, pregnant women, and individuals receiving steroid therapy.

INTESTINAL AMOEBIASIS

Pathogenesis

Intestinal invasive amoebiasis is associated with a myriad of clinical presentations and surgical complications (**Tables 1 and 2**).

The typical amoebic intestinal ulcers are found in the caecum, sigmoid colon, and rectum. These ulcers are characteristically shallow with broad elevated margins.

Post intestinal infection with *E. histolytica*, the antibodies (IgA and IgE) response develops after an unknown period. The protective role of secretory (IgA and IgE) in amoebiasis has not been established. They can be detected for more than three years after an invasive amoebic episode, in the absence of any recurrent infection.

Table 1: Clinical Syndromes Associated with *E. histolytica* Infection

Intestinal amoebiasis
Asymptomatic cyst passers
Acute amoebic colitis
Mucosal disease
Transmural disease
Ulcerative postdysenteric colitis
Appendicitis
Amoeboma
Amoebic stricture
Extraintestinal amoebiasis
Amoebic liver abscess
Perforation and peritonitis
Pleuropulmonary amoebiasis
Amoebic pericarditis
Cutaneous amoebiasis

Table 2: Surgical Complications of Intestinal Amoebiasis

Fulminant colitis
Toxic dilatation
Necrosis
Perforation
Bleeding
Stricture

Clinical Features

Patients with acute amoebic dysentery present with a 1 to 2 week history of abdominal pain, tenesmus, and frequent loose, watery stools containing blood and mucous. Despite the presence of mucosal ulcerations and occult blood in stools, leucocytes may not be found in faeces because of the lytic activities of the parasites. Colonoscopy may show the characteristic appearance of the punctate, haemorrhagic ulcers dispersed throughout a normal appearing mucosa.

Diagnosis

A definitive diagnosis of invasive intestinal amoebiasis is made by demonstration of *E. histolytica* cysts/trophozoites in the stool. These amoebae may have ingested red blood cells (haematophagus trophozoites). The cysts may remain viable for some time in unpreserved stools while trophozoites are labile and remain in stool for about 30 minutes. The diagnostic yield is better if the specimen is collected over a period of 3 days or longer.

Serum antibodies in amoebiasis develop only during *E. histolytica* infection and not during *E. dispar* infection. The absence of serum antibodies to *E. histolytica* after 1 week of symptoms is strong evidence against the diagnosis of invasive amoebiasis of the colon or liver. Serum antibodies to amoebae are detected in 85% to 95% of all patients who present with invasive amoebiasis or liver abscess. However, as antibodies persist for many years, ELISA or an indirect haemagglutination (IHA) cannot differentiate acute from remote infection in areas of high endemicity.

Treatment

The drug treatment of uncomplicated amoebiasis is given in **Table 3**.

Table 3: Pharmacotherapy for *E. histolytica* Infection in Adults

Intraluminal infection	Diloxanide furoate 500 mg PO tid × 20 days
	Paromomycin 30 mg/kg/day PO × 10 days (3 divided doses)
	Iodoquinol 650 mg PO tid × 20 days
Invasive colitis	Metronidazole 800 mg PO tid × 5 days
	Tinidazole 1 g PO bd × 3 days
Amoebic liver abscess	Metronidazole 800 mg PO tid × 14 days (500 mg qid IV)

EXTRAINTESTINAL AMOEBIASIS

Syndromes of extraintestinal amoebiasis include amoebic liver abscess, and abscess involving the pleura, lung, pericardium or peritoneum, brain, skin, and, rarely, genitourinary disease. Lesions in the lung and brain are complications of amoebic liver abscess. Genital amoebiasis is rare and is probably sexually transmitted.

Amoebic liver abscess (ALA) is the most common form of extraintestinal amoebiasis. It is an inflammatory space occupying lesion of the liver caused by *E. histolytica*.

Epidemiology

The incidence of ALA varies between 3% and 9% of all cases of amoebiasis. A liver abscess accounts for about 0.2% of hospital admissions and for about 75% of all liver abscesses.

Clinical Features

Amoebic liver abscess occurs most commonly in the age group of 20 to 45 years and has been noted infrequently at the extremes of age. It is seven to nine times more common in males.

It is classified by the duration of illness and severity into:

Acute	Acute benign
	Acute aggressive
Chronic	Chronic benign
	Chronic accelerated

Most patients present with acute symptoms of less than two weeks. The main presenting symptoms are abdominal pain, fever and anorexia. Abdominal pain is usually moderate and localised to the right upper quadrant or epigastrium.

Epigastric pain is commonly seen in left lobe abscesses. Fever is of moderate degree in most instances, while high fever with chills is suggestive of secondary bacterial infection. Cough, with or without expectoration and pleuritic chest pain, is also seen in ALA.

During the course of illness one-third of the patients may develop clinical jaundice. Diarrhoea and weight loss are not uncommonly seen.

Tender hepatomegaly is detected in up to 80% of patients. The liver surface is generally smooth. Ascites developing in patients with ALA suggest the development or presence of inferior vena caval obstruction; and cough with copious expectoration suggests rupture and communication with the right lower lobe bronchus.

ALA usually occurs in the right lobe of the liver and is solitary (30% to 70%). Unusual presentations include multiple lobe abscesses, left lobe abscesses, abscesses presenting as compressive lesion and abscesses rupturing into viscera.

Diagnosis

Ultrasound is very useful for the diagnosis of amoebic liver abscesses. Classically, the abscess appears as a non-homogeneous hypoechoic round or oval mass with well defined borders. Complete sonologic resolution of an amoebic liver abscess may take up to two years. The CT scan shows the liver abscess well, but is infrequently required.

Treatment

Drug therapy with nitroimidazole is highly effective and the requirement of invasive aspiration or surgical procedure is required rarely and especially in late cases (**Tables 4 and 5**).

Table 4: Indications of Aspiration in Liver Abscess

Lack of clinical improvement in 2-3 days
Left lobe abscess
Thin rim of liver tissue around the abscess (<10 mm)
Seronegative abscess

Table 5: Poor Prognostic Markers in Amoebic Liver Abscess

Bilirubin >3.5 mg/dL
Encephalopathy
High volume
Hypoalbuminaemia (<2g/dL)

Medical therapy

Nitroimidazoles including metronidazole are effective in over 90% of cases. Therapy should continue for at least 14 days. The dose of metronidazole is 40 mg/kg/dL in divided dosages. Chloroquine, emetine and dehydrometine have also been used.

Surgical therapy

Open surgical drainage is infrequently required. Relative indications include a large abscess with a poor yield on needle aspiration, clinical deterioration despite aspiration, and repeated symptomatic recurrences after aspiration. Rupture into the peritoneal cavity is an absolute indication.

Long-term follow-up

The mean time for disappearance of the sonographic abnormality is 6-9 months. Relapses are very uncommon and the sonographic abnormality does not warrant continued therapy. Clinical resolution does not correlate with ultrasonographic resolution, and clinical criteria rather than ultrasonography should monitor the result of therapy.

Vaccine

Recombinant peptides of three *E. histolytica* antigens show promise for prevention of experimental amoebic liver abscess: the serine-rich *E. histolytica* protein (SREHP), the 170 kDa subunit of the N-acetyl D-galactosamine inhibitable lectin, and the 29 kDa cysteine-rich antigen.

17.54 Leishmaniasis

Shyam Sundar

Leishmaniasis occurs in 102 countries, majority of them developing or least developed, and 350 million people are at risk. Annual incidence is 2 million with a prevalence of 12 million. It is caused by unicellular flagellate intracellular protozoa belonging to the genus *Leishmania* (Order Kinetoplastida) comprising of 21 species. Leishmaniasis presents as several diverse clinical syndromes consisting of three broad groups: i) visceral leishmaniasis (VL, kala-azar), ii) cutaneous leishmaniasis (CL), and iii) mucosal leishmaniasis (ML). Clinical syndromes are caused either by zoonotic transmission of parasites from animal reservoirs (chiefly canine and rodents in Old World and big mammals in New World) to humans through phlebotomine sandfly vectors, humans are the only known reservoir (anthroponotic) in major VL foci in India and Sudan.

VECTOR

Different species of sandfly vectors (*Phlebotomus* in Old World, *Lutzomyia* in New World) are responsible for transmission of leishmaniasis. Female sandflies bite during the night and preferentially feed on animals; humans are incidental hosts.

LIFE CYCLE

The parasite occurs in two forms, flagellar promastigotes (10 to 20 μm), found in vectors, and aflagellar amastigotes (2 to 4 μm) in vertebrate hosts including humans. Promastigotes are introduced through the proboscis of the female sandfly into vertebrate hosts. Neutrophils take up the promastigotes where they transform into amastigotes and undergo apoptosis, and released parasites are taken up by macrophages. Once inside the macrophages, they multiply, ultimately causing rupture and invasion of another cell. While feeding on infected hosts, sandflies pick up amastigotes, which transforms into the flagellar form. It multiplies by binary fission in the gut of the vector and infects a new host by migrating to the proboscis.

VISCERAL LEISHMANIASIS (KALA-AZAR)

Visceral leishmaniasis also known as kala-azar (Hindi word for black fever) is caused by the protozoon *Leishmania donovani* complex. An annual incidence of 500,000 is estimated, and 90% of it occurs in India, Sudan, Bangladesh and Brazil. Other regions with low incidence of VL include the Mediterranean, Eastern Africa, China, Arabia, Israel, Brazil and other South American countries.

Immunology and Pathogenesis

A great majority of infected persons mount a successful immune response, and remain asymptomatic. In some individuals, leishmania is able to evade immunity in which significantly elevated levels of immunosuppressive cytokine IL-10 plays an important role. Progressive systemic disease develops with involvement of spleen, liver, bone-marrow and lymph nodes primarily, though lymphadenopathy is rare in India. Other unusual modes of transmissions are *in utero*, through blood transfusion, through needle sharing in drug addicts. Immunosuppression due to HIV infection or immunosuppressive medications makes these patients vulnerable to development of VL.

Clinical Features

Except in Indian subcontinent where all age groups are affected, it is a disease of infants and small children, however, HIV infection predisposes adults to VL. Poor housing conditions (mud or straw houses), high level of humidity, sleeping on the floor, living in close proximity of animals leads to increased vector density and exposure. The incubation period ranges from weeks to months. Clinical illness is heralded by high grade fever with rigour and chills. Spleen soon becomes palpable, and becomes remarkably enlarged. Fever decreases over time and patient may become afebrile for short periods, however, fever relapses. Mild hepatomegaly might occur at a later stage. Pancytopaenia is an important feature, and occurs early in the course of illness. Anaemia may become severe enough leading to cardiac failure and other related manifestations. Thrombocytopaenia might result in epistaxis, retinal haemorrhages and gastrointestinal bleed. Hypoalbuminaemia, leading to anasarca suggests advanced illness and indicates poor prognosis. Though initially there is leishmania specific immunosuppression, in later stages profound immunosuppression occurs leading to secondary infections like tuberculosis, pneumonia, herpes zoster, chicken pox, recurrent gastrointestinal infection. Skin infections like boils, cellulitis and scabies are common. Without adequate treatment, VL is fatal.

Laboratory Features

Granulocytopaenia occurs very early accompanied by anaemia and thrombocytopaenia soon thereafter. Polyclonal hypergammaglobulinaemia is a feature of advanced disease. Patients are anergic to leishmanin antigen skin test (LST), which recovers after successful chemotherapy. Immunological parameters measuring T-helper lymphocyte activity suggest absence of a polarised response as increased levels of the pro-inflammatory Th1 cytokine, γ-interferon as well as that of the anti-inflammatory Th2 cytokine, interleukin-10 are detected in lesions.

Diagnosis

Parasites (amastigotes) can be demonstrated in tissue smears from spleen (**Figure 1**), bone-marrow or lymph nodes. Splenic smear is highly sensitive, but carries the risk of serious haemorrhage; sensitivity with other tissues is unsatisfactory. In HIV co-infected, buffy coat smears may demonstrate parasites. Culture, though efficient, is seldom used in diagnosis as it is expensive and extensive facilities are needed. Detection of nucleic acids through polymerase chain reaction (PCR) from peripheral blood is an efficient non-invasive way, but yet to be used routinely. Serodiagnosis, by ELISA, or

immunofluorescence antibody test, is used in the developed world. In endemic regions, however, rapid immunochromatographic k39 strip test have become increasingly popular being simple and it does not require any expertise or equipment and can be performed anywhere. Up to 30% of healthy people in endemic region test positive, and these tests remain reactive for years after cure; thus, results must be interpreted in light of strong clinical suspicion. Tests relying on the raised globulin levels (e.g. Aldehyde test) have no value in the diagnosis of VL.

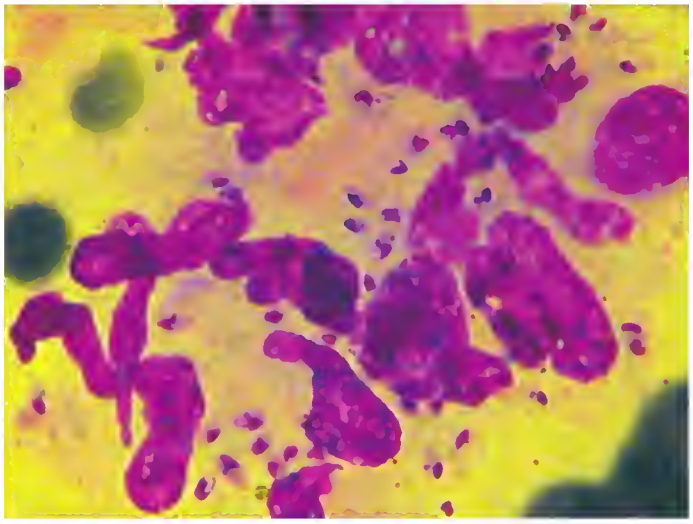

Figure 1: Splenic aspirate smear showing multiple amastigotes (LD bodies).

Differential Diagnosis

Malaria is the commonest illness which may be mistaken for VL. Other common illnesses which might mimic VL include enteric fever, tuberculosis, chronic myeloid leukaemia, portal hypertension and other infectious diseases with splenomegaly with/without lymphadenopathy.

Treatment

For more than eight decades, pentavalent antimonials have been used for the treatment of all forms of leishmaniasis. It is available as sodium stibogluconate (100 mg/ml) in India. Its daily dose is 20 mg/kg body weight intravenous (IV) or intramuscular (IM) for 28 to 30 days. Adverse events are common and include arthralgias, myalgias and raised hepatic transaminases. Chemical pancreatitis is common in HIV co-infected patients, cardiotoxicity-manifested by concave ST segment elevation and prolongation of QTc >0.5 sec are ominous features. Unfortunately, in Northern Bihar in India, more than 50% patients are refractory to antimonials.

Amphotericin B deoxycholate has powerful antileishmanial activity, and is now used as 15 intravenous infusions (dose 0.75 to 1 mg/kg body weight), daily or on alternate days as first line drug in the antimony refractory regions. Though its cure rate is approximately 100%, infusion related adverse events like high grade fever with chills, thrombophlebitis are almost universal, gastrointestinal symptoms like vomiting or diarrhoea, renal insufficiency occur occasionally. Life-threatening toxicity like myocarditis, refractory hypokalaemia are rarely seen. Several lipid formulations of amphotericin B have been developed to alleviate the organ toxicity, however, liposomal amphotericin B (AmBisome, Gilead Sciences, USA) has the best safety profile, and is approved by US Food and Drug Administration (FDA) of USA for VL. For immunocompetent patients, recommended total doses are – in the Indian subcontinent 10-15 mg/kg, in Africa ~18 mg/kg and 21-24 mg/kg for South America and Europe. Orally administrable alkyl phospholipid, miltefosine is approved in India for treating VL. The doses are 50 mg twice daily for adults weighing ≥ 25 kg, and once daily for those <25 kg, after meals for 28 days. For children between 2 and 11 years, the dose is 2.5 mg/kg for 28 days. Mild gastrointestinal adverse events like vomiting and diarrhoea are common. Nephro- and hepatotoxicity can occur rarely. Being teratogenic, miltefosine cannot be used in pregnancy and contraception up to three months after the end of treatment is advised for women with pregnancy potentials. Paromomycin, an aminoglycoside, is highly effective if given intramuscularly at 15 mg/kg body weight daily for three weeks. It was approved in 2006 in India for treatment of VL, no significant auditory or renal toxicity is seen.

Due to limited number of antileishmanial drugs, their inherent weaknesses like long half life of miltefosine, long regimens of 3-4 weeks, and frequent non-compliance makes these drugs vulnerable to development of drug resistance and these could become rapidly ineffective if not used judiciously. Multi-drug regimens are being tested to shorten the duration of therapy, and perhaps prolong the effective life of these drugs.

Successful treatment results in prompt resolution of fever, weight gain, regression of spleen and blood counts recover toward normalcy. Patients must be followed adequately to detect relapse of the disease. Increase in the spleen size, fever, and drop in blood counts indicate relapse, and it should be treated with amphotericin B.

POST KALA-AZAR DERMAL LEISHMANIASIS (PKDL)

After complete recovery from VL, some patients (~1%) develop hypopigmented areas (macules) or nodules (occasionally may appear as papule or plaque) on skin six months to several years later in the Indian subcontinent. The lesions occur predominantly over face in the area around chin (**Figure 2**). In Sudan, PKDL occurs in 50% of patients, and may occur concomitantly with VL or shortly after recovery. Sudanese PKDL occurs like a generalised rash, a papular or nodular form is most frequent; ulceration might occur. In contrast to Sudanese PKDL where spontaneous recovery is the rule, it is not so in India. Diagnosis is clinched by typical clinical features in a background of VL, and positive serology, however, demonstration of parasites in slit skin smears or culture of aspirate material can only be done from nodules, but recovery of parasites from macules is uncommon. PKDL is treated with sodium stibogluconate in the usual daily doses for 120 days or up to 60 amphotericin B infusions. In Sudanese PKDL, treatment with Sb^{v} for up to 2 months is required only in exceptional patients with persistent skin lesions. Since there are no systemic symptoms, non-compliance is the rule.

HIV-VISCERAL LEISHMANIASIS CO-INFECTION

Immunosuppression due to HIV infection increases the vulnerability of VL co-infection several hundred fold. Though initially majority of HIV-VL co-infected cases were from Southern Europe (Spain, South France, Italy, Greece and Portugal), after the introduction of antiretroviral therapy (ART), the incidence has reduced significantly. However, there has been an increase

Figure 2: Post kala-azar dermal leishmaniasis – extensive nodules over face along with facial erythema.

in the co-infected cases from Ethiopia in Africa, Brazil and India. Classical presentation of fever, pancytopaenia, and hepatosplenomegaly/lymphadenopathy is found only in 75%. Atypical presentations, common in those with low CD4+ counts, comprise of dysphagia or odynophagia and diarrhoea or rectal discomfort. Other manifestations include ascites, pleural or pericardial effusion, and involvement of tonsil, oral mucosa, or skin. Parasitic diagnosis is easy as amastigotes can be demonstrated in the buffy coat or recovered from mucosa (gastrointestinal biopsies, bronchoalveolar lavage). PCR detection of nucleic acid from peripheral blood is highly sensitive, and is used in tracking parasites for relapses and re-infections. Sensitivity of serological tests is lower in HIV co-infected patients.

Treatment of HIV co-infected patients is similar with a different outcome. In Europe, the drug of choice is AmBisome (4 mg/kg on day 1-5, 10, 17, 24, 31, 38), though this regimen induces high cure rate, relapse rate is high. Sodium stibogluconate (20 mg/kg for 28 to 30 days) is effective in Africa, amphotericin B deoxycholate (regimen similar to immunocompetent patients) is used in Bihar, India. Miltefosine was less effective than sodium stibogluconate in a large study from Ethiopia. Though every locally effective regimen is expected to induce high initial cure rate, most patients experience relapse within one year. It is important to initiate ART regimen, which is likely to increase the duration of symptom free periods.

CUTANEOUS LEISHMANIASIS

In Old World, anthroponotic CL (oriental sore; caused by *L. tropica*) occurs mostly in urban and suburban areas, and Afghanistan is currently the biggest focus, though western deserts of India, Pakistan, Iran, Iraq, Syria and other areas of Middle East are highly endemic, and in sub-saharan West Africa and Sudan, around the Mediterranean basin, the disease is also endemic. There has been an increase in the incidence of Zoonotic CL (ZCL) in both Old and New World, largely due to man-made ecological changes, transmission cycle, and increase in the animal reservoir population (small rodents in Old and big mammals in New World). Old World ZCL is caused by *L. major, L. aethiopica* and dermotropic *L. infantum*. New World CL is caused by *L. mexicana* complex comprising of *L. mexicana, L. amazonensis*, and *L. venezuelensis*; and Viannia subgenus *L. (V) braziliensis* complex constituted by *L. (V) guyanensis, L. (V) panamensis, L. (V) braziliensis*, and *L. (V) peruviana*. Species causing CL is important, as the clinical presentation, treatment and outcome vary.

Clinical Features

After inoculation, parasites are taken by the dermal macrophages and multiply. After an incubation period of 2-3 months, a papule develops followed by skin ulceration with raised margins (**Figure 3**). Satellite lesions might develop especially in *L. major* and, occasionally, in *L. tropica* infections. Secondary bacterial infection, pain and regional lymphadenopathy are common. *L. mexicana* and *L. peruviana* produce lesions similar to those seen in the Old World, but chronic and destructive lesions on the pinna of the ear are common. Self healing is common in presence of good immunity in *L. tropica, L. major* and *L. mexicana* lesions. However, in patients with anergy to leishmania, the ulcerative skin lesions of *L. aethiopica, L. mexicana*, and *L. amazonensis* infections develop into diffuse cutaneous leishmaniasis characterised by non-ulcerative nodules involving the whole body including face. Persistent relapse of *L. tropica* infections, after apparent healing is called as recidivans (lupoid) leishmaniasis.

Figure 3: Ulcers due to cutaneous leishmaniasis with secondary infection.

MUCOSAL LEISHMANIASIS

Prevalence of the *Vianna* subgenus is extensive in the New World from the Amazon basin as far as Paraguay and Costa Rica and is responsible for deep sores and mucosal leishmaniasis. In *L. (V) braziliensis* complex infections, initial cutaneous ulcers may culminate into mucosal spread of the disease concurrently or in later years. Mucosal lesions begin

as a perivascular infiltration; later endarteritis may cause destruction of the surrounding tissues, up to 40% of patients develop metastatic lesions in the mucosa of the nose or mouth (espundia), with erythema and thickening of the nasal mucosa typically starting at the junction of the nose and upper lip. At a later stage it ulcerates, and involves lips, soft palate, fauces and larynx, ultimately destruction and deformity occur (**Figure 4**). Massive destruction of the pharynx causes severe respiratory tract infections, and death may occur. There is no self healing of ML.

Figure 4: Mucosal leishmaniasis leading to extensive destruction of nasopharynx.

Laboratory Diagnosis of CL and ML

Diagnosis: Slit-skin smears from the nodular edge of lesion or scrapping from within the ulcer may demonstrate parasites. Impression smears or culture of aspiration material yield parasites. PCR is now increasingly employed both for diagnosis and speciation. Demonstration of parasites is usually difficult in mucosal leishmaniasis. Leishmanin skin test is usually positive except in diffuse cutaneous leishmaniasis.

Management

Small lesions may self-heal. Treatment is individualised on the basis of severity of lesions, local resistance pattern, and leishmania species responsible for the illness. Fewer and small lesions at obscure sites can be treated with local therapy with intralesional antimony (0.2-0.8 ml/lesion) every other day for 30 days up to a total of 2 gm. Topical application of Paromomycin 15% plus methylbenzethonium chloride 12% is beneficial in both Old and New World CL. Local cryotherapy with liquid nitrogen or heat therapy through a FDA approved radiofrequency generator (ThermoMed) have also been used. Multiple lesions and those at disfiguring sites are best treated with parenteral Sb^v (20 mg/kg) for 20 days. Pentamidine is the drug of choice in French Guyana in lesions caused by *L. guyanensis* (2 injections in doses of 4 mg/kg 48 hours apart). Fluconazole 200 mg daily for six weeks was effective in *L. major* CL in Saudi Arabia. In India, itraconazole 200 mg daily for 6 weeks was effective in *L. tropica* CL. Drug resistant CL or ML should be treated with amphotericin B.

PREVENTION AND CONTROL OF LEISHMANIASIS

In the absence of prophylactic vaccine against any form of leishmaniasis, vector control remains the key public health measure. Sandflies are extremely sensitive to insecticides, residual insecticide spray is extremely effective. Insecticide impregnated mosquito nets or curtains treated with insecticides will keep out the tiny sandflies. Other measures include active and early detection and treatment of human infections, which will reduce the reservoir and control the epidemic.

17.55 Toxoplasmosis

Madhukar Rai

Toxoplasmosis is caused by an obligate intracellular coccidian parasite *Toxoplasma gondii*. It is among the most prevalent of human infections with an estimated one third of the world's population infected by *T. gondii*. However, in immunocompetent host the infection is mostly asymptomatic and when it causes clinical disease, manifestions are usually mild in form of chorioretinitis, lymphadenitis and rarely myocarditis or myositis. In majority of those symptomatically or asymptomatically infected individuals the infection becomes latent and chronic, which can get activated on encountering immune-compromised state in the host.

T. gondii cause severe and life-threatening illness when it infects or gets reactivated in immune-suppressed host, especially with impaired T cell function (patient of haematological malignancies, bone marrow or solid organ transplant recipients and HIV infection). It also causes significant disease in foetus and newborn of mother infected with toxoplasmosis during pregnancy.

AETIOLOGY

T. gondii has sexual cycle which is completed only in the gastrointestinal tract of the definitive host; the cat family and asexual cycle in the secondary hosts, which are warm blooded animals like birds, rodents and mammals including humans. It exists in three forms; in definitive host, oocyst containing sporozoite, excreted in cat faeces; while in secondary host it exists as tachyzoites (disease producing stage) and tissue cyst containing bradyzoites (dormant form).

EPIDEMIOLOGY AND TRANSMISSION

Prevalence of *T. gondii*-specific antibodies increases with advancing age, proximity to cat, undercooked non-vegetarian diet, and warm moist climate. In developed countries, incidence of IgG positivity is around 10% to 80%. Few data are available from India. Seroprevalence of *T. gondii* in India on 23,094 serum samples tested for *T. gondii* IgG and IgM antibodies and use of a solid-phase immunocapture ELISA revealed antibodies (IgG) in 24.3%; IgM antibodies in 2% of the samples. The lowest seroprevalences were in the northern parts of India, with the highest in the south. These data probably reflect the effects of significantly drier conditions and, therefore, a negative impact on the survivability of *T. gondii* oocysts.

TRANSMISSION

All the three stages of parasite are infectious. Oral transmission occurs through ingestion of sporulated oocyst through contamination of food, unwashed vegetable, unfiltered contaminated water, or through undercooked meat containing bradyzoites. Transplacental transmission occurs due to acute infection during pregnancy. Direct transmission occurs due to administration of infected blood or transplantation of toxoplasma-positive organ in negative recipient.

PATHOGENESIS AND IMMUNITY

Sporozoites or bradyzoite infects intestinal epithelial cells and tachyzoites are formed. They multiply and disseminate particularly to lymphatic tissue, skeletal muscle, myocardium, retina, placenta and CNS. Cell death and focal necrosis with surrounding inflammatory reaction develops. In immunocompetent individual, immune mechanisms like macrophage, CD8+ cells, natural killer cell with help of interferon gamma, IL-12, IL-2 tries to kill or inhibit replication of this organism. Humoral antibodies like IgA, IgM, and IgG develop. Tissue cysts are formed in as early as 7 days and remain dormant for the life span of host. Tissue cyst is around 60 µm in diameter and contain up to 60,000 organisms. They are responsible for reactivation of disease and chorio-retinitis in children. In patients with AIDS, bradyzoites reactivation in 12 months correlates with CD4 count, i.e. 48% in < 50 cells/mm^3 to 20% in 150-100 cells/mm^3. HLA-DQ3 is associated with high susceptibility.

PATHOLOGY

Changes depend upon dissemination of parasite, cytolytic action of it and immune response of host. Tissue necrosis and intense mononuclear inflammatory response containing monocyte, lymphocyte and plasma cells is seen. Lymph node biopsy reveals follicular hyperplasia and macrophages with eosinophilic cytoplasm. Granulomatous lesions are present in retina and choroid. CNS shows necrosis and microglial nodules in focal or diffuse form. Interstitial pneumonia with mononuclear cells and plasma cell infiltration is observed in lungs. Focal necrosis with inflammation and muscle cysts is seen in heart. Disseminated infection will lead to necrosis and destructive changes in variety of organs leading to myositis, pancreatitis, glomerulonephritis and others.

CLINICAL MANIFESTATIONS

Immunocompetent Patient

Acute stage toxoplasma infections can be asymptomatic in 80% to 90% patients, but often give flu-like symptoms in the early acute stages. The acute stage fades in a few days to months, leading to the latent stage. In symptomatic patient headache, malaise, fever, cervical lymphadenopathy will occur. Myositis, chorioretinitis and other complications are rare. Lymphadenopathy needs differentiation from infectious mononucleosis, lymphoma, CMV, cat-scratch disease and tuberculosis. Latent infection is normally asymptomatic.

Immunocompromised Patient

In the case of immunocompromised patients severe toxoplasmosis can develop. Acute infection or reactivation of bradyzoites occurs in them. The most notable manifestation of toxoplasmosis in immunocompromised patients is toxoplasmic encephalitis, which can be deadly. Toxoplasma encephalitis (TE)

will have either focal dysfunction to non-focal meningo-encephalitis due to vasculitis, oedema and haemorrhage. Patient has altered mentation (75%), seizures (30%), focal neurological signs (60%), headache (56%) and fever (50%). Motor or sensory deficit, brainstem basal ganglia or cerebellar dysfunction, movement disorder and many other manifestations can be seen. Meningeal signs, spinal cord involvement, hydrocephalus, pituitary involvement are uncommon. CSF is usually normal or shows rise in protein and cell count. Differential diagnosis includes cryptococcal meningitis, herpes simplex encephalitis, tuberculoma and tuberculous meningitis and primary CNS lymphoma. Lung involvement shows ARDS, haemoptysis, DIC and needs differentiation from *Pneumocystis carinii* infection. Multiple other organ involvement in these patients is documented on post-mortem.

Ocular Toxoplasmosis

Retinal lesion can be detected at birth or in second/third decade. Fundoscopy reveals yellow-white elevated cotton-wool patches during active stage and punched out and pigmented (black) lesions during quiescent stage. Severe congenital disease has cataract, micro-ophthalmia, strabismus and nystagmus.

Congenital Toxoplasmosis

It occurs when toxoplasma infection occurs during first time in pregnancy. Transmission rate to the foetus is 10% to 25% in first, 30% to 54% in second and 60% to 65% in third trimester. However, the severity of congenital disease decreases with increasing gestational age. Clinical manifestations vary a lot, like chorioretinitis, strabismus, blindness, epilepsy, psychomotor or mental retardation, anaemia, jaundice, rash, microcephaly, intracranial calcification, hydrocephalus, and pneumonitis. The symptoms may be present at birth or develop later in life, leading to blindness, psychomotor retardation, and hearing difficulties. Infants with HIV infection and toxoplasmosis run rapid course. Congenital toxoplasmosis needs to be differentiated from CMV, ruboella, herpes simplex, syphilis, listeriosis and other infections.

DIAGNOSIS

Strong suspicion is required for proper diagnosis. Isolation of *T. gondii* by tissue culture and mouse inoculation can be done from body fluids. Isolation of *T. gondii* from amniotic fluid is diagnostic of congenital toxoplasmosis. Detection of its antigen in blood or body fluid by ELISA indicates acute infection. Histological diagnosis is made by fluorescent antibody and immunoperoxide staining. Polymerase chain reaction (PCR) is useful.

Lymphocytic transformation to *T. gondii* antigen is an indicator of previous toxoplasma infection in adults. IgG antibodies could be detected by specific neutralisation test for toxoplasma (Sabin Feldman dye test) or by immuno-fluorescent antibody test which denote prior infection. Parallel testing of IgG showing four-fold rise in paired sera of 3 weeks apart indicates acute infection. IgG has low avidity in acute infection and high avidity in chronic infection. IgM, IgE and IgA antibodies denote new infection. Double sandwich IgM ELISA is most specific and sensitive to detect acute infection.

CT brain in AIDS patient with TE classically shows multiple bilateral hypodense lesions, ring enhancing lesions with asymmetric target sign in basal ganglia region. However, solitary lesion may also be seen. MRI with gadolinium contrast is superior to CT and may detect lesions not seen on CT. Decreased Thallium^{201} uptake on SPECT scan and decrease activity on PET scan is suggestive of infection (to differentiate from CNS lymphoma). Response to empiric therapy is also used for diagnostic purpose.

MANAGEMENT

Treatment is directed against tachyzoites. Combination therapy is preferred. Pyrimethamine in combination with sulphdiazine is most effective. Folinic acid is used to avoid megaloblastic anaemia. Treatment schedule is shown in **Table 1**.

Table 1: Treatment Schedule

Group	Treatment	Duration
AIDS and immuno-compromised patients	Pyrimethamine: 200 mg loading + 75 mg/dL + Sulphadiazine 1 gm qid *or* clindamycin 600 mg-1200 mg qid *or* TMP + SMX: 20 mg/kg/dL of trimethoprim in four divided doses (without pyrimethamine in resource poor setting) + *Folinic acid: 5-10 mg/dL*	To continue in full dose till cessation of disease activity followed by maintenance till CD4 $\geq$ 200 for 3 months
Immunocompetent	—	—
Acute chorioretinitis	Pyrimethamine:100 mg loading + 25-50 mg/day + sulphadiazine 1 gm qid + folinic acid	Usually for 6 weeks but as per clinical response
Acute lymphadenitis	No treatment	
Pregnancy	Spiramycin 1 gm tid (if no evidence of foetal infection)	Till term
Other drugs which can be used		
TMP-SMX	20 mg/kg/dL of trimethoprim	
Atovaquone	1500 mg 12 hourly	
Clarithromycin	500 mg 12 hourly	
Azithromycin	900-1200 mg/dL	
Dapsone	100 mg once a day	

In immunocompetent patient disease is self-limited. Treatment for 2 to 4 weeks is indicated, if severe persistent symptoms occur.

In immunocompromised patients, treatment is recommended for 4 to 6 weeks or till there is no evidence of disease activity. Response is seen in 68% to 95% patients with TE. Measures to control increased intracranial tension and seizures should also be included in treatment. Maintenance therapy of pyrimethamine 25 mg with sulphadiazine 500 mg four times a day is required. Maintenance therapy is withdrawn, if CD4 cells >200/mm^3 on HAART for a period of more than 6 months. For primary prophylaxis, all AIDS patients with CD4 <100 cells/mm^3 should receive TMP-SMX one double strength tablet per day. Primary prophylaxis is discontinued, if on HAART, CD4 cells > 200/mm^3 for 3 months.

For congenital infection, oral pyrimethamine 0.5-1 mg/kg and sulphadiazine 100 mg/kg for one year is given. In addition spiramycin 100 mg/kg with prednisolone 1 mg/kg/dL has shown improvement.

In pregnancy to prevent transmission to foetus, spiramycin 3 gm/dL is continued throughout pregnancy. Since, spiramycin does not cross placental barrier, if foetus is suspected to have infection then usual treatment should be used. However, pyrimethamine is contraindicated in first 12 to 14 weeks of gestation.

PREVENTION

To reduce primary infection in AIDS patients, avoid undercooked meat, oocyst contaminated material and feed domestic cat on canned or dried commercial food. Serological screening and prophylaxis should be used for organ transplant recipient and to prevent congenital toxoplasmosis.

17.56 Trypanosomiasis

Prashant P Joshi

Protozoan parasites of the genus *Trypanosoma* cause trypanosomiasis. Human trypanosomiasis, a vector borne disease, is endemic in sub-Saharan Africa and South America. In Africa it is known as Human African Trypanosomiasis (HAT), or 'sleeping sickness', whereas in South America it is known as Chagas disease. Trypanosomiasis is common in cattle in India and is called 'Surra'.

HUMAN AFRICAN TRYPANOSOMIASIS (SLEEPING SICKNESS)

Sleeping sickness is caused by human strain of *Trypanosoma brucei* (**Figure 1**) and it is found in two forms, depending on the two protozoan parasite species of *Trypanosoma brucei*, that are morphologically similar but cause different diseases: (a) chronic sleeping sickness or West African Trypanosomiasis, caused by *Trypanosoma brucei gambiense*, occurs in Central and West Africa. Symptoms may be virtually absent for several years, and when they do appear, the disease is already in advanced stage. Its reservoir is mainly human, (b) acute sleeping sickness or East African Trypanosomiasis, caused by *Trypanosoma brucei rhodesiense* occurs in East Africa. It has an acute, virulent and faster course causing death in a matter of weeks or months. It has a large animal reservoir. It is transmitted by infected saliva of blood sucking tsetse flies (**Figure 2**) of the genus *Glossinia* species during its blood meal.

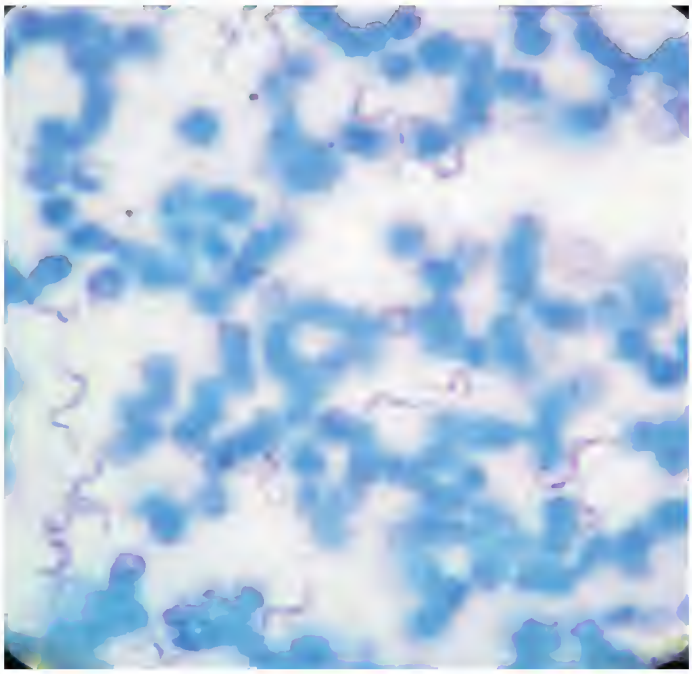

Figure 1: Plenty of long, slender, flagellated, dividing forms of trypanosomes.

Clinical Course

At the site of inoculation, a painful trypanosomal chancre accompanied by regional lymphadenopathy develops after five days in many cases. Symptoms begin with fever, headaches, and joint pains with haematogenous spread. *Stage 1 or Haemolymphatic stage* is characterised by fever, cervical lymphadenopathy, especially in the posterior triangle (Winterbottom's sign), splenomegaly, rash, pruritus, muscular pain, anaemia, thrombocytopaenia, and carditis, which can sometimes be fatal. This is followed by *Stage 2, the neurological phase or the meningoencephalitic stage* with central nervous system (CNS) invasion, in which there is marked sleep disturbance characterised by day-time somnolence and night-time insomnia. Behaviour changes, lack of concentration, mood changes, headache, personality changes, incoordination, ataxia, chorea and cachexia develop with bouts of lethargy alternating with manic and aggressive periods progressing to confusion, delirium, convulsions and coma. 'Sleeping sickness' gets its name from symptoms of second stage. Damage caused in the neurological phase can be irreversible.

Figure 2: Glossinia (Tsetse Fly).

Diagnosis

A definitive diagnosis is made by demonstration of the parasite in blood, bone marrow, lymph node aspirate or chancre aspirate, which is fixed and stained with Giemsa. The mini-anion exchange centrifugation technique (mAECT), a chromatographic-based system concentrates and purifies trypanosomes in the blood. CSF involvement indicates Stage 2. Serological tests, like card agglutination test for trypanosomes (CATT), have varying sensitivity and specificity and are particularly useful in epidemiological surveys. Molecular studies [polymerase chain reaction (PCR)] help in species identification.

Management Issues

Drugs (suramin, malarsoprol and eflornithine) used to treat sleeping sickness are toxic and expensive. The treatment is not standardised due to lack of evidence from good randomised clinical trials. Although not available in India; drugs can be

obtained on request from WHO free of cost. Concomitant parasitic, bacterial, viral infections, nutritional deficiencies, and severe anaemia should be treated prior to administration of anti-trypanosomal drugs so as to improve the patient's general condition.

Choice of drug therapy depends on: (a) stage of disease, (b) species of the parasite involved, (c) adverse reactions and (d) Drug resistance. Treatment began in the 1920s with suramin while eflornithine (difluoromethylornithine or DFMO), is the most modern treatment. Trials of combination therapy are ongoing in cases of drug resistance.

Prognosis

The disease is fatal if left untreated. If treatment is initiated in early *Stage 1* cure rates are high, but initiation of treatment in late *Stage 2* cannot prevent irreversible neurological damage.

Prevention

Vector control using screens and traps, surveillance of the population at risk and treatment of infected individuals are the main focus of control programmes. Risk of trypanosomiasis can be reduced by wearing protective clothes, use of insect repellants, avoiding tsetse infested areas. No chemoprophylaxis is recommended nor is any vaccine available.

HUMAN TRYPANOSOMIASIS IN INDIA

Recently, a new form of human trypanosomiasis, has been described with the report from India of the first formally identified human case of trypanosomiasis, caused by cattle species *Trypanosoma evansi*, which was probably transmitted from infected cattle blood. *T. evansi* was not known previously to cause infection in humans and tsetse fly is not found in India; however, this patient had significant fluctuating trypanosome parasitaemia due to *T. evansi*, associated with febrile episodes for five months, without CNS involvement. He was successfully treated and completely cured with suramin, a drug used exclusively in early stage HAT with no CNS invasion. The disease is linked to the absence of the trypanolytic factor apolipoprotein L-I in the patient. In contrast to human trypanosomiasis, which is endemic in Africa and South America, animal trypanosomiasis is distributed worldwide. Trypanosomiasis due to *T. evansi* is common in Indian livestock and causes a disease called 'Surra' (derived from Hindi word meaning rotten) in cattle. High seropositivity prevalence for *T. evansi* among other villagers of the area indicates frequent exposure to *T. evansi* in the villagers. Subsequently, one infant from Mumbai and another adult from Pune have been diagnosed with trypanosomiasis. There are also reports of a few scientifically unconfirmed cases of human carriers of animal trypanosomes during the last century in India, Malaysia and in Sri Lanka, and these cases always had transient infections (suggesting infection with *T. lewisi*, a common rat parasite). The disease is unlikely to be a major threat to human health, if the human infective strains of *T. evansi* do not infect the central nervous system and remain sensitive to suramin or cause only transient self limiting infection.

AMERICAN TRYPANOSOMIASIS OR CHAGAS DISEASE

Chagas disease is caused by flagellate protozoan, *Trypanosoma cruzi* and is transmitted to man by infected faeces of haematophagous triatomine insects, often called reduviid (kissing) bugs. Contamination of bite wound with infected faeces passed by reduviid bugs result in human infection. Chagas disease can also be transmitted through blood transfusions, organ transplantation, transplacentally, breast milk, consumption of uncooked contaminated food and by accidental laboratory exposure. The disease is characterised by an asymptomatic latent period followed by chronic cardiac and gastrointestinal symptoms.

Clinical Features

There are three stages:

1. *Acute stage* occurs shortly after infection. A local skin nodule accompanied by erythema and induration called a *chagoma* can appear at the site of inoculation with regional lymphadenopathy. *Romana's sign* (unilateral painless periorbital oedema, conjunctivitis and periauricular lymphadenitis) occurs when inoculation site is conjunctiva. Fever, malaise, tiredness, lymphadenopathy, hepatosplenomegaly, rash, myocarditis and meningoencephalitis can be present. The acute phase resolves in 8 to 10 weeks and is followed by
2. *Asymptomatic or indeterminate stage,* in which the infected persons have no symptoms.
3. The *symptomatic chronic stage* develops after 10 to 20 years of infection and some people develop serious irreversible damage to the heart and gastroinstestinal tract. The myocardial damage results in cardiomyopathy, right bundle branch block, atrioventricular block, premature beats, arrhythmias, heart failure, and thromboembolism. Gastrointestinal system involvement causes dilatation of oesophagus (megaoesophagus) and colon (megacolon), with symptoms of dysphagia and constipation. Dementia can also occur in some patients. Most patients die due to cardiomyopathy, if left untreated.

Laboratory Diagnosis

T. cruzi can be demonstrated by microscopic examination of fresh anticoagulated blood or buffy coat and thick and thin blood smears stained with Geimsa. The agent can be isolated by mouse inoculation, culture of blood in specialised media (e.g. NNN, LIT), or xenodiagnosis (where uninfected reduviid bugs are fed on the patient's blood, and their gut contents examined for parasites 4 weeks later). Serologic tests to detect antibodies to *T. cruzi* can be used like complement-fixation or immunofluorescence tests and ELISA. Diagnosis based on molecular techniques like PCR are promising, but not available for routine use.

Treatment

The treatment is unsatisfactorys and effective only when initiated in the acute stage. **Tables 1 and 2** tabulate the drugs, dosage and side effects. Nifurtimox or benznidazole are both toxic and resistance is reported. Amphotericin is used as second line drug, but is also toxic. Allopurinol, fluconazole, itraconazole and recombinant interferon γ are under evaluation. Cardiac and gastrointestinal complications are treated symptomatically.

Prevention

Prevention is important since drug therapy is unsatisfactory and no vaccine is available for commercial use. Preventive measures focus on vector control by use of insecticide sprays and paints,

Table 1: Anti-trypanosomal Drugs

Drug	Indication	Dose	Adverse Effects
Suramin	Stage 1 of *T b. rhodesiense*	20 mg/kg (maximum dose 1 gm per injection), at weekly intervals x 5 doses, as slow IV infusion of freshly prepared 10% aqueous solution, preceded by a test dose of 0.2 ml IV	Common: anaphylactic reactions, renal complications, fever, photophobia, pruritus, arthralgias, exfoliative dermatitis, nausea, vomiting
Pentamidine	Stage 1 *T b. gambiense*	4 mg/kg/day by IM injection for seven consecutive days	Rare and reversible: Hypotension, pancreatitis, hypoglycaemia, arrhythmias, reversible renal failure
Melarsoprol	Stage 2 of *T b. rhodesiense* or *T b. gambiense*	3.6 mg/kg/day slow IV injections for 3 consecutive days. Three such courses repeated at intervals of 8 to 10 days	Severe, sometimes fatal: Reactive encephalopathy (coma, convulsions), in 5 to 10% of treated cases, (fatal in 10 to 70% of afflicted patients), thrombophlebitis, necrosis if drug extravasates, significant drug resistance, exfoliative dermatitis
Elornithine	*T. b gambiense*	400 mg/kg/day administered in four doses daily slow IV infusions diluted in 250 cc isotonic saline solution over 2 hours, (in children 150 mg/kg per infusion) for 7 days where melarsoprol has failed and for 14 days when used as first-line treatment	Common: Anaemia, thrombocytopaenia, diarrhoea, convulsions, hearing loss, vomiting
Nifurtimox	*T. Cruzi*	8 to 10 mg/kg for adults, 12.5 to 15 mg/kg for adolescents, 15 to 20 mg/kg for children 1 to 10 years of age, given orally in four divided doses each day for 90 to 120 days	Abdominal pain, anorexia, nausea, vomiting, and weight loss. Neurological reactions to the drug may include restlessness, disorientation, insomnia, twitching, paraesthesia, polyneuritis and seizures

Table 2: Choice of Anti-trypanosomal Drugs

	Stage 1	Stage 2
West African Trypanosomiasis *(T b. gambiense)*	First line: Pentamidine Second line: Eflornithine or Melarsoprol	Eflornithine or Melarsoprol
East African Trypanosomiasis *(T b. rhodesiense)*	First line: Suramin Second line: Melarsoprol	First line: Melarsoprol Second line: Nifurtimox combined with Melarsoprol

improvement of housing and screening the parasite before blood transfusion in endemic areas.

17.57 Cryptosporidiosis, Trichomoniasis, Balantidiasis and Isosporiasis

Atul Bhasin

CRYPTOSPORIDIOSIS

Introduction

Cryptosporidiosis is caused by *Cryptosporidium*, a protozoan that was identified in 1976, and is one of the most common water-borne diseases found worldwide. Though initially thought to be caused by single species, but recent molecular studies have revealed that several species cause human cryptosporidiosis and there are different hosts for various species—*Cryptosporidium hominis* (human host) and *Cryptosporidium parvum* (bovine and human host). Parasite typically causes acute short-term infection via faeco-oral route through contaminated water. It is an intracellular but extra-cytoplasmic parasite, which contributes to marked resistance to treatment. Contact with fresh water bodies, including recreational (swimming pool), insufficiently treated water supplies, contaminated food, or exposure to faeces makes more susceptible to infection. Single host life cycle results in microbial oocyst stage, which are highly infectious. 10^1 to 10^3 oocysts are required to cause human disease (50% infectious dose, 10^2). These when excreted in faeces are fully capable of transmission to a new host. When ingested, they excyst in the small intestine resulting in an infection of intestinal epithelium. Though it usually presents as self-limiting diarrhoea in immunocompetent host, but it can be fatal in immunocompromised individuals. *Cryptosporidium* is most commonly isolated in HIV positive patients presenting with diarrhoea. Increased risk of transmission is seen in those who swim in pools with insufficient sanitation (chlorine resistant strains of *Cryptosporidium*), child care workers, parents and health care associated workers taking care of people with cryptosporidiosis. Drinking unfiltered, untreated water and people exposed to human faeces through rectal sexual contact are also at risk.

Clinical Features

Presentation is asymptomatic, acute or persistent chronic diarrhoea. Diarrhoea with mucous, abdominal cramps, low-grade fever, nausea, vomiting and dehydration is seen in acute cases, while chronic infection presents with persistent loose stools, malabsorption and weight loss. The parasite can infect the biliary tract, causing biliary cryptosporidiosis, resulting in cholecystitis, cholangitis and pancreatitis. Immunocompromised people and those at extremes of age have very severe disease. Water loss exceeding up to 2 litres per day, severe malabsorption with weight loss are seen in severest forms. In AIDS, extra-intestinal involvement is seen involving lungs, middle ear, pancreas, biliary tract.

Diagnosis

It is diagnosed by stool microscopy—staining and detection of antibodies. Microscopic identification of oocysts in faeces by using concentrating methods like modified formalin-ethyl acetate (FEA), modified zinc sulphate centrifugal floatation technique and Sheather's sugar floatation procedure are utilised. Inspection of at least 3 stool samples increase sensitivity. Fluorescent microscopy is done by staining with auramine. Detection by modified acid-fast or direct fluorescent antibody (DFA), indirect immunofluorescence assay and ELISA are helpful. Polymerase chain reaction (PCR) can identify the species specifically.

Treatment

Immunocompetent host usually has self-limiting disease, thus requiring only supportive rehydration till spontaneous recovery is achieved. Nitazoxanide 500 mg twice daily for 3 days can be used to combat diarrhoea, while spiramycin can help shorten the amount of time oocytes are passed as well as duration of diarrhoea in children. In immunocompromised individuals, Cryptosporidiosis resolves slowly or never at all. Patients with CD4+ counts greater than 180 cells/mm^3 recover well with medication and supportive care, but in counts below 50 cells/mm^3 it is fatal within 3 to 6 months. Nitazoxanide, paromomycin, and azithromycin in combination with anti-retroviral therapy that includes an HIV protease inhibitor is associated with marked improvement. Nucleoside reverse transcriptase inhibitors are malabsorbed in chronic cryptosporidiosis, thus active anti-parasitic drugs should be administered prior to anti-retroviral therapy.

Prevention

Enhancing the immune status with probiotic, *Saccharomyces boulardii*, and somatostatin analogues (octreotide acetate) are partially beneficial in reducing resistant secretory diarrhoea. Handwashing after contacting stool and sanitation system prevents its spread. Patients should avoid anal sexual activity and swimming in communal bathing areas for at least 2 weeks after diarrhoea stops, as *Cryptosporidium* resides in the ano-genital region. Boiling water and filtering with conventional filtration technologies, slow sand filters diatomaceous earth filter and membranes can remove 99% of *Cryptosporidium*.

TRICHOMONIASIS

Introduction

Trichomoniasis is a sexually transmitted disease caused by protozoan *Trichomonas vaginalis* and is a common cause of vaginitis. It is primarily an infection of the urogenital tract.

Clinical Features

It usually presents as intense itching and burning sensation with frothy and foul-smelling discharge. Incubation period is 5 to 28 days, though dormant infection can last for years. Women are more symptomatic then men. Men usually present with irritation inside the penis, discharge, or burning after urination/ejaculation.

Diagnosis

It can be done microscopically by PAP test or smear demonstrating trichomonas (pear-shaped multi-flagellar parasites with whip like tails at one end). Chronic infection causes increased risk of premature births, cervical cancers, transmission of HIV in women and prostatic cancers in males.

Treatment

In both pregnant and non-pregnant women, metronidazole or tinidazole 2 g by mouth as single dose can be given except in the first trimester of pregnancy, where clotrimazole is used topically. Single high dose of metronidazole could cause nausea and vomiting and, therefore, alternatively metronidazole 500 mg twice a day for 7 days can be administered. In pregnant women clotrimazole vaginal tablets are administered at night for 14 days. It decreases symptoms, but the cure rate is only 20%. Asymptomatic sexual partners need concurrent treatment as re-infection often causes treatment failure. Use of male condoms may help in preventing its spread.

BALANTIDIASIS

Introduction

Balantidiasis also known as balantidiosis, is a large-intestinal infection (from caecum to rectum) with a protozoan called *Balantidium coli*. It is the largest ciliated protozoan, infecting humans handling pigs or water and fertiliser contaminated with pig excrement. Protozoa dwell in the intestinal lumen, but can cause penetrating mucosal ulcers.

Clinical Features

Immunocompetent individuals are asymptomatic. Usual symptoms are diarrhoea (watery, bloody and mucoid), nausea, vomiting, abdominal pain, anorexia, weight loss, fever and marked fluid loss.

Diagnosis

Microscopic examination of stool or tissue obtained via colonoscopy, demonstrate trophozoites. Repeated stool collection and immediate examination enhances its detection.

Treatment

Drug of choice is tetracycline. Metronidazole and iodoquinol are alternatives. Tetracycline is contraindicated in pregnancy and in children less than 8 years of age.

Prevention

Effective personal and community hygiene, purification of drinking water, proper handling of food, careful disposal of human faeces and monitoring the contacts of balantidiasis patients contains its spread.

ISOSPORIASIS

Introduction

Isosporiasis is an intestinal disease caused by the protozoan *Isospora belli* seen commonly in tropical and sub-tropical areas in immunocompromised individuals. Humanbeings are the only known hosts for *Isospora belli*, with no known animal reservoir. Commonly seen in persons with AIDS, but is being increasingly reported in patients with lymphoma, leukaemia, renal and liver transplant recipients. Increased prevalence is being seen due to widespread use of *Pneumocystis jiroveci* pneumonia prophylaxis with trimethoprim-sulphamethoxazole in HIV-infection.

Clinical Features and Diagnosis

It is an initial AIDS-defining illness in approximately 0.2% of patients. This infection is transmitted from person to person by faeco-oral route and usually has a mild and protracted course, unless host is immunocompromised. Profuse, watery, non-bloody, offensive-smelling diarrhoea, with mucous, cramping pain, vomiting, anorexia, weight loss, low-grade fever and steatorrhoea are usual presentations. Peripheral eosinophilia is an important clue. Multiple stool specimens showing large oocysts on modified acid-fast stains along with Charcot-Leyden crystals clinch the diagnosis. There are no serologic tests for isosporiasis. Auramine-rhodamine fluorescent, modified Kinyoun acid-fast stain, ultraviolet autofluorescence microscopy, zinc sulphate or sugar floatation-stool concentration technique and a recent promising real-time polymerase chain reaction (PCR) are helpful in diagnosing the parasitic infestation. Examination of duodenal aspirate or string test may aid in the diagnosis.

Treatment

Treatment of choice is with trimethoprim-sulphamethoxazole 160/800 mg 4 times per day for 10 days. For HIV-infected individuals, extended treatment, 3 times daily for 3 more weeks is required. In patients intolerant to TMP-SMX combination, pyrimethamine 50 to 75 mg daily can be given for 2 to 4 weeks.

17.58 Ankylostomiasis, Ascariasis and Other Nematodal Infestations

Narender Pal Jain

Diseases caused by Helminths are referred to as Helminthiasis. It is estimated that more than 3 billion people live with helminths across the world. Helminths are intestinal parasitic worms, nematodes (roundworms) and two groups of the trematodes (flukes) and cestodes (tapeworm). They have large variation in size, complex life cycle and migratory habits within their host. Helminths do not multiply in humans (*Strongyloides stercoralis* being an exception), so repeated or prolonged exposure may be needed for acquisition of sufficiently high worm burdens for symptomatic infections to develop. Stool examination helps in the diagnosis (**Figure 1**).

NEMATODES

Nematodes belong to the phylum nematoda (Ancient Greek words- nema and ode means thread and like, respectively). Nematodes commonly parasitic on humans include ascarids (*Ascaris*), filarids, hookworms, pinworms (*Enterobius*), and whipworms (*Trichuris trichiura*). They are non-segmented, fusiform, cylindrical shape with a complete digestive system with oral and anal openings; and have a tough outer coating (cuticle) that may be smooth or textured, generally cream-white in colour. They are divided into intestinal, tissue-dwelling roundworms and those which are parasitic to humans only or zoonotic infections (**Table 1**).

Table 1: Nematodes or Round Worms

Intestinal human nematodes: *Enterobius vermicularis, Ascaris lumbricoides, Trichuris trichiura. Necator americanus, Ankylostoma duodenale, Strongyloides stercoralis, Capillaria philippinensis*

Tissue-dwelling human nematodes: *Wuchereria bancrofti, Brugia malayi, Loa loa, Onchocerca volvulus* (all filarial worms), *Dracunculus medinensis* (Guinea worm)

Zoonotic nematodes: *Toxocara canis, Ankylostoma braziliense, Oesophagostenum* species, *Angiostrongylys cantonensis, Trichinella spiralis, Gnathostoma spinigerum*

INTESTINAL HUMAN NEMATODES

Ankylostomiasis (Hookworm Infestation)

Aetiopathogenesis and epidemiology

Common hookworms are *Ankylostoma duodenale* and *Necator americanus*. Both species may infect the same person. The highest incidence of infection is in men in their second and third decades of life.

The two principal species vary slightly in size and structure, with the adult female *Ankylostoma duodenale* measuring 10 to 13 mm in length and 0.6 mm in diameter, whereas the male is 8 to 11 mm long and 0.45 mm wide. *Necator americanus* is a shorter and more slender worm, with the female measuring 9 to 11 mm in length by 0.35 mm in width and the male being 5 to 9 mm long by 0.3 mm wide. Adult hookworms are creamy white in colour when alive but grey when dead. When engorged with blood, they are reddish-brown.

The adult hookworm may remain alive in the intestine for as long as 6 years. The female *Ankylostoma* produces 25,000 to 35,000 eggs per day or up to 50 million in her life-time; the female *Necator* is less productive, producing a mere 6,000 to 20,000 eggs per day. Within 48 hours, eggs double in size, molts, and become a second-stage rhabditiform larva. Within a week after first hatching, it will again molt to become a third-stage or infective filariform larva while feeding upon the faeces in moist earth or water.

Humans are infected when larvae penetrate the skin of the foot and then they enter venules or lymphatics. By either route they reach the pulmonary capillaries and break into alveoli, from where they migrate up the bronchioles and trachea and pass over the epiglottis and down the oesophagus to mature in the small intestine, usually the jejunum. Here they molt again to become fourth-stage larvae possessing a buccal capsule by which they attach themselves to the intestinal mucosa. Within a week, a fourth and final molt results in development of the adult parasite. Female begins laying eggs within 2 months after the larvae penetrate the skin (**Figure 2**).

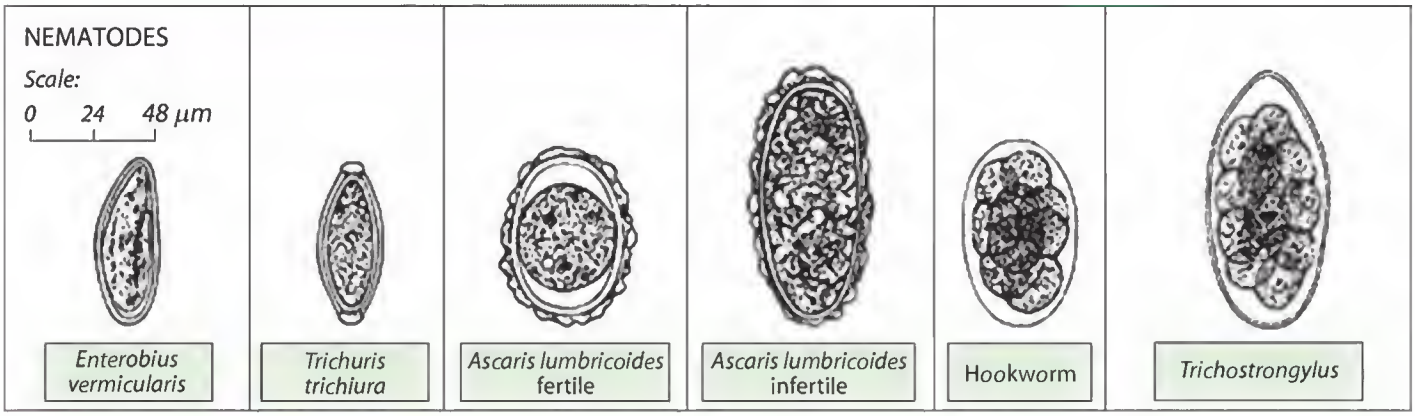

Figure 1: Ova and cysts of helminths found in the stool.

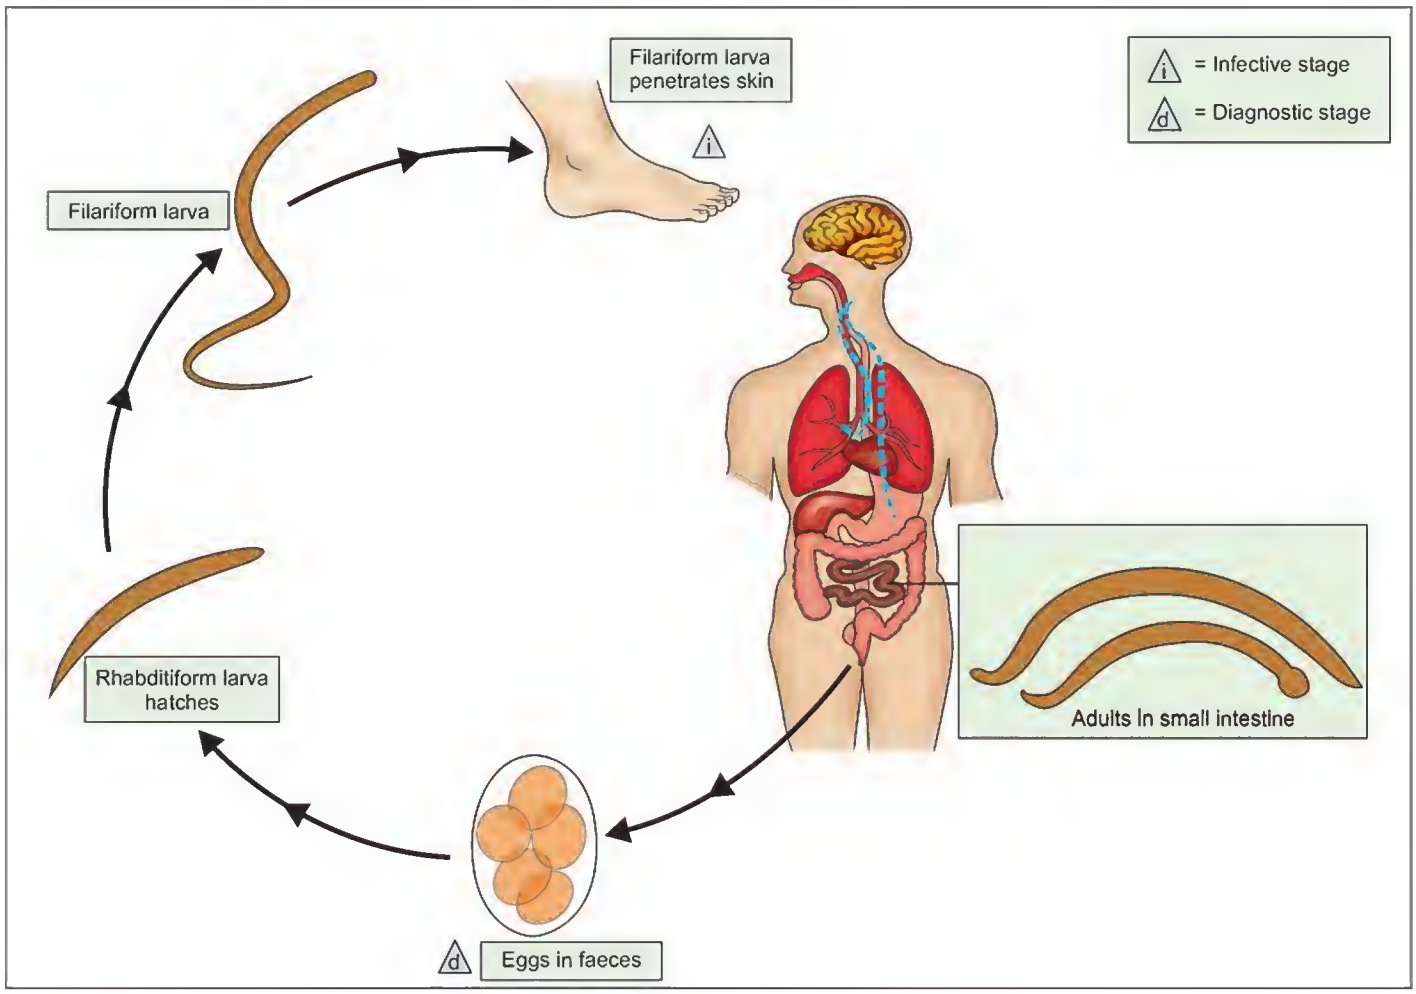

Figure 2: Life-cycle of *Ankylostoma duodenale*.

Clinical features

The disease caused by worms is classified into two phases clinically; namely, the phase of migration and development, and the symptomatic phase. In the migratory phase, pruritus, erythema and vesiculation will occur once the filariform larvae have penetrated the skin of the feet or hands. This is known as 'ground or dew itch' in people who go barefoot. Within 1 to 2 weeks, pulmonary symptoms may develop. The pulmonary symptoms are more common with *A. duodenale* and enteritis with *N. americanus* infection.

Diagnosis

The diagnosis of clinical Ankylostomiasis is usually made by counting the number of eggs in direct saline smear of a fresh sample of faeces or by a stool concentration method. Sputum examination may reveal occult blood, eosinophils and rarely migrating larvae. A skin test antigen derived from *N. americanus* has been used for screening populations.

Treatment

Mebendazole 100 mg twice a day for three days or single dose of albendazole 400 mg. Alternative drugs are pyrantel pamoate 10 mg/kg dL for 3 or 4 doses and a single dose of ivermectin 200 µg/kg.

Ascariasis

Ascaris lumbricoides is the largest of the intestinal nematodes affecting humans, measuring 15 to 35 cm in length in adulthood. The gravid female produces 2, 50,000 eggs daily. These take 3 or 4 weeks to develop into infective stage. Once ingested, eggs hatch, usually in the small intestine, releasing small larvae that penetrate the intestinal wall. Larvae migrate to the pulmonary vascular beds and then to the alveoli via the portal veins usually 1 to 2 weeks after infection. After migrating up the respiratory tract and being swallowed, they mature, copulate and lay eggs in the intestines. Adult worms may live in the gut for 6 to 24 months, where they can cause partial or complete bowel obstruction in large numbers, or they can migrate into the appendix, hepatobiliary system, pancreatic ducts, kidneys or brain (**Figure 3**).

Clinical features

Most patients are asymptomatic. When symptoms occur, they are divided into 2 categories: early (larval migration) and late (mechanical effects).

- In the early phase (4 to 16 days after egg ingestion), respiratory symptoms result from the migration of larvae through the lungs with symptoms of eosinophilic pneumonia (Löffler syndrome). Patient may present with fever, non-productive cough, dyspnoea, wheezing.
- In the late phase (6 to 8 weeks after egg ingestion), gastrointestinal symptoms may occur. Patient may present with passage of worms (from mouth, nose and anus) diffuse abdominal pain, nausea, vomiting, biliary and intestinal obstruction, appendicitis and pancreatitis.

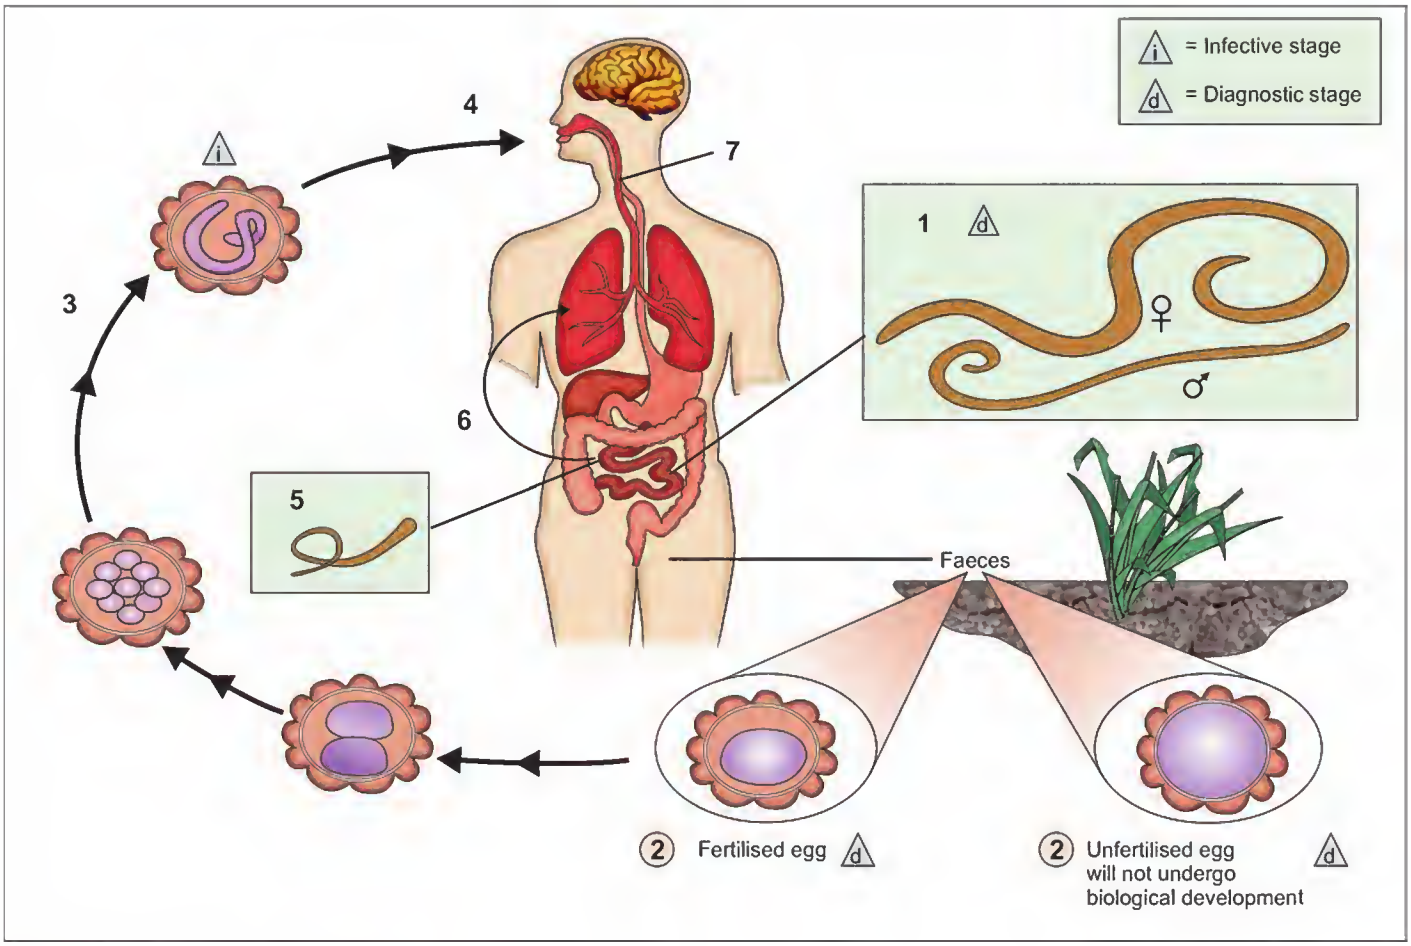

Figure 3: Life-cycle of *Ascaris lumbricoides*.

Diagnosis

1. In early infection (larval migration) complete blood count (CBC) may show peripheral eosinophilia. Sputum analysis may reveal larvae or Charcot-Leyden crystals. Chest radiograph may reveal patchy infiltrates of eosinophilic pneumonia.
2. In late infection (adult phase): Microscopic examination findings of stool show characteristic eggs. Abdominal radiographs or contrast computed tomography scans may reveal adult worms or cylindrical filling defects, respectively. Magnetic resonance cholangiopancreatography (MRCP) may detect adult worms in bile or pancreatic ducts.

Treatment

Albendazole 400 mg one dose orally is the drug of choice. Alternative therapy is mebendazole 100 mg bid for three days, pyrantel pamoate 10 mg/kg, and nitazoxanide 500 mg bid for three days.

Mebendazole is not recommended during pregnancy. Paralysing vermifuges (e.g. pyrantel pamoate, piperazine, ivermectin) should be avoided in patients with complete or partial intestinal obstruction since the paralysed worms may necessitate or further complicate surgery.

Surgical therapy

Conservative management of partial intestinal obstruction and biliary ascariasis is usually effective.

- Recommended criteria for surgical exploration include the following:
  - Passage of blood per rectum
  - Multiple air fluid levels on abdominal radiographs
  - An ill child with abdominal distension and rebound tenderness
  - Unsatisfactory response to conservative therapy
  - Appendicitis and primary peritonitis
  - Hepatobiliary disease
  - Pancreatic pseudocyst

Enterobiasis

Pinworm (*Enterobius vermicularis*), is prevalent throughout the temperate regions of the world.

Aetiopathogenesis

E. vermicularis is a white slender nematode with a pointed tail. In humans, they reside in the caecum, appendix and ascending colon. Female pinworms (8 to 13 mm long) are larger than their male counterparts (2 to 5 mm long). Pinworm infection is primarily a paediatric condition. Transmission can occur via direct contact with contaminated furniture, bed clothes, toilets and sexual contact. A gravid female pinworm migrates to the anal area and inserts her tail pin into the mucosa for ova deposition (**Figure 4**).

Clinical features

Pinworm infection is generally asymptomatic. The primary symptoms of pinworm infection usually occur at night which include pruritus or a prickling sensation in the perianal area.

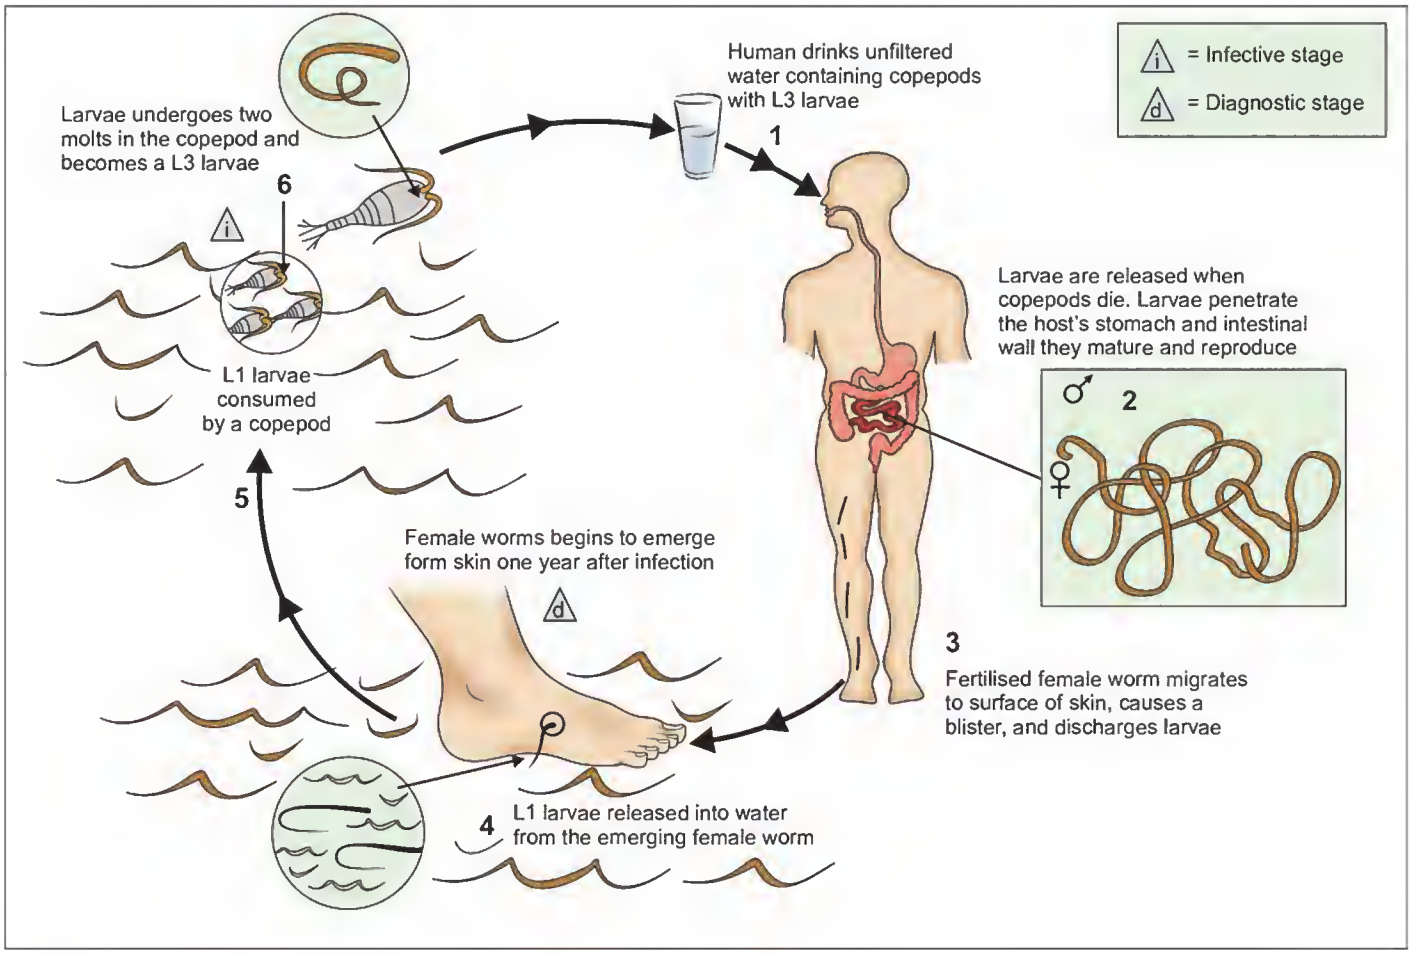

Figure 4: Life-cycle of *Entrobius vermicularis*.

Diagnosis

Use a perianal cellophane swab or cellophane tape to detect eggs.

Treatment

A single dose of mebendazole 100 mg or pyrantel pamoate 10 mg/kg or piperazine 4 gm is given and may be repeated after 2 weeks to control auto-reinfection. Treat all family members. Prescribe drugs at least 3 times at 3-week intervals.

Trichuriasis

Trichuris trichiura (whipworm) infects about one quarter of the world's population.

Aetiopathogenesis and epidemiology

The infection is common in India and South-East Asia. Poor hygiene and poor sanitary conditions are associated with trichuriasis transmission, and children are especially more vulnerable to the disease.

The whipworm derives its name from its characteristic whiplike shape; the adult male is 30 to 45 mm in length and adult female is 35 to 50 mm in length. It buries its thin, thread-like anterior half into the intestinal mucosa and feeds on tissue secretions, not on blood. The caecum, descending colon and rectum are the most commonly infected sites (**Figure 5**).

Clinical features

Most patients are asymptomatic. Patients may present with nocturnal loose stools, failure to thrive, vague abdominal discomfort, stunted growth. *Trichuris* spreads via faecal-oral transmission. Worms may live from one to five years. Adult female poduces up to 20,000 eggs per day.

Diagnosis

Complete blood count shows eosinophilia and anaemia. Stool examination reveals oval eggs with transparent bipolar plugs. Sigmoidoscopy shows adult worms attached to the bowel mucosa.

Treatment

Mebendazole 100 mg 12 hourly for 3 to 5 days or a single dose of pyrantel palmoate 10 mg/kg is effective.

Strongyloidiasis

The most common and clinically important pathogenic species in humans is *Strongyloides stercoralis*. The parasitic female worm is a very small nematode (2 mm × 0.4 mm).

Aetiopathogenesis

The life-cycle of *S. stercoralis* is complex and has two types of life-cycles – a free living life cycle and a parasitic life-cycle.

Human infection is acquired via penetration of intact skin by filariform larvae during contact with contaminated soil. The larvae then enter the circulation and are carried haematogenously to the lungs, where they enter the alveolar space. They then ascend the tracheobronchial tree and are swallowed. When they reach the small bowel, they molt twice and mature into adult females (2 mm × 0.05 mm in diameter).

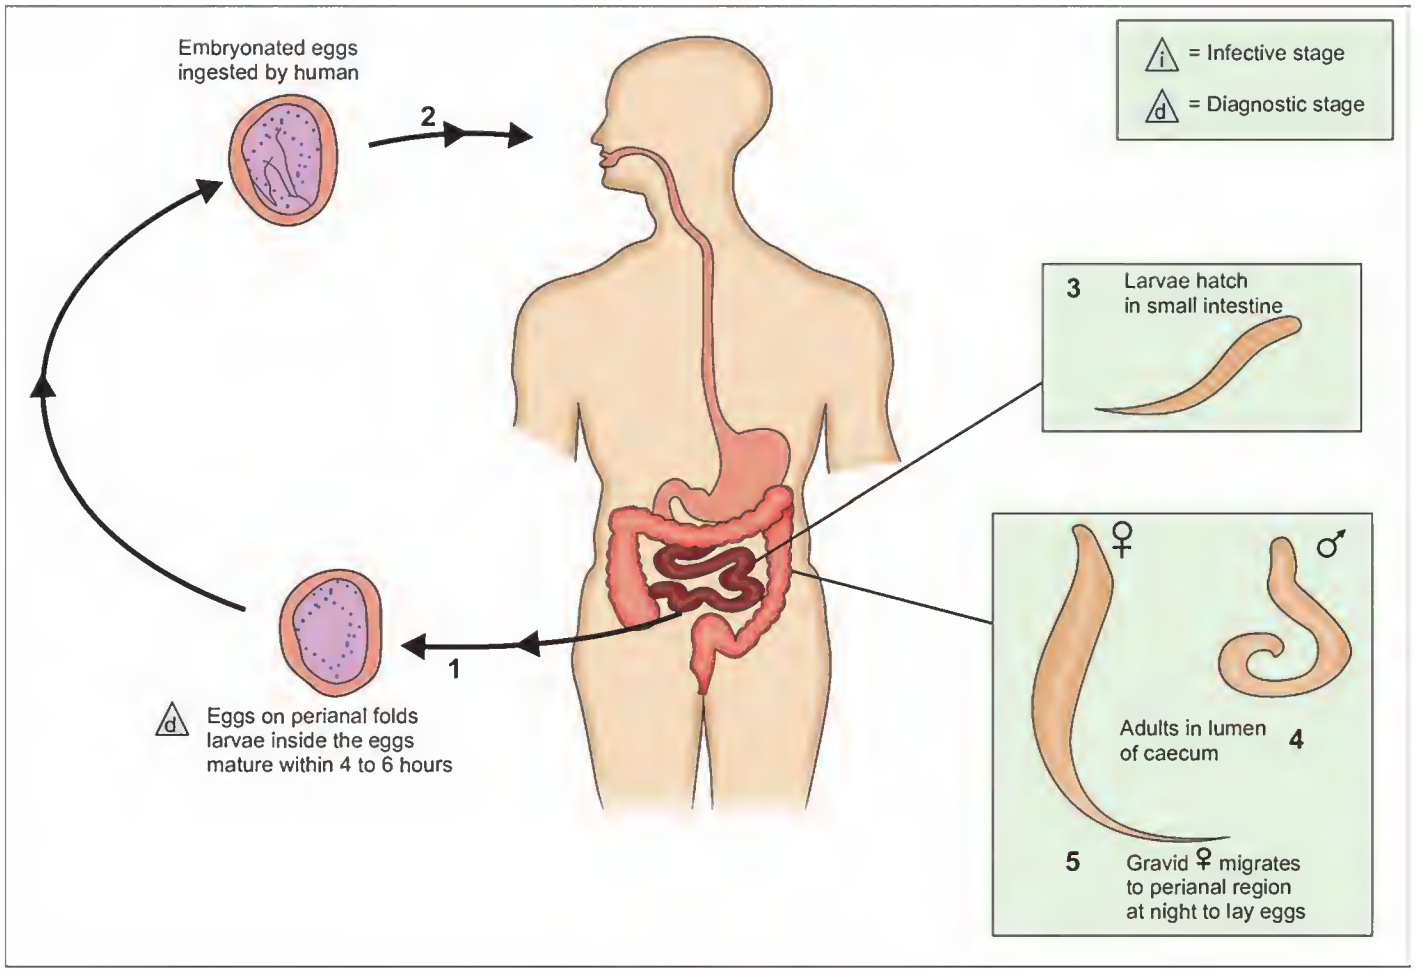

Figure 5: Life-cycle of *Trichuris trichiura*.

All parasitic adult worms are females. The parasitic females produce eggs via parthenogenesis. These eggs hatch into non-infective rhabditiform larvae, which may then be passed through the stool into the environment, where they mature into adult males and females. Alternatively, they may cause autoinfection (**Figure 6**).

Clinical features

- Acute strongyloidiasis presents with pruritic erythematous maculopapules at the site of larval skin penetration, usually on the feet, wheezing, low grade fever.
- Chronic strongyloidiasis presents with epigastric tenderness, urticaria. Larva currens ('racing larva') – Rapidly progressive serpiginous wheels beginning perianally and extending to the buttocks, upper thighs and abdomen at a rate of 5 to 10 cm/hr.
- Severe strongyloidiasis presents with diffuse abdominal tenderness, abdominal distension, absent bowel sounds, vomiting, haematemesis and haematochezia; altered mental status, rash over the trunk and proximal extremities, cough, wheezing, haemoptysis and fever.

Investigations

Complete blood count with eosinophillia (600/mm^3) is common in acute infection.

Diagnosis is established by motile larvae seen on microscopic examination of the faeces, by using special methods, such as the Baermann funnel method, the Harada-Mori filter paper method and the agar plate method. Serology (e.g. enzyme immunoassay, indirect fluorescent antibody) is helpful.

Treatment

Ivermectin 200 µg/kg as a single dose or 2 doses. Albendazole can be given in dose of 15 mg/kg twice daily for 3 days. For systemic strongyloidosis, ivermectin is given at 200 µg/kg on day 1, 2, 15 and 16.

Dracunculiasis

Dracunculiasis is an infection caused by the nematode *Dracunculus medinesis*, also known as the guinea fire worm. It was eradicated from India about a decade before.

ZOONOTIC NEMATODES

Toxocariasis

Visceral larva migrans is caused by the migration of larvae through the internal organs of humans and the resulting inflammatory reaction. It is mainly caused by migrating larvae in the dog (*Toxocara canis*) and cat (*T. oxocara catis*).

Epidemiology and aetiopathogenesis

Adult worms of the *Toxocara* species live in the small intestine of dogs and puppies. During the summer and in wet conditions, Toxocara eggs are embryonated in 2 to 5 weeks and become infective. They survive for years in the environment, and humans typically ingest the eggs via oral contact with contaminated

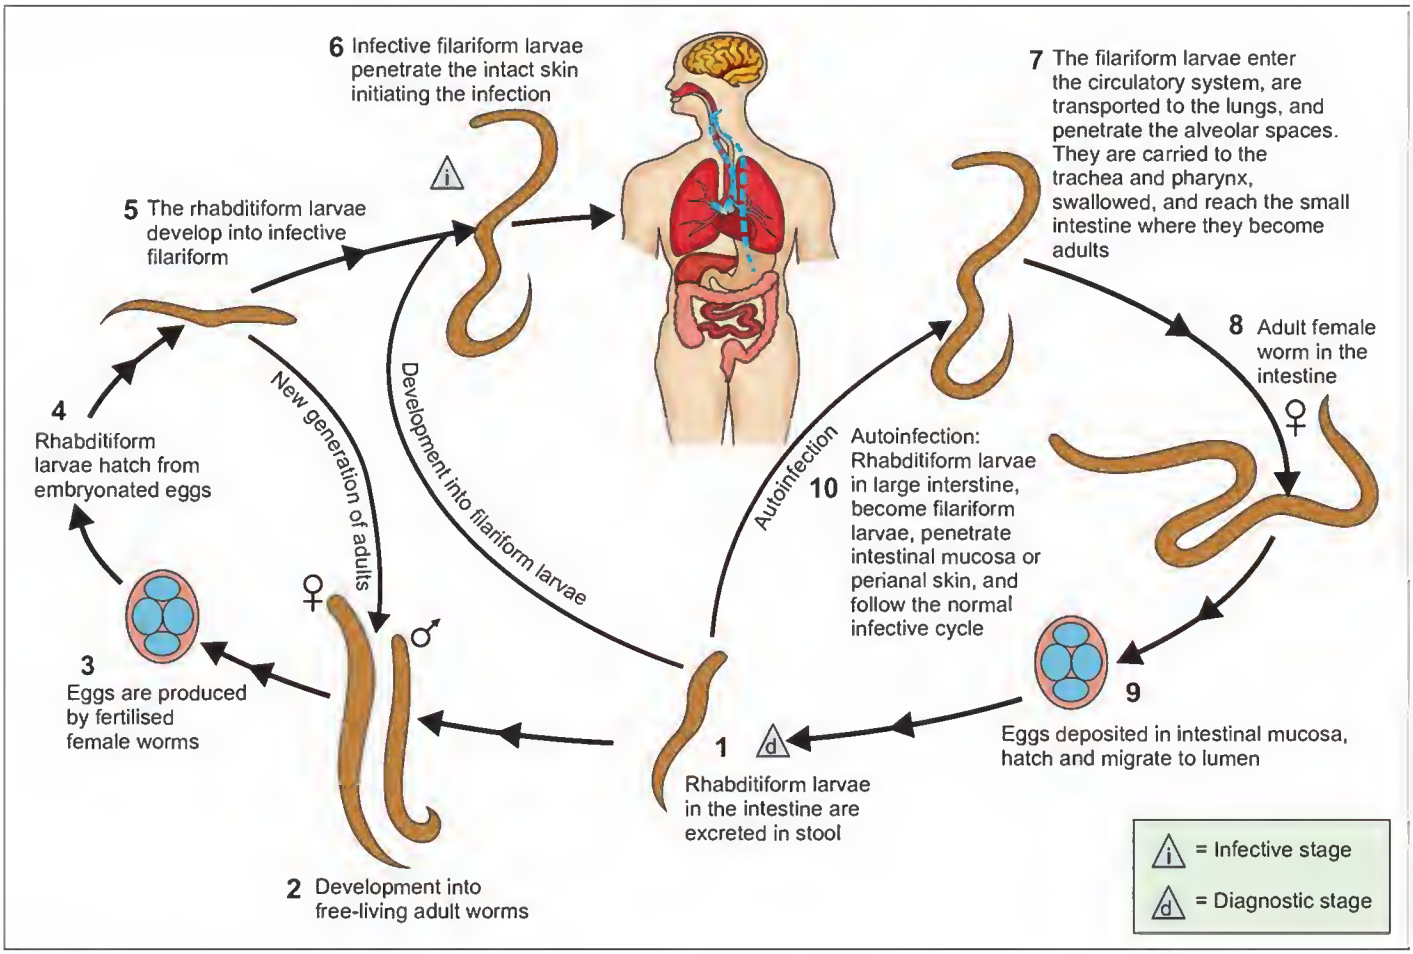

Figure 6: Life-cycle of *Strongyloides stercoralis*.

hands. Once introduced into the human intestine, the eggs decorticate, releasing the larvae. The larval form is visible only under a microscope because it is less than 0.5 mm in length and 0.02 mm wide. The larvae penetrate the bowel wall and migrate through vessels to the muscles, liver, lungs and sometimes to the eye and brain.

Clinical features

Toxocariasis cause two different clinical pictures, subclinical toxocariasis or the classical visceral larva migrans syndrome and the ocular toxocariasis.

Classical visceral larva migrans: Patients in the acute phase may have abdominal pain, decreased appetite, fever, wheezing, history of seizures, ocular involvement- decreased visual acuity, seeing floaters or bubble like images.

Ocular larva migrans: Patients with ocular involvement may present with retinal detachment due to traction caused by retinal fibrosis, pre-papillary inflammation and peripheral retinal exudates. Fundoscopic examination reveals rounded swelling near the optic disc.

Diagnosis

Leucocytosis with peripheral blood eosinophilia is the most important finding. When ocular toxocariasis is suspected ELISA of aqueous fluid for toxicariasis is useful. Chest radiography may show multiple pulmonary nodules or pleural effusion. Ultrasonography reveals multiple hypoechoic areas in the liver. CT scan may reveal hepatic lesions, multiple pulmonary nodules and surrounding ground-glass opacities or, pleural effusion or CNS granulomas.

Treatment

Mebendazole 1 gm 3 times a day for 21 days or Thiabendazole 25 mg/kg twice daily for 5 days is effective.

In ocular larva migrans, ocular involvement with retinal detachment, photocoagulation by laser treatment may be considered. Vitrectomy and use of steroids (local and intraocular) have shown good results.

Trichinosis

Trichinosis is the result of infection by the nematode *Trichinella spiralis*. Humans are infected incidentally when they eat inadequately cooked meat that contains larvae of *Trichinella* species.

Epidemiology and aetiopathogenesis

Trichinella species require 2 hosts to maintain their life-cycle. The free larvae migrate into the small intestine. After 4 molts and over a period of 30 to 36 hours, they develop into adult worms. The adult male measures 1.5 × 0.05 mm, and the adult female measures 3.5 × 0.06 mm. Approximately 5 days after infection, the female begins shedding live newborn larvae (L1 stage). The female remains in the intestine for 4 weeks, releasing up to 1500 larvae. After an adequate inflammatory response develops in the intestine, the female is eventually expelled in the faeces.

The newborn larvae enter the lymphatics and blood circulatory system and migrate to well-vascularised striated skeletal muscle. The larvae continue to grow over the next 2 to 3 weeks until they reach the fully developed L1 infective stage, when they increase in size up to 10-fold. The complete cycle takes 17 to 21 days. Life-cycle is complete when a compatible host ingests the infected muscle.

Clinical features

The degree of infection is categorised as light (0 to 10 larvae ingested), moderate (50 to 500 larvae ingested), or severe (>1000 larvae ingested).

Trichinellosis may manifest as an enteric (i.e. intestinal) phase, parenteral (i.e. invasive) phase, convalescence phase.

The enteric phase (intestinal) causes symptoms in the first week of illness. The patients may have diarrhoea, constipation, anorexia, and diffuse weakness may occur.

The parenteral (invasive) phase corresponds to the migration of the larvae from the intestine to the circulatory system and eventually to the striated muscles. This phase is associated with severe myalgia, headache, deafness, ocular disturbances, monoparesis, dyspnoea, cough and hoarseness.

The convalescent phase, which corresponds to encystment and repair, may be present for months to years after infection. The encystment of larvae can lead to cachexia, oedema and extreme dehydration.

Diagnosis

It is based on clinical, laboratory and epidemiological criteria:

- Clinical criteria: At least 3 of the following: (1) fever, (2) muscle soreness and pain, (3) gastrointestinal symptoms, (4) facial oedema, (5) eosinophilia (> 1000 eosinophils/mm^3) or (6) subconjunctival, subungual, and retinal haemorrhages.
- Laboratory criteria: At least 1 of the following: (1) demonstration of *Trichinella* larvae in tissue obtained by muscle biopsy, or (2) demonstration of *Trichinella*-specific antibody response by indirect immunofluorescence, ELISA, or Western blot.
- Epidemiological criteria: At least one of the following:
  1. Consumption of laboratory-confirmed parasitised meat
  2. Consumption of potentially parasitised products from a laboratory-confirmed infected animal
  3. Epidemiological link to a laboratory-confirmed human case by exposure to the same common source.

Treatment

If tissue invasion occurs, the most effective treatment modalities include bed rest, analgesics and antipyretics. Within one week of ingestion of contaminated meat, administer albendazole (5 mg/kg/dL for 1 week), mebendazole (5 mg/kg/dL for 8 to 14 days), or thiabendazole (25 mg/kg/dL for 8 to 14 days). Prednisone at 50 mg/dL can be used in involvement of the central nervous system, cardiac or pulmonary system.

Angiostrongyliasis

Cerebrospinal angiostrongyliasis (eosinophilic meningitis)

Angiostrongyliasis is caused by *Angiostrongylus cantonensis*, a nematode parasite that is considered the most common infectious cause of eosinophilic meningitis. Most of the described cases have occurred in Asia and the Pacific Basin.

Pathogenesis: Various species of rats are the definitive hosts of the parasite, also known as the rat lungworm. Infected rats shed first-stage larvae in their faeces, which are infective for snails and slugs but not for humans or for transport hosts.

Snails and slugs serve as intermediate hosts. Snails, fresh water shrimps, prawns, crabs, frogs and slugs become infected by ingesting first-stage larvae in rat faeces. These immature larvae mature to third-stage larvae, which are infective for rats (in which they develop to adult worms), humans, and various other animals.

Clinical features: Ingested larvae can migrate to the central nervous system and cause eosinophilic meningitis. Typically, the incubation period is 1 to 3 weeks. Common manifestations include fever, headache, photophobia, stiff neck, nausea, vomiting, fatigue and body aches. Abnormal skin sensations (e.g. tingling or painful feelings) are more common. Severe cases can be associated with sequelae (e.g. paralysis, blindness) or death.

Diagnosis: Cerebrospinal fluid examination in bright light with hand lens may show tiny moving larva. The opening pressure of CSF is usually high, over 500 mm of water. RBCs may be seen occasionally and eosinophils form 10% to 90% of cells in the CSF. Confirmation of the diagnosis is by detecting *Angiostrongyliasis cantonensis* larvae in the CSF.

Treatment and clinical course: The larvae die spontaneously, and supportive care usually suffices (e.g. analgesics and sedatives). Antihelminthics should not be given because the reaction to the dead worms in the brain can be disastrous.

The use of corticosteroids like prednisolone 0.5 to 1.0 mg/kg/dL is advocated in critical cases with cerebral involvement and in those with cranial nerve involvement.

Abdominal angiostrongyliasis (eosinophilic enteritis)

Abdominal angiostrongyliasis (eosinophilic enteritis) is caused by *Angiostrongylus costaricensis*. Cases have been reported from Central and South America and occur most commonly in young children.

17.59 Tapeworm and Hydatid Diseases

Anurag Saxena

Parasitic helminthic infestations are an important cause of morbidity and mortality in the humans, worldwide, but the low-income countries are the worst affected. The helminths that commonly infest humans include soil-transmitted intestinal nematodes (roundworms), trematodes (flukes) and cestodes (tapeworms).

INTRODUCTION

The adult tapeworm consists of a head (scolex); a neck; and a segmented body, which contains multiple segments, called proglottids (**Figure 1**). Once anchored to the host's intestinal wall with its scolex, the tapeworm absorbs nutrients through its integument as the food being digested by the host flows past it and it begins to grow a long tail, with each proglottid containing an independent digestive system and reproductive tract. True tapeworms are exclusively hermaphrodites having both male and female reproductive systems in each of their proglottids. Older proglottids are pushed toward the tip of the tail as new ones are produced by the neckpiece. These mature and gravid proglottids leave the host in its faeces. Adult tapeworms, especially. *Taenia* species, can measure up to 50 feet long and can survive as long as 20 years in a host.

CLASSIFICATION OF TAPEWORMS

There are three tapeworm species that are commonly found in the Indian subcontinent – *Taenia solium* (pork tapeworm), *Taenia saginata* (beef tapeworm) and *Echinococcus granulosus* (hydatid tapeworm).

TAENIA SOLIUM AND TAENIA SAGINATA

Out of about nine Taenia species causing infection in humans (*T. solium, T. saginata, T. asiatica, T. taeniformis, T. bremneri, T. africanus, T. multiceps, T. serialis and T. glomerulatus*), *Taenia solium* (pork tapeworm) and *Taenia saginata* (beef tapeworm) are the commonest tapeworm infections that are prevalent in India. *Taenia solium* is Latin for 'Ribbon Throne'. Ribbon is a reference to the flattened appearance of the tapeworms in the genus *Taenia*, while 'throne' is a reference to the ring of hooks present on its scolex.

Pathogenesis

Taeniasis (taenia infection) spreads by ingestion of raw or undercooked beef (*T. saginata*) or pork (*T. solium*) infected with cysticerci or by ingestion of tapeworm eggs through contaminated water and food. Humans are the primary host harbouring the adult tapeworm. The life-cycle of both *T. solium* and *T. saginata* are similar, with the exception of having a different intermediate host-pig for *T. solium* and cattle for *T. saginata* (**Figure 2**).

T. solium (pork tapeworm) larvae—cysticerci, can invade the human tissue and inhabit various organs of the human body, e.g. skeletal-muscles, brain, spinal cord or eyes. The most common of these sites being the brain tissue and this infection is known as neurocysticercosis (NCC). In humans, adult *T. solium* worm infestation also carries a risk of autoinfection (in approximately 25% of cases) due to reverse peristalsis of gravid

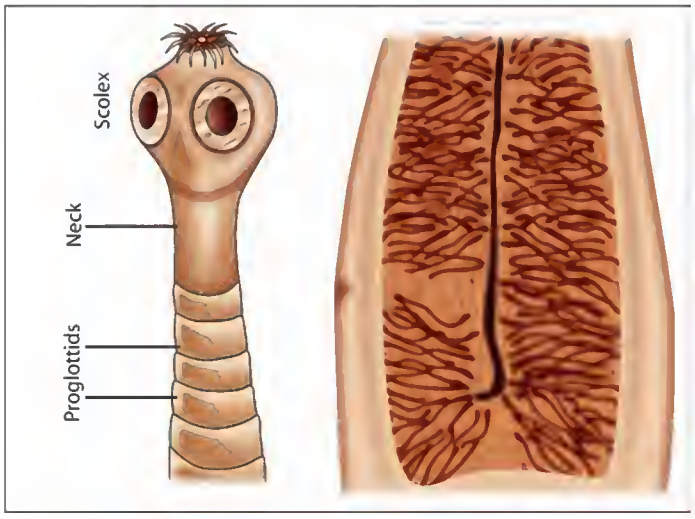

Figure 1: Tapeworm showing scolex, neck and gravid proglottid.

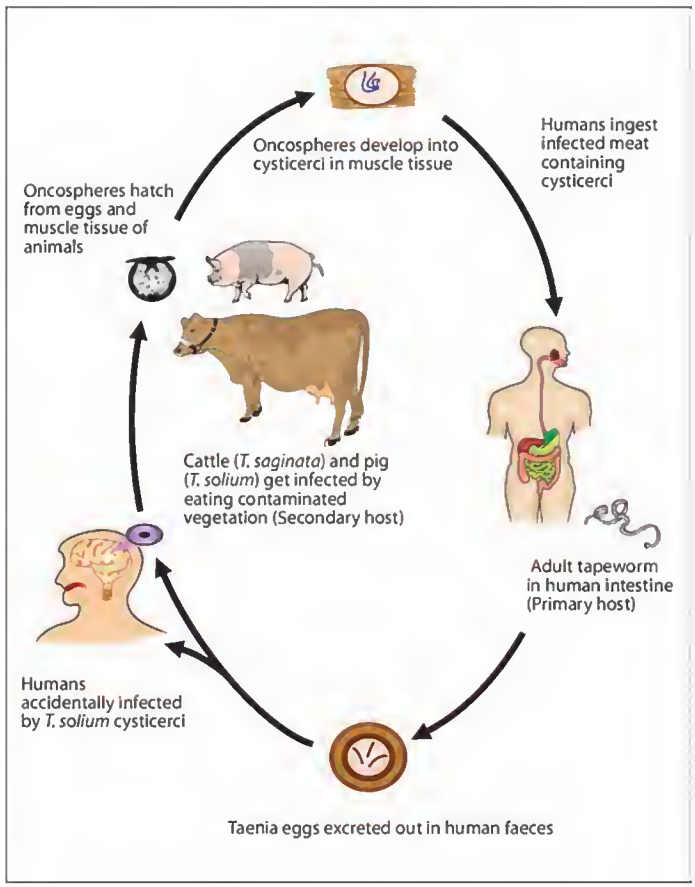

Figure 2: Life-cycle of *Taenia solium* and *Taenia saginata*.

proglottids resulting in cysticercosis. Unlike *T. solium*, *T. saginata* (beef tapeworm) does not utilise man as an intermediate host, and therefore, pathology due to its larval form (cysticercosis) is not a feature in *T. saginata* infection.

Clinical Presentation

Intestinal T. solium and T. saginata infestations are usually asymptomatic; however, patients may have generalised complaints including epigastric or periumbilical discomfort; nausea; weight loss with anorexia or increased appetite.

Neurocysticercosis (NCC) has seizures as its most common form of presentation, occurring in up to 80% of patients with parenchymal brain cysts or calcifications. Most patients have normal neurologic examinations. However, few may present with focal neurologic deficits along with possible hydrocephalus, meningitis, and dementia.

There are certain unique features of NCC in India. The solitary form of the disease (solitary cysticercus granuloma, SCG) is the most common presentation and is seen in nearly two-third of all patients with NCC. Anywhere between 26% to 50% of all Indian patients presenting with partial seizures are diagnosed with a SCG on the CT scan. More than 95% of Indian patients with NCC are vegetarians or who do not consume pork. The cause of infection in such patients is probably autoinfection or from food contaminated with *T. solium* ova.

Spinal, ventricular or menigeal neurocysticercosis manifestations are non-specific and dependent on the size and the location of the cysts.

Ocular cysticercosis presents with decreased vision, pain and recurrent redness of the affected eye and it can affect almost all parts of eye, including the anterior and posterior chambers and the retina.

Cholangitis or biliary obstruction can be seen due to reverse peristaltic movement of proglottids in some *T. saginata* infestations.

Diagnosis

Laboratory studies

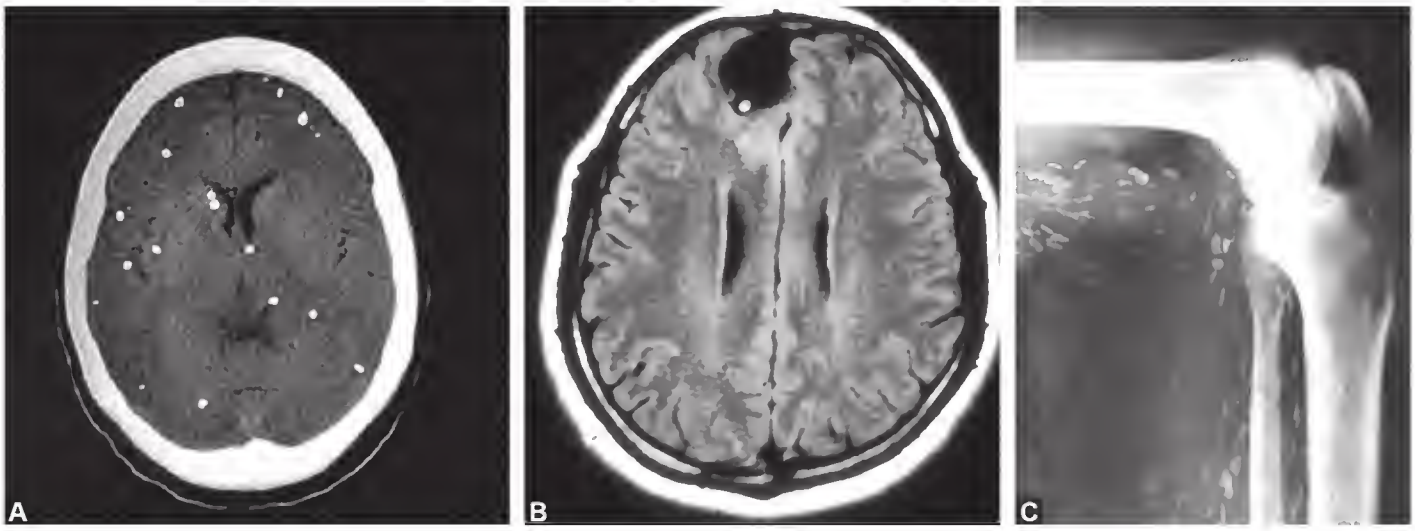
Stool test and perianal swab: Diagnosis of intestinal taeniasis can be made by recovery of the characteristic ova or proglottids in the stool. The ova of *T. solium* and *T. saginata* are identical and diagnosis is made by the recovery of the proglottids or scolex. Collecting 2 to 3 stools samples is necessary for detection of the parasite because eggs and proglottids are released irregularly into the stool, thus rendering stool microscopy relatively insensitive. In *T. saginata* infections, eggs may be observed in the perianal area and can be detected by using a cellophane tape swab. This method detects eggs in 85% to 90% of patients.

Eosinophil count and serum IgE levels: Eosinophilia and raised serum IgE levels are sporadically present in taeniasis, but it does not correlate with the severity of the infection, thus rendering them diagnostically unreliable.

Imaging studies

In NCC, neuro-imaging studies like CT or MRI are not only useful in differential diagnosis and evaluation, but are also important in identifying the number, location, and the stage of the infestation e.g. vesicular stage (viable parasite) or calcified stage (dead parasite) of the lesion (**Figures 3A and B**).

Generally, MRI is better than CT for the diagnosis of NCC, detecting up to 60% of cases missed on a CT scan. However, MRI is less sensitive than CT in identifying small calcifications, as many patients have parenchymal calcifications as the sole evidence of the disease (up to 40% of symptomatic patients).



Ocular cysticercosis, can be seen on ophthalmologic examination of the eye. Ultrasonography may be useful in evaluation of patients with orbital cysticercosis.

Cysticercosis of the muscle and subcutaneous tissues can be palpated or seen on a plain radiograph and is most typically seen as spindle-shaped calcifications, most numerous in the thighs (**Figure 3C**).

Serology

(a) Stool antigen testing detects at least 2 to 3 times more cases of *Taenia* infection than stool microscopy.

(b) Various serological tests like complement fixation, haemagglutination, radioimmunoassay, ELISA, and immunoblot can be used for the detection of anticysticercal

Figures 3A to C: CT scan showing multiple calcified neurocysticercosis (A), MRI scan showing solitary cyst in frontal lobe with a scolex (B), and X-Ray of leg showing calcified cysticerci in muscle and subcutaneous tissue (C).

antibodies in serum, cerebrospinal fluid (CSF), and saliva. Imaging studies only reveal the presence of lesions in cysticercosis. However, the confirmation of its aetiology can only be done by serological testing.

The immunoblot (QualiCodeTM Cysticercosis Kit) is the most effective, with sensitivity and specificity as high as 100% and 98%, respectively; however, the sensitivity decreases to about 70% in patients with a single cyst or in those with only calcified lesions. In NCC, ELISA is more reliable when performed in CSF than in serum, but the accuracy depends on the viability and location of the cysticerci.

Treatment

Anthelmintics

Treatment of intestinal taeniasis: Most anthelmintic drugs have broad spectrum of activity and are well tolerated. They are used as single dose for several helmintic infections. The most recommended drugs for tapeworm infestations are Albendazole or Praziquantel. In intestinal taeniasis, albendazole 400 mg daily for 3 days is prescribed and may be repeated after 3 weeks. Praziquantel dose for intestinal taeniasis is 10 to 20 mg/kg PO once. Mebendazole, 100 mg PO bid for 3 days or Niclosamide, 2 g PO once can also be used. It has a cure rate of about 90% for *Taenia* species. Ivermectin, a broad-spectrum anti-parasitic drug, is not effective against tapeworms. In *T. solium* infection, a purgative following the anthelmintic medication is recommended to flush out the ova released after the death of adult worm.

Treatment of neurocysticercosis: Albendazole 15 mg/kg/dL PO in two divided doses to a maximum of 800 mg/d for 8 to 30 days. Even a 7 day course has been reported to have similar efficacy. Praziquantel is now less preferred as the duration of therapy is longer (50 mg/kg/dL PO divided tid for 14 days).

In neurocysticercosis, inflammatory response to dead and dying parasites may lead to fever, cerebral oedema, raised intracranial pressure and convulsions. Thus, if either drug is used, the patient must be started on dexamethasone. Patients with cysticercotic encephalitis develop intracranial hypertension with anthelmintic use and thus, may require a ventricular shunt prior to drug therapy. Antiepileptic drugs are needed in patients with seizures.

Surgery

In neurocysticercosis, some patients require surgery in addition to anthelmintic treatment. For example, subarachnoid neurocysticercosis with hydrocephalus and cysticercotic encephalitis requires shunting surgery and intraventricular cysts require neuroendoscopic removal. Surgery is the treatment of choice for intraocular cysts. However, in extra-ocular muscles these cysts can be treated with anthelmintic drugs or surgery. In either case, it must be administered with steroids.

In skeletal muscle and subcutaneous tissues the problem is mainly aesthetic, not medical, as these cysts cause no further problems. They are usually left untreated, unless they are painful, in which case, surgical removal is the most common course of action.

HYDATID DISEASE

Hydatid disease is a parasitic infestation caused by the larvae of the tapeworm *Echinococcus*. Among all the echinococcal species found to infect humans (*E. granulosus*, *E. multilocularis*, *E. vogeli*, *E. canadensis* and *E. borealis*), *E. granulosus* is most commonly found in India.

Pathogenesis

The adult worm of *E. granulosus* lives in the intestine of carnivores, and the larval stages parasitise in various mammalian intermediate hosts. The larval or metacestode forms are referred to as hydatid cysts and the diseases caused by them as hydatidosis or hydatid disease. Dogs and other canines are the primary hosts and the intermediate hosts include sheep, cattle, and humans. The sheep is the optimum intermediate host, and man is an accidental host (**Figure 4**).

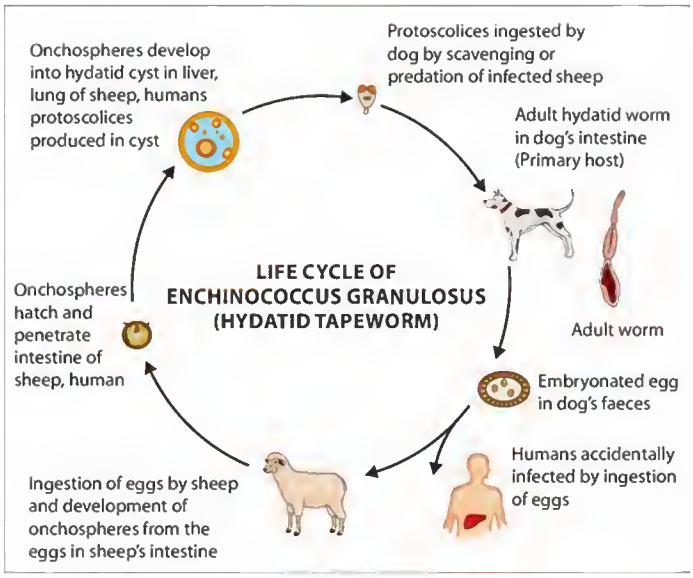


Figure 4: Life-cycle of hydatid tapeworm.

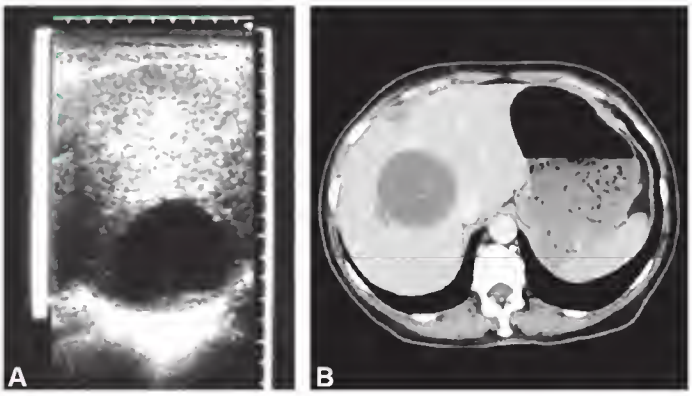
In humans, liver is the most common site (60% to 70%) of hydatid cyst development, followed by the lungs (10% to 30%), peritoneal cavity (8%), kidneys (3%) and brain (1%). Cardiac involvement is rare, with a reported occurrence between 0.5% and 2.0% of all hydatid disease. Hydatid cysts in the liver may be approximately 20 cm in diameter, but those found in the peritoneal cavity may sometimes be larger, containing several litres of fluid.

Clinical Presentation

Echinococcus infestations are potentially dangerous because they typically remain asymptomatic until the cysts cause a mass effect on an organ, which can occur 5 to 20 years after the initial infestation. Hepatic hydatid cysts can cause epigastric pain and dyspepsia (up to 35%) and can mimic cholelithiasis or jaundice (up to 45%) from compression in the bile duct. In one third of the cases, the disease is found incidentally during the check-up for non-specific symptoms (fatigue, weight loss, hepatomegaly). Hydatid cysts do not metastasise. Hydatid cyst may disseminate by accidental spillage. Rupture or leakage of the hydatid cyst due to blows to the body, muscular strain, or during operations causes contents of the hydatid to be released into the body's

circulatory system, and the liberated protoscolices may give rise to numerous secondary cysts throughout the body. The hydatid cyst fluid is highly allergenic and accidental cyst rupture may result in anaphylactic shock and rapid death.



Alveolar hydatid disease presents as a lesion that does not appear as a cyst but is a firm solid mass primarily in the liver. Approximately 60% to 80% of the cysts are located in the right lobe of the liver. Single or multiple foci may be present.

Pulmonary cystic rupture may result in clinically impressive and misleading symptoms of cough, chest pain, and haemoptysis.

Diagnosis

Imaging studies

Ultrasonography, CT and MRI are the modalities used to diagnose hydatid cysts. CT is better in detecting calcified lesions, and MRI visualises necrotic or fibrotic non-calcified lesions and extrahepatic lesions of alveolar echinococcosis more clearly (**Figures 5A and B**).

Figures 5A and B: Ultrasonographic and MRI appearance of hydatid cysts .

Serological tests

In echinococcosis, ELISA is positive in more than 90% of patients with hepatic cysts, however, only 50% of patients with pulmonary hydatid cysts have the same.

One serological test which has proved to be of value to diagnosing hydatid disease is the Western Blot (Qualicode TM Hydatid Disease Kit). The test presents a definitive means for detection of human antibodies to *E. granulosus*. Diagnosis can be achieved using the Western Blot assay for the detection of IgG antibodies in serum reactive with *E. granulosus* antigens present on a membrane. Field studies support a sensitivity of 80% and specificity of 100% in patients with hepatic cysts.

Treatment

The treatment of echinococcosis requires drug therapy (albendazole) along with surgical drainage or excision of the cyst.

Drug therapy

Albendazole reduces the viability of protoscolices and cysts. It is active against the larval cestodes. Drug therapy is also indicated in inoperable cases (where long-term therapy is used), spontaneous or operative rupture of the cyst, or before and after aspiration and surgery. The recommended dose of albendazole is 400 mg twice daily (or 10 to 15 mg/kg/day) for 3 to 6 months started 1 to 3 months before surgical intervention.

Surgery

Surgical resection of the hydatid cysts is the definitive treatment. Surgical resections performed along with medical treatment; has significantly dropped the operative mortality rate from about 7% to 23% before 1980 to 0% to 5% in more recent years.

A newer modality called PAIR (puncture, aspiration, injection and re-aspiration) has also been described as an alternative treatment for hepatic cysts. Here the cysts are punctured percutaneously and fluid is aspirated out. Following this, a protoscolicidal agent (e.g. cetrimide) is injected in the cyst and then cyst is re-aspirated. Currently, the efficacy and safety of the PAIR method has not been confirmed, therefore, this method cannot be regarded as an established alternative to surgery.

PREVENTION OF TAPEWORM DISEASES

Despite the high cure rates re-infection is very high in cestode infections. Improving basic sanitation, proper hygiene education, wearing shoes, anti-worm treatment of all household members, periodic mass treatment of targeted population groups and de-worming of livestock and domestic animals is required to prevent re-infection.

Treating *Taenia solium* infected livestock with oxfendazole (OFZ) is another way of reducing the incidence. Treatment of porcine cysticercosis with OFZ should, in combination with other intervention measures be considered as an important, cost-effective measure in the control of taeniasis and cysticercosis. OFZ is equally effective in treating infected sheep and goats having echinococcosis and thus, helps in the eradication of hydatid disease.

IMMUNISATION

Immunisation against experimental infection with cestode parasites has been highly successful, in marked contrast with the relative in effectiveness of vaccines against infection with most non-cestode parasitic organisms. A recombinant antigen vaccine against infection in sheep with the parasite *Taenia ovis*, the first highly effective, non-living vaccine against a parasitic infection in animals or humans, has been developed recently. The cestode vaccines are now being developed towards practical and commercial application. The high level of efficacy of the vaccines against *T. saginata*, *T. solium*, cysticercosis and *E. granulosus* in animals brings hope for the development of an effective vaccine for human use in near future.

17.60 Filariasis and Other Related Infestations

Sanjay Zachariah

DEFINITION

Lymphatic filariasis is a mosquito borne parasitic disease caused by the three lymphatic dwelling nematode parasites: *Wuchereria bancrofti*, *Brugia malayi* and *Brugia timori*. It is characterised by progressive lymphoedema leading to disfiguring elephantiasis. It is the second leading cause of permanent disability in South East Asia leading onto social stigmatisation and poverty.

EPIDEMIOLOGY

According to WHO estimates approximately 120 million people in tropical and subtropical countries are infected with filariasis of whom 25 million men have genital disease and 15 million persons developed lymphoedema. In India a total of 553 million people are at risk, 21 million have symptomatic filariasis and 27 million are microfilaria carriers. Endemic areas in India are illustrated in **Figure 1**. India contributes to 40% of the global burden of filariasis and accounts for 50% of the people at risk of infection. *Wuchereria bancrofti* is the main causative organism accounting for 98% of infection in India (90% worldwide). *Brugia malayi* accounts for 2% of lymphatic filariasis in India and shows a decreasing trend. *Brugia timori* has been found only in Indonesia.

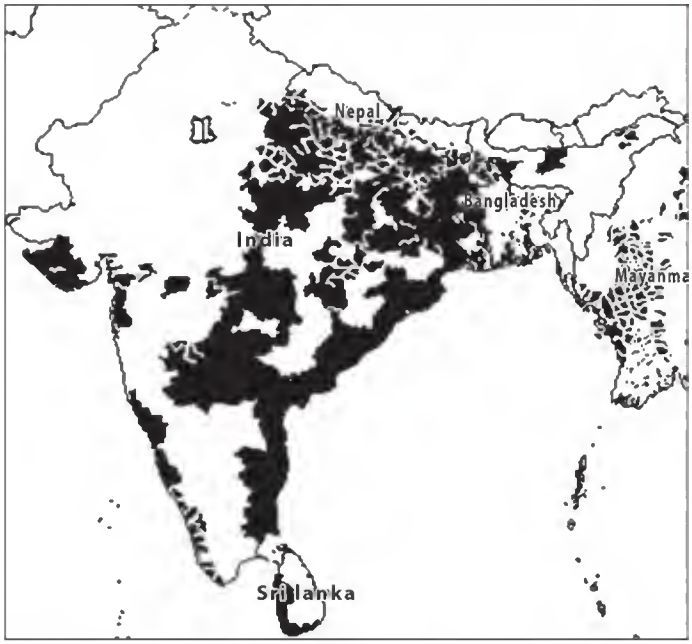

Figure 1: Distribution of filariasis in India.

AETIOLOGY

Wuchereria bancrofti is transmitted in the endemic regions by the ubiquitous day biting mosquito *Culex quinquefasciatus* (by *Aedes* in Nicobar Islands only) and *Brugia malayi* by *Mansonia* spp. Life cycle of both the filarial worms are similar and described in **Figure 2**. The period from the entry of the infective stage 3 larva into the human host till the first appearance of microfilariae in circulation is called the biological incubation period which varies from 8 to 12 months. A gravid female worm can release as many as 50,000 microfilariae per day, which enter the circulation through the thoracic duct. The clinical incubation period which varies from 8 to 16 months denotes the period from the entry of the infective stage three larva to the development of the earliest clinical manifestation.

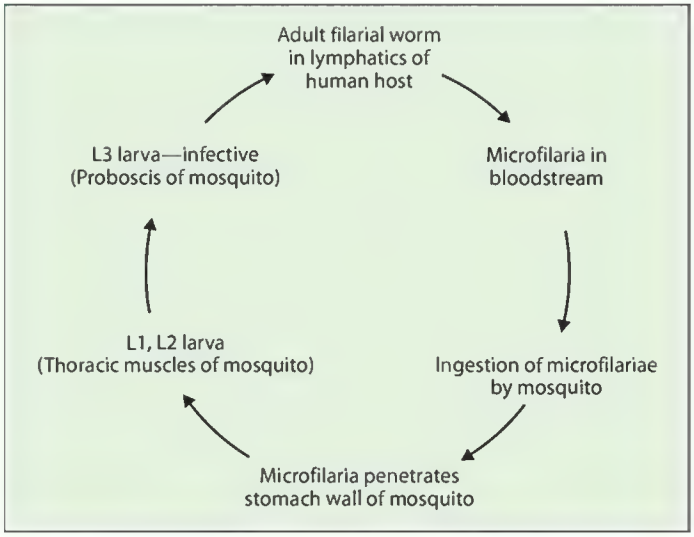

Figure 2: Life cycle of *Wuchereria bancrofti*.

PATHOGENESIS

Once the adult filarial worms take up residence in the lymphatics of the human host, further pathogenesis depends on various host factors like immune response, superadded bacterial infections and agent factors like the *Wolbachia* endosymbionts.

The initial event is lymph vessel dilatation when the adult worms are still alive though at that stage there is little reaction histologically. When they die, either naturally at the end of their life span or with drugs, an inflammatory reaction including granulomas, macrophages and eosinophils develops. At this time the release of *Wolbachia*, which are rickettsial endosymbionts found in the hypodermis of the adult worms, also add to the inflammatory response. The release of *Wolbachia* at worm death and the filarial degeneration products results in an increase in Th1, Th2 and Th17 numbers leading to the release of inflammatory cytokines TNF, IL-1β and IL-6. These contribute to lymphangiectasia and lymphangiogenesis through vascular endothelial growth factors (VEGF-A, VEGF-C, VEGFR-3). Enlarged lymph vessels are less efficient at transporting lymph from the periphery especially in the legs where the movement of lymph is against gravity. This lymph stasis in the legs further predisposes the patient to infections with exogenous microorganisms especially *Streptococci* causing bacterial acute dermatolymphangioadenitis (ADLA). Repeated episodes of

ADLA in legs with previously damaged lymph vessels cause progressively increasing secondary lymphoedema resulting in the irretrievable skin and dermal changes of elephantiasis. The pathophysiology of hydrocoele development does not necessarily involve exogenous bacterial infections. *Wuchereria bancrofti* shows a predilection for localisation in the scrotal lymphatics. Its presence there stimulates the proliferation of lymphatic endothelium and transudation of hydrocoele fluid which is similar to serum chemically. The lymphatic drainage of the penis is separate and more superficial than that of the tunica vaginalis. Therefore, a patient can develop a massive hydrocoele without any elephantiasis of the penis or scrotum. Occasionally there is a vigorous immune reaction against microfilariae reflected by hypereosinophilia and elevated IgE levels leading to tropical pulmonary eosinophilia (TPE).

All infected patients do not develop hydrocoele or elephantiasis. The development of immune tolerance in endemic regions to filarial antigens is mediated through IL-10 promoted IgG4 responses. This leads to a clinical subset of microfilaraemic patients with high parasite numbers and absence of pathological manifestations. Patients who develop lymphoedema typically have few or no parasites.

CLINICAL FEATURES

The clinical manifestations of lymphatic filariasis can vary from asymptomatic to disfiguring and disabling elephantiasis. The common manifestations are listed in **Table 1**.

Table 1: Clinical Manifestations of Lymphatic Filariasis

Acute	Chronic
Tropical Pulmonary Eosinophilia	Hydrocoele
Acute Filarial Lymphangitis	Lymphoedema (Elephantiasis)
Acute Dermatolymphangioadenitis	Chyluria
'Expatriate fever'	

Asymptomatic Carriers

Infected patients who have a downregulated immune system towards filarial antigens demonstrate high levels of microfilariae in their blood with no clinical manifestations. The microfilariae in peripheral blood show nocturnal periodicity with maximum density between 10 pm and 4 am. Even these asymptomatic patients have hidden damage to their lymphatics on lymphoscintigraphy though progression to chronic complications is rare. Patients continue to be infective till 5 years in *Wuchereria* and 3 years in *Brugia* infection.

Acute Manifestations

Tropical pulmonary eosinophilia (TPE)

At the other end of the clinical spectrum, some patients develop an exaggerated immune response to microfilariae. They present with cough, dyspnoea, nocturnal wheezing, and occasionally fever, anorexia and weight loss. Chest radiographs reveal diffuse reticulo-nodular infiltrates and pulmonary function tests show primarily restrictive defects with mild obstruction. Blood tests are characterised by marked peripheral blood eosinophilia (>3000 cells/mm^3) and high serum concentrations of IgE and filarial-specific IgG and IgE antibodies. Patients get rapid relief with diethylcarbamazine (DEC) and might progress to chronic interstitial lung disease if left untreated. Diagnostic criteria for TPE are listed in **Table 2**.

Table 2: Diagnostic Criteria of Tropical Pulmonary Eosinophilia

1. Living in or visited an endemic area
2. Paroxysmal nocturnal cough and breathlessness
3. Pulmonary infiltrations on chest radiograph
4. Absolute eosinophil count > 3000/mm^3
5. Elevated serum IgE levels
6. Elevated serum antifilarial antibodies (IgE or IgG)
7. Clinical improvement with diethylcarbamazine

Acute filarial lymphangitis

Acute filarial lympangitis is uncommon (10% to 20% as compared to ADLA) and is caused by the spontaneous or drug induced destruction of adult worms. Small tender nodules develop at the site of worm death either in the scrotum or along the lymphatics. The inflammation is retrograde progressing from the lymph node to the periphery with the lymphatics standing out as inflamed tender cords. A transient oedema (cold oedema) might occur which resolves along with the other manifestations without treatment. There is no fever, toxaemia or evidence of secondary bacterial infection.

Acute dermatolymphangioadenitis (ADLA)

ADLA is far more common and is important in the progression of lymphoedema. It is caused by secondary bacterial (usually *Streptococci*) infections. It is clinically characterised by fever, toxaemia and a swollen, red, tender extremity. The draining lymph nodes are also enlarged and tender. Minor injuries, insect bites, eczema and fungal infection of toe webs all predispose to episodes of ADLA. Notably, fungal infections of the skin act only as entry points for the bacteria but fungi themselves do not cause ADLA.

Expatriate fever

People from a nonendemic area exposed to the filarial larva for the first time in an endemic area develop a vigorous immune reaction to the same causing an 'expatriate fever'. Acute lymphangitis develops around the larva or the immature adult worm with a primarily eosinophilic infiltrate. Lymphadenitis, genital pain, hepatomegaly, splenomegaly and allergic manifestations like rashes, hives, might all develop.

Chronic Manifestations

Hydrocoele

Hydrocoele is the most common manifestation of lymphatic filariasis. In endemic areas, the prevalence of filarial hydrocoele exceeds 50% in males aged 45 years or more. It is caused only by *W. bancrofti* and not by *Brugia*. A thickened spermatic cord might be found on clinical examination due to the presence of adult filarial worms in its lymphatics.

Lymphoedema

Lymphatic filariasis is the commonest cause of secondary lymphoedema worldwide. Filarial lymphoedema commonly involves the lower limbs (**Figure 3**) and genitalia, but can also affect the upper limbs and breasts. In the initial stages, the lymphoedema is due to lymph stasis and is reversible with postural drainage. The oedema gradually becomes brawny and

non-pitting with hardening of the skin. The swollen limb develops deep skin folds along with hyperkeratosis and hyperpigmentation. The skin folds harbour bacteria and fungi which perpetuate episodes of ADLA. Gradually warty protuberances develop which are nothing but nodular tissue with dilated lymphatics inside. These nodules might breakdown leading to direct leakage of lymph (lymphorrhoea). WHO describes three grades of lymphoedema progressing from: (1) reversible pitting oedema to; (2) irreversible non-pitting oedema; and finally (3) severe swelling with sclerosis and skin changes. A more comprehensive and clinically appropriate staging is described in **Table 3**.

Figure 3: Stage 3 filarial lymphoedema.

Table 3: Dreyer Staging of Filarial Lymphoedema

Stage	Characteristic clinical feature
1	Swelling is reversible overnight
2	Swelling is not reversible overnight
3	Presence of shallow skin folds (base of fold can be seen with movement of leg)
4	Presence of skin knobs
5	Presence of deep skin folds (base of fold can only be seen if opened up)
6	Presence of 'mossy lesions'. Warty looking epidermal skin lesions
7	Unable to care for self or perform daily activities

Chyluria

The rupture of swollen lymphatics into the renal pelvis results in the passage of white milky urine called chyluria. This loss of intestinal lymph (chyle) which is rich in lipids and proteins leads to severe malnutrition, hypoalbuminaemia and weight loss. Occasionally rupture of small vessels at the fistulous site leads to haematochyluria wherein the urine is milk-like with a pale pink colour.

Other Manifestations

Chylous ascites, chylocoele and chylothorax can result from the rupture of swollen lymphatics into the peritoneum, tunica vaginalis and thoracic cavity respectively. Acute glomerulonephritis of a diffuse mesangial proliferative pathology responsive to diethylcarbamazine has been described in filariasis. Rare instances of endomyocardial fibrosis have also been reported. Filarial arthritis of two clinical types have been identified. Oligoarticular filarial arthritis affects a single large joint, commonly the knee and is due to a tissue reaction to filarial worms in the vicinity. Microfilariae are not found in the synovial fluid. The second type, filarial pseudorheumatism is thought to be due to intra-articular deposition of immune complexes. In endemic areas of India and Sri Lanka, filarial granulomas can present as hard nodular masses in the breast fixed to overlying skin mimicking a malignant lesion. Histopathology reveals a eosinophilic granulomatous reaction around degenerating adult filarial worms or microfilariae. Filarial antibodies are usually positive and patients respond very well to diethylcarbamazine.

Filariasis in Children

In endemic areas, filariasis is mostly acquired in childhood as evidenced by widespread presence of filarial antigenaemia, microfilaraemia and demonstration of adult worms on doppler ultrasonography. Children under 10 have prevalence rates averaging 30% and 10 to 19 year olds about 69% of the adult rate. Subclinical damage to the lymphatic system in the form of dilatation is visible on lymphoscintigraphy but children usually develop only lymphadenopathy overtly. Hydrocoele and lymphoedema are seen only after puberty.

DIAGNOSIS

Microfilarial Detection

Microfilariae can be detected in blood, urine or hydrocoele fluid through direct microscopy. A thick and thin blood smear, with the thick part dehaemoglobinised with distilled water, is prepared and stained with Giemsa or Leishman stains. The thick film is used for detection of microfilariae and the thin film for microfilarial morphology. In view of the nocturnal periodicity, blood sample should be collected between 10 pm to 4 am. To increase the sensitivity of the test, blood or other fluid could be passed through a millipore (5 micron pore size) membrane filter which will retain most of the microfilariae. The filter is then washed (to lyse RBC), stained and examined for microfilariae. DEC provocation test is used to facilitate daytime detection of microfilariae. A single dose of DEC (2 mg/kg body weight) is given and blood collected after 30 minutes for microscopy.

Antigen Detection

Detection of specific circulating filarial antigens (CFA) is regarded by WHO as the 'gold standard' for diagnosis of lymphatic filariasis. In comparison with microfilarial detection in blood, testing for CFA has been found to be 94% to 100% sensitive and 90% to 100% specific. An ELISA test which gives semi-quantitative results and an Immuno-chromatographic test (ICT, available as a card test) can be used. The ICT card test is especially useful in the field in view of its simplicity; portability and needing only fingerpick sampling.

DNA Based Diagnosis

Though not as sensitive as antigen detection, DNA based techniques like polymerase chain reaction (PCR) are more specific. PCR amplification of the glutathione peroxidase gene helps in the diagnosis of lymphatic filariasis and restriction fragment length polymorphism (RFLP) enables differentiation of species. These tests have a greater role as epidemiological tools as they detect parasite DNA in both humans and vectors.

Antibody Detection

Elevated levels of anti-filarial IgG4 antibody levels are associated with active lymphatic filarial infections; however cross-reactivity with other filarial parasites (*Onchocerca, Loa loa, Mansonella*) is common. Extremely raised levels of serum IgE might be seen in TPE.

Chest Radiography

Chest radiographs may demonstrate diffuse reticulonodular infiltrates in TPE.

Ultrasonography

In asymptomatic microfilaraemic patients, ultrasonography can visualise adult filarial worms in scrotal lymphatics in males and retroperitoneal and breast lymphatics in females. Spontaneous movement of the worms inside the lymphatics is described as filarial dance sign.

Lymphoscintigraphy

Lymphoscintigraphy though not helpful in diagnosis, has been useful in understanding pathogenesis of lymphoedema in filariasis. A gamma camera is used to visualise the movement of radiolabelled albumin through the lower limb after being injected into the web space of the toes. Lymphatic dilatation is visible even in the early asymptomatic phase, dermal back flow and obstruction becoming evident later.

MANAGEMENT

The management of lymphatic filariasis involves not only antifilarial drug therapy, it also encompasses the management and prevention of ADLA, management of lymphoedema/elephantiasis and patient counselling/education.

Antifilarial Drugs

Diethylcarbamazine (DEC)

DEC has direct cidal effect on both adult worms and microfilariae. It markedly lowers microfilariae levels even in single annual doses of 6 mg/kg body weight which makes it perfect weapon in the campaign to eliminate filarial transmission through mass drug administration. It is effective against the adult worms in only 50% of patients with the effectivity not improving with repeated dosing. Direct adverse effects of DEC are rare; most of the side effects like rash, fever, myalgia and cough are attributed to the rapid destruction of microfilariae and the subsequent immune reaction to the degenerating parasites. These adverse effects last from 24 to 48 hours and require only symptomatic therapy. It is the drug of choice for TPE in which the duration of therapy is 4 weeks.

Albendazole

This commonly used anthelmintic is effective against adult filarial worms destroying them at a dose of 400 mg twice a day for two weeks. It has no direct effect on microfilariae. A single dose of albendazole 400 mg greatly accelerates the microfilaricidal action of DEC. Therefore, the strategy of combining a single annual dose of DEC 6 mg/kg body weight with albendazole 400 mg is appropriate for eliminating filarial transmission in India. This has the added benefit of clearing intestinal helminths thereby improving the nutritional status of the community. Severe scrotal reactions might be induced by the death of the adult worms inside the scrotal lymphatics.

Ivermectin

In single annual doses of 200-400 µg/kg body weight, ivermectin markedly reduces the blood microfilariae count. The adverse effects are similar to DEC but milder due to the slower clearance of parasitaemia. Its principal use is in countries co-endemic for onchocerciasis and loasis where DEC cannot be used due to possible severe immune reaction. It has no proven action against the adult worms. Ivermectin is effective in louse infestations, scabies and against many intestinal helminths.

Doxycycline

Doxycycline is effective in clearing *Wolbachia* endosymbionts from the adult filarial worms apparently leading to long-term adult female worm sterility and subsequent reduction in microfilaraemia. It has to be given in a dose of 200 mg/dL for 8 weeks resulting in a sustained decrease in blood microfilariae levels at 1 year. It is most effective when combined with DEC-albendazole or ivermectin with the added advantage of doxycycline pre-treatment markedly reducing the adverse events following DEC-albendazole administration.

Lymphatic filariasis has a wide variety of clinical presentations and its management could be subdivided into the individual treatment of the three main clinical subgroups, i.e. asymptomatic carriers, ADLA and patients with lymphoedema/elephantiasis.

Asymptomatic Carriers

DEC is the drug of choice for treatment of asymptomatic microfilaraemia at a dosage of 6mg/kg bw/day divided into 3 doses for 12 days, preferably combined with single dose of albendazole or ivermectin. Pre-treatment with doxycycline 200 mg/day for 6 weeks before DEC-albendazole administration gives superior results with less adverse events.

Acute Dermatolymphangioadenitis (ADLA)

Aggressive management and prevention of episodes of ADLA is the key to halting the progression towards elephantiasis. During an acute episode, patients should be treated with crystalline penicillin as the commonest causative organism is *Streptococcus*. Pain could be reduced with cold compresses or soaking the limb in cold water. The patient should take rest, be hydrated well and elevate the limb for as long as possible. Prevention of ADLA is detailed in **Table 4**. Washing and drying of skin should be done in a gentle manner to avoid abrasions or injury. Exercise involves flexion-extension at the ankle and rotatory movement at the ankle joint. In selected cases with repeated episodes of ADLA despite above measures, benzathine penicillin 1.2 MU, deep IM every 3 weeks may be used as a preventive measure.

Table 4: Prevention of Acute Dermatolymphangioadenitis

1. Twice daily gentle washing of limb with soap and water
2. Thorough gentle drying after washing
3. Massage with simple emollients like coconut oil
4. Applying antiseptics to any wounds/abrasion
5. Treatment of any fungal infections with systemic and local therapy
6. Elevate affected limb day and night
7. Constant gentle exercise of affected limb
8. Wearing comfortable shoes preferably with adjustable straps
9. Nails to be kept clean and trimmed.

Lymphoedema/Elephantiasis

All the measures mentioned in **Table 4** for preventing ADLA are just as important in decreasing lymphoedema progression, in some cases even reversing it. Following options can additionally be offered to patients with lymphoedema/elephantiasis:

Manual massage

Massage with an emollient with a gentle upward milking pattern has shown to be effective in reducing lymphoedema. It can be administered by a physiotherapist or by relative/ patient who has received training.

Compression bandage

An ideal compression bandage would apply uniform pressure all around and would adjust to the smaller diameter of the limb as the day proceeds. Crepe bandage is commonly used with the normal activity during the day, increasing lymph flow by muscle pump action. Tailor made elastocrepe stockings are also used. Compression bandaging immediately after a manual massage session helps in maintaining the reduction in limb diameter.

Intermittent pneumatic compression

The limb is encased in a plastic inflatable connected to an electric pump. Pressure is gradually increased to 80-100 mm Hg over 120 seconds and then rested for 30 to 45 seconds. Therapy is usually continued for 2 to 3 hours in a day followed immediately by compression bandaging to maintain volume reduction.

Heat treatment

Application of heat externally in a heated oven (which leads to greater heating of epidermis than dermis) or uniformly with a microwave oven has been tried but is less effective in filariasis though results in lymphoedema of other causes has been better.

Interferential therapy

Interferential therapy is a form of physical therapy in which medium frequency currents are crossed inside the limb tissue to create a low frequency current, mainly used in relieving painful muscle spasms. In filarial lymphoedema a faradic current of 15 to 30 millivolts is passed in 5 second pulses for 30 min through selected portions of the limb. It is less effective than massage or bandaging.

Surgical therapy

Surgery is the last resort in elephantiasis. Drainage procedures like lympho-nodo-venous anastomosis, lymphatico-venous anastomosis and omentoplasty, attempt to enhance lymphatic drainage in the limb. Excisional surgery of the affected skin and subcutaneous tissue, closed by skin flap or graft is usually complicated by lymphorrhoea, haemorrhage and lymphangitis. Hydrocoele would require surgical management when response to medical therapy is incomplete.

Counselling and education

It is very important to educate the patient regarding the nature of the disease, its cause and its progression. Such education will help in enlisting the patient's and relative's assistance for lymphoedema amelioration measures. Lymphatic filariasis leads to physical disfigurement leading to social stigmatisation. Patients suffer from chronic pain, physical disability and sexual dysfunction for which psychological support and counselling is essential.

PREVENTION

The WHO announced the Global Programme to Eliminate Lymphatic Filariasis (GPELF) in 1998 with target for elimination being the year 2020. India is a signatory to the GPELF and through its National Filaria Control Programme (NFCP) has started a campaign of Mass Drug Administration (MDA) of single annual dose of DEC or DEC-Albendazole to interrupt transmission of the disease. DEC medicated salt has been successfully used in Tamil Nadu but has operational problems related to distribution and community acceptance. Vector control is through anti-larval spray at weekly intervals with appropriate larvicides, biological control through larvivorous fishes and environmental engineering through source reduction and water management to eliminate mosquito breeding sites.

17.61 Schistosomiasis/Bilharziasis

Kirti C Patel

HISTORY

Theodor Bilharz in 1851 described this disease. Around 200 to 300 million people are affected in 74 countries of the world. Schistosomiasis is caused by several species of *Schistosoma*, each giving rise to a characteristic form of the disease.

Schistosomiasis is endemic in Egypt, exacerbated by the country's dam and irrigation project along the Nile. Focus of schistosomiasis in Ratnagiri district of Maharashtra, India was described by Gadgil and Shah in 1952. The twentieth century was marked by the development of control measures including effective drugs, particularly praziquantel, for schistosomiasis.

STATUS IN ANIMAL KINGDOM

Phylum *Platyhelminthes* and genus *Schistosoma*. Among these, *S. haematobium*, *S. mansoni* and *S. japonicum* can cause important human diseases (**Table 1**).

Table 1: Common Schistosomiasis

Differentiating Features	*S. haematobium*	*S. mansoni*	*S. japonicum*
Synonym	Vesical blood fluke	Manson's blood fluke	Oriental blood fluke
Location	Tanzania, Middle East, Egypt, Ratanagiri in Maharashtra (India)	Cairo, Egypt, Sudan, USA, East African Coast	China, Japan, Philippines, Taiwan, Sulawesi

LIFE CYCLE

Metacercariae or schistosomules gain entry into the venous system and finally lodge into the portal circulation via the mesenteric artery having gone through the pulmonary circuit. Metacercariae of *S. haematobium* pass into the vesical venous plexus and develop into sexually matured worms. Females lay lateral spined eggs in vesical venules which are passed into the urine. Metacercariae of *S. mansoni* and *S. japonicum* ultimately enter the rectal venous plexuses and mature into adult worms. Females lay eggs in rectal venules with terminal spine or small knob, which enter the rectum and are ultimately expelled into stool. The eggs of all species develop into miracidia and enter the snail. In snails they develop into sporocysts and then fork-tailed cercariae which are released into the surrounding water and are ready to enter human skin.

PATHOLOGICAL FINDINGS

S. haematobium worms may lead to formation of granulomata, ulceration, fibrosis and finally calcification in the bladder. The *S. mansoni* and *S. japonicum* worms are found in the tributaries of inferior mesenteric veins, and consequently, lesions are found in the large intestines. *S. japonicum* have detrimental effect on the portal system. These lesions are located in the upper part of the colon, small intestines and liver.

CLINICAL FEATURES

In the early stages of infection there may be itching lasting 1 to 2 days at the site of penetration. After a symptom-free period of 3 to 5 weeks, acute schistosomiasis (Katayama syndrome) may present with allergic manifestations, such as urticaria, fever, muscle aches, abdominal pain, headache, cough and sweating. Examination reveals hepatomegaly, splenomegaly, lymphadenopathy. Patients with *S. haematobium* infection commonly present with painless haematuria, bladder calculi and malignancy. Manifestations of *S. mansoni* and *S. japonicum* include intestinal colic and bloody diarrhoea. Long standing infection is known to cause cirrhosis of the liver, portal hypertension, haemolysis and progressive anaemia. Increased incidence of urinary bladder stone and malignancy is noticed with *S. haematobium*.

DIAGNOSIS

During acute stage, anaemia, leucocytosis and marked eosinophilia are common. Other causes of haematuria, dysentery and hepatosplenomegaly require to be excluded. Definite diagnosis is established by the demonstration of terminally spined eggs in the centrifuged deposits of urine or in compressed bladder tissue between two slides in case of *S. haematobium*. The rapid simple and inexpensive kato-katz thick smear stool examination is widely used in field studies. Stool examination, proctoscopic aspiration of material and rectal biopsy would be useful to demonstrate species of *S. mansoni* and *S. japonicum*.

Imaging Studies

Lower abdominal plain radiograph may show calcification of bladder wall or ureters. Ultrasonography may show periportal fibrosis and obviates the need for biopsy. However, it might fail to show calcification of bladder or ureter. Computed tomography of abdomen may demonstrate pathognomonic turtle-back calcification. Cystoscopy in advanced cases show sandy patches, ulcers and areas of squamous metaplasia.

TREATMENT

The management is outlined in **Table 2**.

Table 2: Management of Schistosomiasis

Name of Drug	Dose
Praziquantel (effective against all species)	40 mg/kg single oral dose for *S. haematobium*, *S. mansoni* and *S. intercalatum* after meals. 20 mg/kg three oral doses or 30 mg/kg two oral doses for *S. japonicum* and *S. mekongi*.
Metrifonate	10 mg/kg given in three oral doses at an interval of 14 days.
Surgery	Removal of polyps/splenectomy

PREVENTION AND CONTROL

Improved sanitary facilities can prevent eggs excreted by infected persons from reaching water that harbours the intermediate host, the snail. Avoiding swimming or wading through contaminated water is important in the endemic areas. Molluscicidal compounds, like sodium pentochlorphenate can reduce the snail population. Large-scale community-based chemotherapy in the endemic areas may also interrupt the eggs-miracidium-snail cycle, thereby diminishing the risk of severely-damaged organs even though re-infection may occur. Introduction or augmentation of existing crey fish population can control the snail population.

Devastating effect of the disease stems from the immune response initiated by entrapped eggs in tissues. Recombinant derived *Schistosoma mansoni* antigen vaccines have encouraging results.

PROGNOSIS

Co-infection with either hepatitis-B virus (HBV) or hepatitis-C virus may lead to hepatocellular carcinoma than that attributable to HBV alone. Chronic disease has a bad prognosis. In children, schistosomiasis may perpetuate malnutrition and may result in growth retardation.

17.62 Systemic Fungal Infections

Shruti Prem, Rajat Kumar

INTRODUCTION

Systemic or invasive fungal infections refer to bloodstream infection by fungi or involvement of deep seated organs like the lung or the brain. The term differentiates it from the more common superficial fungal infections which have a better prognosis. Invasive fungal infections (IFI) have become more common with the increase in immunocompromised patients. This chapter deals with, systemic fungal disease in immunosuppressed patients but endemic fungal infections (histoplasmosis, blastomycosis, coccidioidomycosis, paracoccidioidomycosis, and sporotrichosis) have been mentioned in passing only.

Changing Epidemiology of Invasive Fungal Infection in Immunocompromised Patients

Candida species are the most common cause of invasive fungal infections in humans, producing infections that range from non life-threatening mucocutaneous disorders to invasive disease that can involve any organ. The most common risk factors from Indian studies are shown in **Table 1**. *Candidemia* is the fourth most common cause of nosocomial bloodstream infections in the United States and in much of the developed world. The attributable mortality of invasive candidiasis is as high as 47%.

In the epidemiology of fungal infections there has been a decrease in *C. albicans*, *C. tropicalis* and *C. parapsilosis* infections with an emergence of occasional infections by azole-resistant species, such as *C. glabrata*, and *C. krusei*. An increase in the incidence of mould infections, particularly aspergillosis, has been observed together with an emergence of infections by other moulds (*Fusarium* spp. *Zygomycetes* and others). *Aspergillus fumigatus* is the most common species recovered from cases of invasive aspergillosis followed by *Aspergillus flavus*, *Aspergillus niger* and *Aspergillus terreus*.

FUNGAL INFECTIONS IN INDIA

Most systemic fungal infections remain undiagnosed in the country. The limited literature, mainly derived from a few tertiary centers, confirms a rising trend of invasive candidiasis, aspergillosis and zygomycosis in India.

Invasive Candidiasis

The most common IFI in India is candidiasis, where the organism enters the blood stream from the gastrointestinal tract or from the skin through indwelling intravenous catheters. The incidence varies from 1 to 12 per thousand admissions in different hospitals across the country. *Candidemia* was associated with a mortality of 55%. *C. tropicalis* is the most common among the non-*C. albicans* candidiasis. The brain, heart, kidneys, liver, spleen and any other organ may be involved. Disseminated macronodular lesions may be present in the skin and fundoscopy may reveal chorioretinitis. Skin and eye involvement suggest a high probability of disseminated deep organ abscesses.

Invasive Aspergillosis

Invasive pulmonary, paranasal and cerebral aspergillosis are common presentations in India, but the infection may be disseminated. The most common isolate is *A. flavus*, rather than *A. fumigatus* which is the most common isolate in temperate countries.

Zygomycosis

Despite the lack of diagnostic mycology facilities, India contributes about 40% of the global burden of the disease. More than 300 cases of zygomycosis have been reported from a single tertiary centre in India. Diagnosis has been made mainly on autopsy, as ante-mortem diagnosis is difficult without high clinical suspicion. Zygomycosis/Mucormycosis refers to several different diseases caused by infection with fungi in the order of *Mucorales*. These

Table 1: Prominent Risk Factors of Mycosis in Indian Studies

Risk Factors	Candidiasis	Aspergillosis	Zygomycosis	Cryptococcosis
Hospitalisation > 30 days	++	++	–	–

Renal transplantation	–	++	–	++
Haematological malignancy	++	++	++	++
Diabetes mellitus-uncontrolled	–	–	+++	+
Human immunodeficiency virus (HIV)	++	++	++	+++

have little intrinsic pathogenicity in normal hosts, but are important causes of fungal disease among immunocompromised individuals. *Rhizopus* species are the most common causative organisms. Others being *Rhizomucor, Cunninghamella, Absidia and Mucor.* The commonest presentation is sino-nasal infection which may extend into the brain. Pulmonary, cutaneous, and gastro-intestinal infections are also recognised. Successful treatment requires correction of the underlying risk factors. Surgical debridement of necrotic tissue in combination with medical therapy is mandatory for survival. The mortality rate associated with rhinocerebral disease is 50% to 70%. Disseminated disease carries a mortality rate that approaches 100%.

Cryptococcosis

Cryptococcus neoformans is a yeast fungus and has been isolated from the droppings of pigeons, munia birds and canaries. *Cryptococcus grubii* (serotype A) is the most prevalent (>90%) of *Cryptococci* isolated in India. Its main clinical manifestation is a meningoencephalitis with markedly raised intracranial pressure. The route of infection is via inhalation. It occasionally causes pneumonia, skin lesions that resemble molluscum contagiosum or a frankly disseminated illness. It is common in individuals with advanced AIDS. Controlling cerebrospinal fluid (CSF) pressure with repeated lumbar punctures or other manoeuvres is important in management. Long-term anti-fungal suppressive therapy till the immunosuppressed state improves is necessary to prevent relapse.

Diagnosis

The diagnosis of invasive fungal infections is generally based on the following three steps:

(a) High index of suspicionbased on risk factors and clinical situation.
(b) Recognising clinical syndromes associated with invasive fungal infections, such as persistent fever, pneumonia, paranasal sinusitis.
(c) Specific investigations: microbiology, histopathology, detection of fungal antigens in body fluids and radiology.

Microscopy

The diagnostic yield for microscopy is more than that of culture alone in fungal infections. Another advantage is the rapidity of microscopy, with results being available in 2 to 4 hours of a sample being received. Microscopy can also differentiate between septate *(aspergillus)* or non-septate *(mucor)* mould.

Culture

All fungi (yeasts and moulds) obtained from sterile sites including blood, intravenous line-tips, urine should be identified up to species level by referral to a specialist laboratory. Bronchoscopy fluid is deemed sterile in this context for all fungi except for *Candida* species. Blood cultures in aspergillosis are of limited utility, because the results are often not positive even in disseminated infection. Bronchoalveolar lavage, transthoracic percutaneous needle aspiration, or video assisted thoracoscopic biopsy are standard procedures for establishing a diagnosis of invasive pulmonary aspergillosis. For serious candidal infections, blood cultures remain the standard for diagnosis although serial mucosal cultures have an excellent negative predictive value (NPV) and an acceptable positive predictive value (PPV). Growth of *Candida* from respiratory secretions rarely indicates invasive candidiasis.

Histopathology

All tissues from immunocompromised patients with suspected infection should be stained with fungal stains, such as periodic acid-schiff, silver or fluorescent stains, in parallel with regular stains. Identification of a fungus invading tissue accompanied by evidence of an inflammatory response is required for confirmation of diagnosis. This is especially true for *Aspergillus* infection, as *Aspergillus* is ubiquitous and can float from the air onto biopsy material. When positive, an India ink preparation of cerebrospinal fluid is diagnostic for cryptococcosis.

Radiology

Imaging plays an important role in diagnosis and management of pulmonary mould infection, fungal sinusitis, meningitis, endocarditis and disseminated candidiasis. Chest radiographs are often falsely negative in invasive pulmonary aspergillosis whereas high-resolution CT scans of the chest give the best results. The lung findings in invasive aspergillosis include nodules with 'halo sign' (due to haemorrhage secondary to angio-invasion by fungus) during early phase of severe neutropaenia, this may be followed by 'air-crescent sign' (due to cavitation in an area of consolidation) on recovery from myelosuppression. Of note, an increase in size of pulmonary lesions does not necessarily mean progression of infection as it could be related to the immune recovery. Immunocompromised patients with new neurological features (seizure, stroke, persistent headache, or possible meningitis) should have a CT or MRI of the brain. If a lesion is identified, a biopsy or aspirate should be done, if feasible. Characteristic signs are shown in **Figures 1 to 5**.

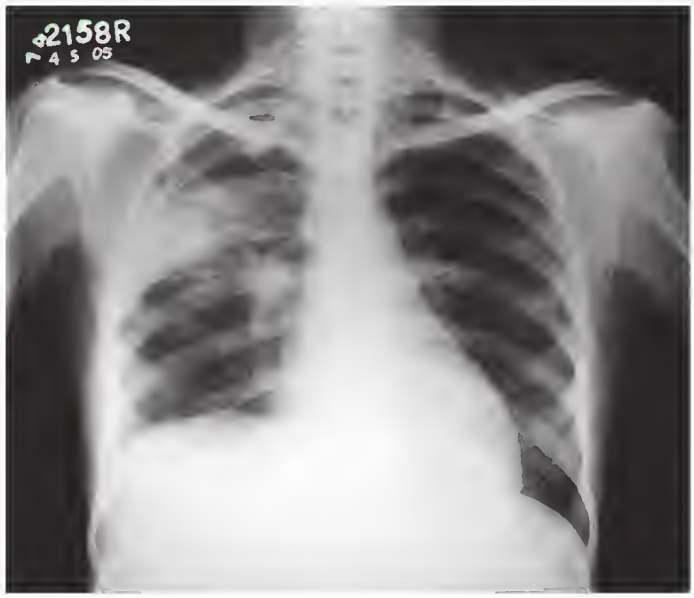

Figure 1: Chest radiograph showing consolidation and air-crescent sign in a patient of *Aspergillus* pneumonia.

Serology

The availability of enzyme linked immunosorbent assay (ELISA) for detection of circulating serum galactomannan (an *Aspergillus* cell wall antigen) has contributed toward a non-culture-based diagnosis of invasive aspergillosis. Galactomannan antigen has also been detected in CSF samples from patients with central nervous system (CNS) aspergillosis and in bronchoalveolar lavage fluid specimens

from patients with invasive pulmonary aspergillosis. The galactomannan antigen test has several advantages: it is non-invasive, easy to use, semi-quantitative and specific for *Aspergillus* species. False positive results may be observed in patients receiving piperacillin/tazobactam or amoxicillin/clavulanate. Another promising test is the 3-beta-D-glucan antigen test that appears to be useful in detecting all fungal infections (yeasts and moulds) in the bloodstream and is currently undergoing evaluation. Polymerase chain reaction (PCR) is a very sensitive test for detecting *Aspergillus* nucleic acids in various tissues.

Consensus Definitions

The European Organisation for Research in Treatment of Cancer-Invasive Fungal Infection Cooperative Group and National Institute of Allergy and Infectious Diseases Mycoses Study Group (EORTC-MSG study group) formed a Consensus Committee to develop a standard definitions for invasive fungal infections for clinical research. These definitions are principally applicable to immunocompromised patients with cancer and haematopoietic stem cell transplantation (HSCT) recipients. Although the definitions are intended for use in the context of clinical and/or epidemiological research, they provide a standard set of criteria. Three levels of certainty of invasive aspergillosis were defined: proven, probable and possible (**Tables 2 and 3**).

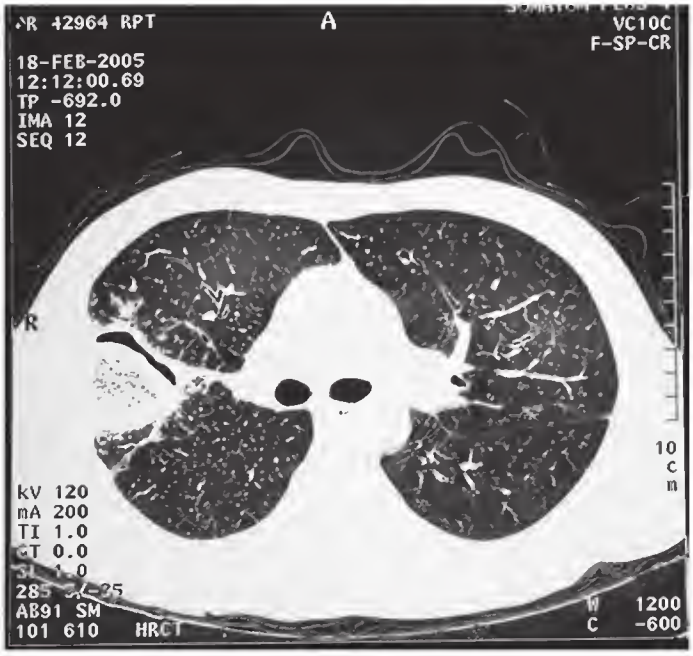

Figure 2: CT chest showing consolidation and air-crescent sign in a patient of *Aspergillus* pneumonia.

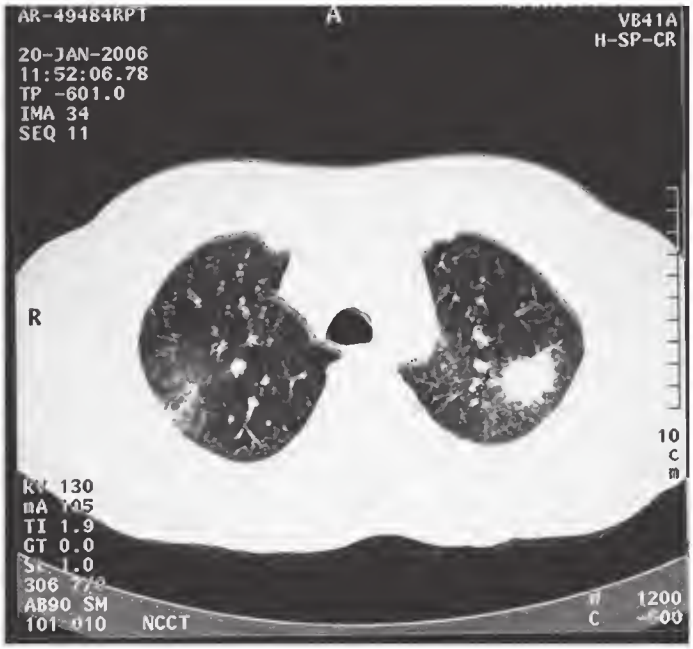

Figure 3: CECT chest showing consolidation/nodule with surrounding 'halo sign'.

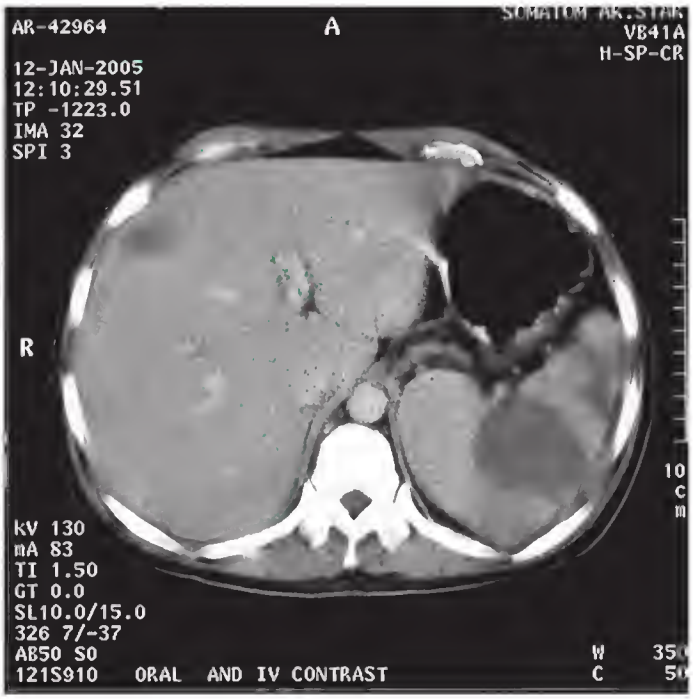

Figure 4: CECT abdomen showing hypoechoic lesions in liver and spleen in a case of disseminated aspergillosis.

Figure 5: CECT paranasal sinuses showing opacification of all the sinuses and bony destruction of the orbital floor in a patient of fungal sinusitis.

Table 2: Criteria for Proven Invasive Fungal Disease (Except for Endemic Mycosis)

Analysis and Specimen	Moulds	Yeasts
Microscopic analysis: sterile material	Histolopathologic, cytopathologic or direct microscopic examination of specimen obtained by needle aspiration or biopsy in which hyphae or melanised yeast-like forms are seen accompanied by associated tissue damage	Findings as in mould infection: from normally sterile site (other than mucus membrane) showing yeast cells
Culture: sterile material	Recovery of mould or 'black yeast' by culture of specimen from normally sterile and clinically/radiologically abnormal site* (excluding bronchoalveolar lavage, cranial sinus cavity and urine)	Recovery of yeast by culture of sample obtained by sterile procedure and from normally sterile site showing clinical or radiological abnormality*
Culture: Blood	Yields a mould (e.g. *Fusarium species*)*	Yields yeast or yeast like fungi
Serological analysis: CSF	Not applicable	Cryptococcal antigen in CSF indicates disseminated cryptococcosis

**Consistent with infectious process.*

Table 3: Outline of Criteria for Probable and Possible Invasive Fungal Disease (Except Endemic Mycosis)*

Host factors	Severe neutropaenia (<500 neutrophils/µl) for >10 days, temporally related to onset of fungal disease
	Recipient of allogeneic stem cell transplant
	Prolonged use of corticosteroids (mean minimum dose 0.3 mg/kg/dL of prednisolone equivalent for >3 weeks)
	Treatment with T-cell immunosuppressants during past 90 days
	Inherited severe immunodeficiency
Clinical criteria	Lower respiratory tract fungal disease
	Presence of one of the following three signs on CT scan chest: (a) Dense, well-circumscribed lesion(s) +/- halo sign, (b) Air-crescent sign, (c) Cavity
	Tracheobronchitis: Ulceration, nodule, pseudomembrane, plaque or eschar on bronchoscopy
	Sinonasal: Imaging showing sinusitis plus at least one of the following three signs: (a) acute localised pain, (b) nasal ulcer with black eschar, (c) extension from paranasal sinus across bony barrier, including into orbit.
	CNS infection: one of the following two signs: (a) focal lesions on imaging, (b) meningeal enhancement on MRI or CT
	Disseminated candidiasis: At least one of the following two entities after an episode of candidemia within the previous 2 weeks (a) small, target-like abscesses in liver or spleen, (b) progressive retinal exudates
Mycological criteria	Direct test (cytology, microscopy, culture)
	Mould in sputum, bronchoalveolar lavage, bronchial brush, or sinus aspirate, indicated by one of the following: (a) presence of fungal element indicating a mould, or (b) recovery by culture of a mould (*Aspergillus*, *Fusarium*, *Zygomycetes* or *Scedosporium*)
	Indirect tests (detection of antigen or cell-wall constituent): (a) Aspergillosis: Galactomannan antigen in plasma, serum, bronchoalveolar lavage, or CSF, (b) invasive fungal disease other than cryptococcosis or zygomycosis: beta-D-glucan detected in serum

**Probable IFD: Requires presence of o host foctor, o clinicol criterion ond o mycologicol criterion; Possible IFD: Requires criterion for o host ond clinicol feotures, but for which mycologicol criterion ore missing.*

One of the Indian Experience

In a study conducted in All India Institute of Medical Sciences (AIIMS), New Delhi, patients with persistent febrile neutropaenia unresponsive to broad spectrum antibiotics were screened for invasive pulmonary aspergillosis (IPA) using high resolution CT scan of the chest, fungal cultures and serology for galactomannan over one year. According to EORTC defining criteria there were 32 cases of suspected IPA based on clinical and microbiological criteria (including galactomannan serology) and the overall sensitivity and specificity of radiology for diagnosing IPA was 96% and 65.4% respectively.The sensitivity and specificity of the halo sign was 39.3% and 81.1% and that of the air crescent sign was 28.6% and 94.3% in diagnosing IPA. Some of the larger nodules and consolidations in patients with suspected IPA showed a central hypodensity on non-contrast CT ('hypodense sign'). These radiological findings were useful in the early institution of anti-fungal therapy in these patients. The overall mortality in patients of IPA was 43.75%.

Treatment

Anti-fungal therapy can be classified into four groups:

1. *Prophylactic therapy:* It targets a population of patients at risk for IFI over a defined period of risk, but who do not yet have evidence of either infection or clinical disease.
2. *Pre-emptive or presumptive therapy:* It targets a population of patients with evidence of IFI based upon a surrogate marker such as an antigen or genomic detection test, but without evidence of clinical disease.
3. *Empirical anti-fungal therapy:* It may be regarded as a variant of pre-emptive therapy where persistent neutropaenic fever despite broad-spectrum anti-bacterial therapy is considered the surrogate marker of IFI.
4. *Directed or targeted therapy:* It applies to patients with evidence of infection and clinical disease.

Anti-fungal agents

The three major groups of anti-fungal agents are: polyenes, azoles, echinocandins (**Table 4**). The first effective antifungal agent against systemic fungal infections was conventional Amphotericin B deoxycholate preparation (AmB). A comparison of the available agents is given in **Table 5**. In most of the affluent countries, the liposomal preparations are used in preference to the deoxycholate preparation. In India, where cost is a major limiting factor, AmB is still used in most patients as first line therapy. The major advantage of AmB is that it has the most broad spectrum anti-fungal spectrum activity even against zygomycosis and low rates of resistance. The azoles are available in oral and intravenous form (**Table 6**). The echinocandins have three preparations licensed for use: caspofungin, micafungin and anidulafungin. These have no renal toxicity and are among the safest anti-fungals but are expensive.

Table 4: Comparison of Major Systemic Antifungal Drugs

Features	Polyenes	Azoles	Echinocandins
Examples of class agent	Amphotericin	Voriconazole	Caspofungin
Mechanism of action	Binds to cell membrane ergosterol, altering membrane permeabilty	Inhibits synthesis of cell membrane ergosterol	Inhibits cell wall formation by inhibiting glucan synthase
Activity	Fungicidal	Fungistatic	Fungicidal for *Candida*, fungistatic for *Aspergillus*
Preparation	Parenteral	Oral and parentral	Parenteral
Class side-effect	Infusional toxicity, nephrotoxic, electrolyte disturbances	Hepatotoxic	Safe, dose reduction in patients with moderate hepatic impairment
Efficacy	Broadest spectrum, also active against zygomycosis, resistance rare	(a) Against *Candida* (b) New agents against aspergillosis (c) *C. glabrata* resistant to voriconazole and posaconazole	Against *Candida*, and Aspergillosis *C. parapsilosis* less susceptible

Table 5: Comparison of Amphotericin B and its Lipid Preparations

	Amphotericin B (AmB)	Liposomal AmB	AmB lipid complex (ABLC)	AmB colloidal dispersion (ABCD)
Therapeutic dose	0.6-1.5 mg/kg/day	3-5 mg/kg/day	5 mg/kg/day (low doses 1mg/kg/d also effective)	2-6 mg/kg/dL
Infusional toxicity	+++	+	+	++
Nephrotoxicity	++++	+	++	++
Cost	Low	+++	++	++
Efficacy	Same	Same	Same	Same

Table 6: Comparison of Different Azole Preparations

	Fluconazole	Itraconazole	Voriconazole	Posaconazole
Preparation	Oral/IV	Oral (capsule and suspension)/IV	Oral/IV	Oral
Therapeutic dose	400 to 800 mg	200 mg bd	IV: Loading 6 mg/kg q12h, maintenance: 4 mg/kg q 12h Oral: Loading 400 mg q 12 h, maintenance: 200 mgq12h	400 mg bd
Limitation		Oral absorption erratic		
Toxicity	Hepatotoxic	Hepatotoxic, gastrointestinal toxicity, Oral suspension and IV preparation contain cyclodextrin (nephrotoxic)	Hepatotoxic with increased liver enzymes in 12%, Visual disturbances (transient) in 30%, skin rashes, Drug interactions frequent. Avoid IV preparation in renal failure as it contains cyclodextrin	Hepatotoxicity, Cardiac arrythmias in patients with QT prolongation or hypokalaemia, drug interactions
Efficacy	*Candida*, *Cryptococcus*	*Candida*, *Aspergillus* (less effective)	*Candida*, *Aspergillus*, *Scedosporium*, *Fusarium*	*Candida*, *Aspergillus*, *Zygomycetes* (mucormycosis)
Ineffective against	*Aspergillus*, mucormycosis, *Scedosporium* , Less effective against *C. glabrata*, *C. krusei*	Zygomycosis	Zygomycosis	

Recommendations for anti-fungal therapy

For IFI caused by common organisms, the anti-fungal agents recommended for use are summarised in **Table 7**. For severe infections, parenteral preparations are preferred. Immunosuppression should be reversed, as far as possible. For neutropaenic patients, recovery from neutropaenia is crucial.

CONCLUSION

It is not easy to make a definitive or even a probable diagnosis of fungal disease in many hospitals with limited facilities. The clinical presentation, radiological features and an active attempt to reach a mycological diagnosis will help in detecting fungal disease. Many of the recently available anti-fungal agents are very effective and devoid of serious toxicity, but the cost is a limiting factor. Amphotericin B is the most affordable anti-fungal agent available in public sector hospitals.

Table 7: Summary of Recommendations for Anti-Fungal Agents

Indication	First line	Second line	Comments
Disseminated candidiasis	Caspofungin, Anidulafungin, Micafungin	Fluconazole Voriconazole Amphotericin or its lipid preparations	The choice of 1st line or 2nd line depends on the microbiological epidemiology in an institution and immune status of the patient
Invasive aspergillosis	Voriconazole	Amphotericin B, Caspofungin, Posaconazole, Micafungin, Itraconazole	Surgical debridement if indicated
Zygomycosis (Mucormycosis)	Amphotericin or its lipid preparations	Posaconazole (limited literature)	Aggressive surgical debridement. No role for azoles (other than posaconazole) or echinocandins
Empirical therapy for persistent neutropaenic fever (not responding to antibiotics)	Amphotericin B or lipid preparations, Caspofungin	Voriconazole	
CNS *Aspergillus* infection	Voriconazole	Amphotericin B	No role for Caspofungin
Cryptococcal meningitis	Amphotericin B or lipid preparation plus Flucytosine		

OTHER FUNGAL INFECTIONS

Histoplasmosis

Histoplasma capsulatum infection is endemic in certain areas of North, Central, and South America, Africa and Asia. Clinical manifestations include acute and chronic pulmonary infection, mediastinal lymphadenitis, mediastinal granuloma, ocular and CNS involvement.

Treatment

(a) Moderately severe to severe pulmonary histoplasmosis: Lipid formulation of amphotericin B for 1 to 2 weeks followed by itraconazole for a total of 12 weeks.

(b) Mild to moderate pulmonary histoplasmosis and mediastinal lymphadenitis/granuloma: Treatment is usually unnecessary. Itraconazole for 6 to 12 weeks is recommended for patients symptomatic for more than a month.

(c) Progressive disseminated histoplasmosis and CNS histoplasmosis: Liposomal amphotericin B is recommended for 1 to 2 weeks, followed by oral itraconazole for a total of at least 12 months.

Pneumocystis Infection

See chapter 63 of section 17.

17.63 *Pneumocystis Jirovecii* Infections

Prasanta Raghab Mohapatra

INTRODUCTION

Pneumocystis carinii was renamed as *Pneumocystis jirovecii* infections. *Pneumocystis carinii* was considered a protozoal disease but now it is considered to be a fungal infection and hence the change in nomenclature. Pneumocystis has gained significant importance since last decade due to changes in the spectrum of HIV related pulmonary infection and increasing use of immunosuppressive drugs. Pneumocystis pneumonia is a severe opportunistic infection, associated with a high mortality rate.

HISTORICAL BACKGROUND

Pneumocystis was first identified as a protozoan by Chagas (1909) and Antonio Carini (1910) in the lung of guinea pigs and rats respectively and was named *Pneumocystis carinii*, in the honour of the latter. In 1952, Czech pathologists Vanek and Jirovec reported the organism from humans. It was reclassified as a fungus in 1988. In 2001, it was renamed as *Pneumocystis jirovecii* that infects humans. The acronym 'PCP' was retained and stands for pneumocystis pneumonia (earlier *Pneumocystis carinii* pneumonia).

EPIDEMIOLOGY

The route of transmission of human pneumocystis infection is still not understood. The existence of pneumocystis in environment is uncertain. Pneumocystis is fairly common in humans who have depressed immune function. Pneumocystis colonisation is more prevalent in the HIV-infected population (CD4 counts <200/mm^3) and the colonisation has been demonstrated in patients with diabetes mellitus, multiple myeloma, chronic lymphoid leukaemia, sarcoidosis, corticosteroid treatment, pregnancy, chronic obstructive pulmonary disease, children below 2 years with bronchiolitis or acute respiratory infection, infants dying of sudden infant death syndrome and aborted foetuses from immunocompetent women. Person-to-person transmission has been suggested during hospital outbreaks of pneumocystis pneumonia. The PCP is reported in immunocomprised patients who are HIV negative.

BIOLOGY, IMMUNOPATHOGENESIS AND PATHOLOGY

There are two life-cycle forms, the trophic form and the cyst form. In an infected host, pneumocystis exists almost exclusively within the alveoli of the lung. The trophic forms are tightly attached to one another and to the alveolar epithelium, through interdigitation of their cell membranes with those of the host cells. Pneumocystis maintains an extracellular existence within alveoli, and probably obtains essential nutrients from the alveolar fluid or living cells. Alveolar macrophages are the primary resident phagocytes that mediate uptake, degradation and clearance of the organisms from the lung and mount an inflammatory response by releasing mediators viz. macrophage-derived tumour necrosis factor α (TNF-α) and interleukin-1 involving T cells. This response may be subdued in HIV-infection and may contribute to colonisation. The alveoli are filled with a typical foamy, vacuolated exudate. Severe disease may include interstitial oedema, fibrosis, and hyaline membrane formation.

CLINICAL FEATURES

Pneumocystis pneumonia classically presents with insidious onset progressive dyspnoea, non-productive cough, and low-grade fever developing over 1 to 3 weeks. Physical examination is dominated by tachypnoea and tachycardia. The breath sounds on auscultation may be normal. Severe hypoxaemia may compel hospitalisation. Acute dyspnoea with pleuritic chest pain may be a sign of the development of a pneumothorax. HIV-infected persons may present with a subacute course and longer symptom duration than other immunocompromised persons. Respiratory involvement is usually less severe in HIV-infected persons, with a high arterial oxygen tension and a lower respiratory rate.

RADIOLOGICAL FEATURES

On chest radiograph, PCP usually presents with bilateral, diffuse, reticular, or granular opacities. The chest radiograph may be normal at diagnosis but typically displays bilateral interstitial infiltrates (**Figure 1**). High-resolution computed tomography (HRCT) scanning is more useful when chest radiograph is non-contributory. A CT scan typically shows ground-glass opacities with patchy distribution, predominating in perihilar regions of lungs. These interstitial infiltrates become increasingly homogeneous and diffuse as the disease progresses (**Figure 2**). Thickened septal lines and areas of consolidation may be present. Less commonly, multiple bilateral cysts are observed. Cyst formation increases the risk of pneumothorax. Other atypical manifestations include multiple thick-walled cavitatory nodules and non-cavitatory nodules. Lymphadenopathy and effusions are infrequent.

Figure 1: Chest radiograph (PA view) showing bilateral reticulo-nodular shadows with dense consolidation predominantly in lower and mid zones.

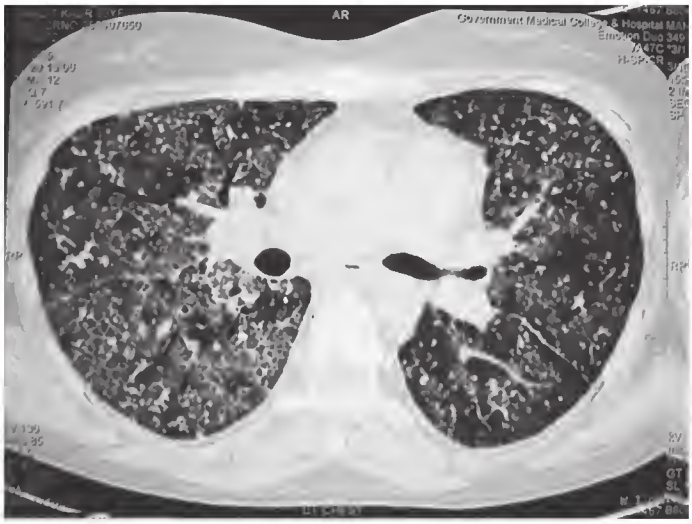

Figure 2: HRCT scan of the thorax at the level of carina showing bilateral patchy ground glass opacity with reticulations and septal thickening.

DIAGNOSIS

Pneumocystis pneumonia is not easy to diagnose because of multiple co-infections like cytomegalovirus and moreover, it cannot be cultured in the laboratory. The diagnosis is made by microscopic demonstration of the characteristic organisms in respiratory specimens such as BAL fluid or induced sputum. Trophic forms can be detected with the use of certain stains, such as modified Papanicolaou, Giemsa, or Gram-Weigert. Cysts can be stained with Gomori-methenamine silver (**Figure 3**) cresyl violet, and toluidine blue O or Calcofluor white. Fluorescein-labeled monoclonal anti-pneumocystis antibodies have the ability to stain both trophic forms and cysts, which is important because the trophic forms are generally more abundant during PCP. Monoclonal antibodies are more sensitive than the general stains and represent the 'gold standard' technique for the diagnosis of PCP.

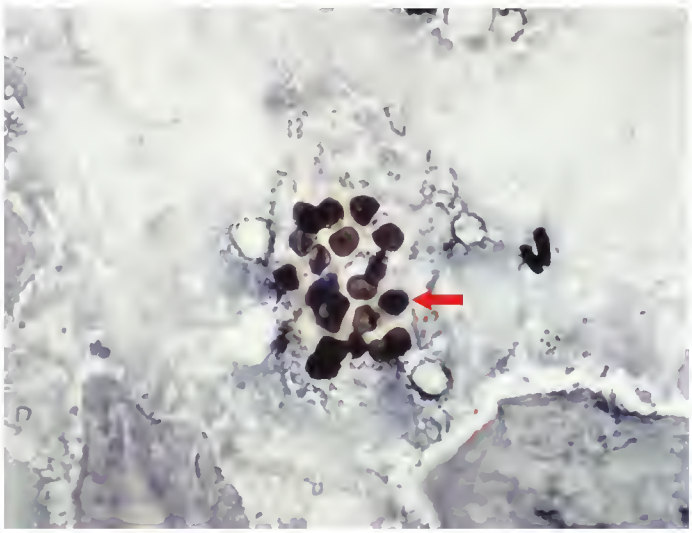

Figure 3: Photomicrograph showing cysts of *Pneumocystis jirovecii* (arrow) in bronchoalveolar lavage fluid specimen stained with Gomoris methenamine silver (GMS) stain.

When sputum induction is negative, bronchoscopy with BAL is the preferred diagnostic procedure, with reported sensitivity from 89% to 98% using immunofluorescent monoclonal antibody staining. PCR can be useful for the diagnosis of PCP when BAL microscopy is not diagnostic. But PCR testing of serum samples is not helpful.

Anaemia and lymphocytopaenia may be observed with PCP. Serum lactate dehydrogenase level may be increased. It is possibly reflection of the underlying lung inflammation and injury rather than a specific marker for the disease. Lower levels of plasma S-adenosylmethionine may be observed in some patients with confirmed pneumocystis pneumonia.

DIFFERENTIAL DIAGNOSIS

The differential diagnoses of pneumocystis pneumonia (diffuse reticulo-nodular infiltrates of lung) are miliary tuberculosis, lymphocytic interstitial pneumonia, Kaposi's sarcoma, sarcoidosis, cytomegalovirus, severe influenza, mycoplasma and acute respiratory distress syndrome.

TREATMENT

Mild cases can be treated as outpatient with close follow-up. Hypoxaemic patients with abnormal chest radiograph need hospitalisation. First-line and alternative therapies, adverse reactions are summarised in **Table 1**.

Parenteral pentamidine is nearly as effective as TMP-SMX. Adverse drug reactions occur in 71% of patients, leading to drug withdrawal in 18% patients. Clindamycin-primaquine and dapsone-TMP exhibit comparable efficacy and toxicity to TMP-SMX. A recent systematic review showed that clindamycin-primaquine was associated with a better outcome of second-line treatment compared with pentamidine. Recommended duration of treatment is 3 weeks in HIV-infected patients and two weeks in non-HIV immunocompromised hosts. Treatment should be extended in non-HIV infected patients when a higher organism burden and clinical improvement is prolonged. Caspofungin, a new drug which targets pneumocystis glucans synthetase may be a promising drug as alternate therapy.

Corticosteroids in HIV-Infected Patients

Benefit of survival on corticosteroid administration begins during the first 72 hours of treatment, and is most useful whose arterial oxygen pressure is equal or less than 70 mm Hg or whose alveolar-arterial oxygen gradient is 35 mm Hg or more. The recommended regimen is 40 mg prednisone twice daily for 5 days, then 40 mg once daily for 5 days, followed by 20 mg once daily for 11 days.

Corticosteroids in Non-HIV Infected Patients

Non-HIV immunocompromised hosts constitute a non-homogeneous group of patients and most of them have been on corticosteroids at the time they developed PCP. Tapering of corticosteroid should be avoided and increasing the dose must be individualised.

PROGNOSIS

The mortality with PCP is high. Recent studies demonstrate a better survival (86-92%) in AIDS patients compared to non-AIDS patients (survival 51-80%).

PREVENTION

As PCP is associated with high mortality, prevention is essential for the groups at risk. Respiratory isolation is not currently recommended since person-to-person transmission has not been clearly demonstrated.

CHEMOPROPHYLAXIS

HIV-infected adults and adolescents, including pregnant women and those on antiretroviral therapy, may require

Table 1: Treatment of Pneumocystis Pneumonia

Drug	Dose (daily)	Route	Comments	Adverse reactions
Trimethoprim-sulphamethoxazole (TMP-SMX)	15-20 mg/kg TMP 75-100 mg/kg SMX in divided doses	Oral or intravenous	First choice	Pancytopaenia, skin rash, hepatitis, pancreatitis, renal insufficiency, hyperkalaemia
Pentamidine	4 mg/kg/dL 600 mg/dL	Intravenous Aerosol	Alternate choice	Nephrotoxicity, arrhythmia, dysglycaemia, pancreatitis, hyperkalaemia
Primaquine plus Clindamycin	30 mg/dL 600 mg thrice daily	Oral	Alternate choice	Fever, anaemia, neutropaenia, abdominal pain, methemoglobinaemia

Table 2: Prophylaxis for Pneumocystis Pneumonia

Type of patients	Duration of PCP prophylaxis
HIV-infected (CD4+ count < 200/ml) or oropharyngeal candidiasis CD4+ T-cell percentage of less than 14%	Primary and secondary prophylaxis till CD4+ count > 200/ml for at least 3 months
Non-HIV Hosts	
Acute lymphoblastic leukaemia or haematologic malignancies on T-cell depleting agents Allogenic haematopoietic stem cells transplantation	From engraftment until 6 months and till receiving immunosuppressive therapy
Lung, heart, and heart-lung transplant recipients	Life-long
Liver transplant recipients	One year
In renal transplant recipients	4 months after transplantation or 4 months after a rejection episode
Wegener granulomatosis	While on corticosteroids

Table 3: Drugs for Prophylaxis against Pneumocystis Pneumonia

Drug	Dose	Route	Comments
Trimethoprim-sulphamethoxazole	80-160 mg TMP + 400-800 mg SMX daily	Oral or intravenous	First choice
Dapsone	50 mg twice daily or 100 mg daily	Oral	Contraindication in G6PD deficiency, cross-reaction with sulfa allergy
Dapsone plus pyrimethamine plus leucovorin	50 mg daily 50 mg weekly 25 mg weekly	Oral	—
Dapsone plus pyrimethamine plus leucovorin	200 mg weekly 75 mg weekly 25 mg weekly	Oral	—
Pentamidine	300 mg monthly	Aerosol	Administration in decubitus position to optimise lung distribution

chemoprophylaxis. Indications and duration of prophylaxis in various risk groups are mentioned in **Table 2**.

Generally the protection rates are excellent, reaching 89-100% with TMP-SMX prophylaxis. The drugs and dosages of prophylaxis are mentioned in **Table 3**.

Resistance and Prophylaxis Failure

Mutations of the gene encoding dihydropteroate synthase in pneumocystis have aroused concern about the potential for the emergence of resistance to TMP-SMX and dapsone, which have been the mainstay of prophylaxis and treatment of pneumocystis pneumonia.

18.1 Basic Considerations of Metabolism

BK Sahay

The varied and complex process involved in utilisation and storage of macros and micro-nutrients either assimilated from diet or metabolites, generated *de novo* as well as elimination of undesirable by-products by the organism is called as metabolism. The intricate process involves not only the major organs like the liver but also each and every cell in the body. Metabolic events have a special predilection for particular cell types, e.g. adipocytes in lipid metabolism. Therefore, metabolic abnormality involving one element can manifest with symptoms and signs referable to many systems and organs in the body.

Most of the metabolic disorders are consequent to defects at enzymatic levels, either intracellular or at plasma tissue interface. The current understanding has also revealed that the defect can be involving various substrates, protein or nuclear receptors inside the cell that modulate gene expression and subsequent protein synthesis. From the cellular molecular point of view it appears that metabolic diseases could be secondary to congenital or genetic defects in the metabolic process but in practice the acquired causes are encountered more often.

In inborn errors of metabolism, mutation affects a protein with metabolic activity in such a way that a characteristic clinical and metabolic lesion, which is a defective enzyme or enzyme activator, can be identified. Although the symptoms of metabolic diseases may appear vague and protean, many diseases can be strongly suspected from clinical manifestations (**Table 1**). An inherited disease cannot be diagnosed in the absence of appropriate family history. In the family history specific enquiries should be made about affected siblings, possible parental consanguinity, paternity, miscarriage, perinatal deaths, sex of likely affected relatives and the geographic and ethnic origin of parents.

Metabolic disorders can be classified by mode of inheritance or by abnormal metabolites produced or deficiency on any specific protein or metabolite necessary for that particular metabolic event. The specific enzyme deficiency, gene coding for expression of the specific protein in question can be labeled. This section deals with disorders related to lipids, amino acids, purine, carbohydrates (other than diabetes mellitus), iron, melanin, copper metabolism along with amyloidosis.

Table 1: Clinical Features of Common Inborn Errors of Metabolism

Unexplained acute neonatal illness and/or failure to thrive in infancy
Slowing of development and arrest followed by retrogression
Slowing of development and arrest leading to unexplained mental handicap
Unusual physiognomy, multiple skeletal deformities with developmental delay and retrogression
Multiple skeletal deformities
Gross visceromegaly
Specific dietary intolerance
Haemolytic anaemia
Unusual body odour
Urolithiasis
Cataracts in early life and dislocation of optic lenses
Persistent jaundice in infancy
Abnormal cutaneous photosensitivity, hypopigmentation
History of recurrent perinatal deaths or still-births

Advances in molecular biology, genetics and imaging techniques have improved outlook for early diagnosis, possible gene therapy in treating and preventing some of these disorders. Advances in stem-cell therapy may also offer an effective treatment in some of these diseases.

18.2 Inborn Errors of Carbohydrate Metabolism

Siddharth N Shah

Inborn errors of carbohydrate metabolism include a wide variety of genetic defects relating to storage of carbohydrate in the form of glycogen, gluconeogenesis from its usual precursors, and breakdown of glycogen into glucose during the state of demand and energy requirement. Many types of glycogen storage disorders (GSDs) have been described in literature but 9 types which have been well characterised are discussed.

GLYCOGEN STORAGE DISORDERS

Glycogen is a polymer of glucose where the residues are mostly in 1,4 linkage and may constitute up to 6000 glucose molecules. Decreased or increased branching of residues can lead to abnormalities of glycogen structure and storage (**Table 1**). The rate of glycogen synthesis and degradation to liberate free glucose along with the site of action of the key enzymes is depicted in **Figure 1**.

Free glucose gets converted to glucose-6-phosphate (Glu-6-P) through phosphorylation in the presence of the enzyme glucokinase in the liver and different hexokinases at other tissues. Glu-6-P is then converted to glucose-1-phosphate (Glu-1-P) by phosphoglucomutase and this process is reversible. Uridine diphosphate glucose (UDP Glu) is generated from UDP and Glu-1-P with the help of the enzyme pyrophosphorylase. UDP Glu is the key substrate for glycogen synthesis. Glucose residues from UDP Glu get linked to form glycogen in the presence of glycogen synthase. This linear linkage gets converted to form the highly branched structure of glycogen, under the influence of the branching enzyme system which transfers the linked glucose residues to appropriate 1,6 positions. These processes are stimulated by insulin but inhibited by glucagon and catecholamines.

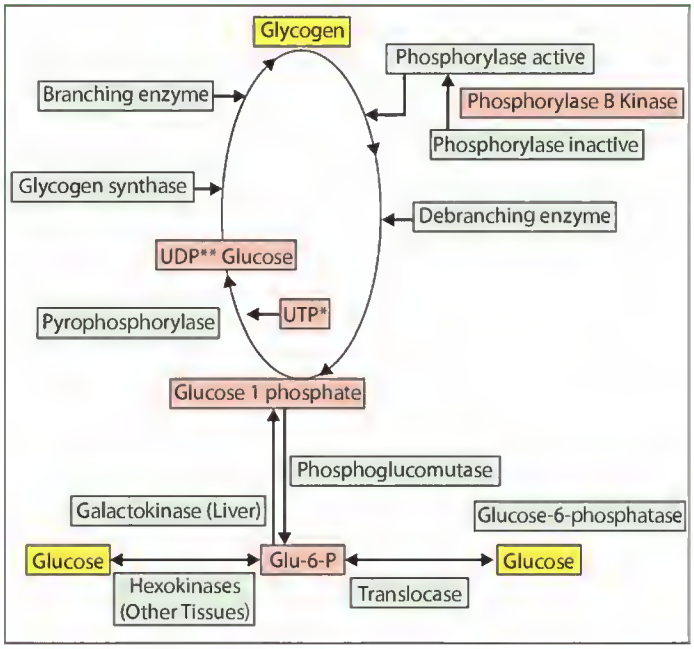

Figure 1: Glycogen metabolism.

**UTP = Uridine 5'-triphosphate; **UDP = Uridine diphosphate.*

Glycogenolysis is an equally complex process where the enzyme phosphorylase acts directly on glycogen and removes individual glucose residues to generate Glu-1-P. This enzyme phosphorylase exists in an inactive form and gets converted to its active form through a series of stimulatory reactions mediated by phosphorylase kinase, which converts inactive phosphorylase to active phosphorylase or re-enters the process of glycogen synthesis depending on the metabolic

Table 1: Glycogen Storage Disorders

Nomenclature	Enzyme Defect	Age at Onset	Mode of Inheritance	Salient Clinical Features
Hepatic hypoglycaemic disorders				
Ia (Von Gierke)	Glu-6-phosphatase	Early infancy	Autosomal recessive	Hypoglycaemia, hepatomegaly, growth retardation, hyperuricaemia, hyperlipidaemia
Ib	Glu-6-P microsomal translocase	Early infancy	Autosomal recessive	Same as Ia and neutropaenia with recurrent infections
III (Cori)	Debrancher enzyme	Post-infancy	Autosomal recessive	Hypoglycaemia, splenomegaly, growth retardation, myopathy
VI (Hers)	Hepatic phosphorylase	Childhood	Autosomal recessive	Hepatomegaly with inconsistent hypoglycaemia
VIb, VIII, IX	Hepatic phosphorylase b kinase	Adult	X-linked in most, autosomal recessive in some	Undiagnosed or hepatomegaly with mild hypoglycaemia
Muscle hypoglycaemic disorders				
V (McArdle)	Muscle phosphorylase	Adult	Heterogenous	Myoglobinuria, muscle pains and cramps
VII (Tauri)	Muscle phosphofructokinase	Adult	Heterogenous	Same as V and haemolytic anaemia
Unclassified disorders with individual pathophysiology				
II (Pompe)	Lysosomal alpha glucosidase	Three forms: infantile, juvenile, adult	?	Hypotonia, congestive heart failure, enlarged tongue
IV (Anderson)	Brancher enzyme	Early infancy	?	Failure to thrive, cirrhosis of liver

demand (**Figure 1**). Besides, the glucose residues can be removed by the debranching enzyme system from glycogen. These glucose residues are in the form of Glu-1-P and get converted to Glu-6-P as discussed above. Glu-6-P then enters the endoplasmic reticulum by the action of the enzyme translocase. There dephosphorylation occurs in the presence of glucose-6-phosphatase and free glucose is liberated. Where glycogen is utilised as source of direct energy, viz. in the muscles, the entire process of glycolysis has to take place along with the activation of glycolytic pathways and the tricarboxylic acid cycle.

Deficiency of required enzymes at any of these steps can lead to abnormalities of glycogen metabolism. Therefore, it is necessary to enumerate GSDs as per the enzyme involved, though the conventional classification is as I to IX. Further, the defect can be in the liver or muscles, producing specific disorders, i.e. hepatic hypoglycaemic or muscle hypoglycaemic pathophysiology-related GSDs. Besides these, there are a few unclassified varieties with individual pathophysiology.

HEPATIC HYPOGLYCAEMIC DISORDERS

Type Ia, Glucose-6-Phosphatase Deficiency (Von Gierke)

This was first described by Von Gierke in 1929 and accounts for nearly one-third of the cases with GSDs. It usually manifests in the first year of life and has an autosomal recessive mode of transmission. Repeated attacks of hypoglycaemia are the presenting symptom and the blood glucose level may be as low as 15 mg/dL. Hepatosplenomegaly is the most marked sign. Round face, protuberant abdomen due to hepatomegaly, thin limbs with presence of xanthoma, or lipaemia retinalis may herald the diagnosis of type Ia GSD. Hypoglycaemia in infancy often produces convulsions but mental development is usually normal. Initial somatic growth may be normal but retardation with delayed adolescence is usual. Lactic acidosis occurs frequently and may be life-threatening while hyperuricaemia can lead to gouty arthropathy and nephropathy. Deficiency of glucose occurs in the cytosol and nuclei of hepatocytes as well as there is renal tubular dysfunction. Hyperlipidaemia makes the patients susceptible to accelerated atherosclerosis. Haematological abnormalities like platelet dysfunction cause epistaxis and bleeding.

Diagnosis is made by liver biopsy. Assay of glucose-6-phosphatase enzyme level reveals very low values in hepatocytes. Microscopy shows deposition of glycogen within hepatocytes with presence of lipid vacuoles but absence of fibrosis. Plasma levels of lipids and uric acid are often high.

Frequent feeds with diet containing about 60% carbohydrates are the treatment of choice. Foods rich in galactose or fructose should be avoided as they cannot be metabolised to maintain glucose homoeostasis. Patients with elevated serum uric acid levels have to be treated with allopurinol. Management requires a team effort by all family members.

Type Ib, Glucose-6-Phosphate Microsomal Translocase Deficiency (Pseudo Von Gierke's Disease)

This was often referred to as pseudo von Gierke's disease. The defect is at the level of the endoplasmic reticulum and so formation of Glu-6-P is normal while liberation of free glucose is deficient (**Figure 1**). The patients have a more severe course than those with Type Ia as there is marked neutropaenia and recurrent infections.

Type III, Debrancher Deficiency (Cori Disease)

This is the next common type of GSDs and is usually known as Cori disease. It is an autosomal recessive disorder seen more frequently in Jews originating from North Africa. Cleavage of glycogen stops short at the branching points in the absence of the enzyme. Partially degraded glycogen accumulates in the liver, heart and muscles. Symptoms appear after the first year of life. Hepatomegaly and hypoglycaemia are less severe than in Type I and tend to ameliorate with adolescence. Ketosis is common but not lactic acidosis. Splenomegaly is more marked. Some patients have deficiency of this enzyme only in the muscles. There is growth retardation and abdominal protuberance due to hepatosplenomegaly. Some cases may present with myopathy at a later age.

Glucagon and epinephrine are effective in raising blood glucose only if injected closely after meals. Excess of glycogen can be demonstrated in liver tissue and erythrocytes in all patients but in the muscles of a few. Management consists of frequent feeds with diet containing more protein and unrestricted milk, cane sugar, fruits or sorbitol.

Type VI, Hepatic Phosphorylase Deficiency (Hers' Disease)

This is an autosomal recessive disorder also called Hers' disease where the primary defect is deficiency of hepatic phosphorylase. The disease is suspected in a child with hepatomegaly and frequent attacks of hypoglycaemia. This is a milder form of GSD and the management is similar to that of Type III.

Type VIII/Type IX/Type VIb, Phosphorylase B Kinase Deficiency

This constitutes a heterogenous group of disorders as the enzyme phosphorylase kinase is made of various subunits and a defect in any of the subunits can lead to the disorder. Although X-linked in most cases, it could be autosomal recessive in some. Therefore different nomenclatures, i.e. Type VII, Type IX and Type VIb, have been assigned to this group of disorders. Depending on the severity of the condition it may remain undiagnosed or may present with hepatomegaly, hypoglycaemia and growth retardation in a child. The management is similar to that in Type III.

MUSCLE ENERGY HYPOGLYCAEMIC DISORDERS

See chapter 32 Section 20.

INBORN ERRORS OF GALACTOSE METABOLISM (GALACTOSAEMIA)

Lactose, the principal sugar of milk, is a disaccharide containing glucose and galactose. Galactose is metabolically available only on conversion to glucose, which occurs in the liver through the following steps:

$$\text{Galactose} + \text{ATP} \xrightarrow{\text{Galactokinase}} \text{Galactose-1-phosphate} + \text{ADP}$$

$$\text{Galactose -1 - phosphate} + \text{UDP Glucose} \xrightarrow{\text{Transferase}} \text{UDP - Galactose} + \text{Glucose-1-phosphate}$$

$$\text{UDP - Galactose} \xrightarrow{\text{Epimerase}} \text{UDP - Glucose}$$

The first reaction is mediated by the enzyme galactokinase, the gene for which is located on chromosome 17; the next step is catalysed by galactotransferase, an enzyme encoded in a gene on chromosome 9.

Galactosaemia develops when conversion of galactose to glucose fails to occur due to deficiency of one of the key enzymes. The disorders are inherited as autosomal recessive.

CLASSICAL GALACTOSAEMIA

Galactose-1-Phosphate Uridyl Transferase Deficiency

The disease is rare, with an incidence around 1:60,000 live-births. Damage to liver and nerve tissue occurs possibly due to accumulation of Glu-1-P and galactitol. In the more severe forms, symptoms start with feeding of breast milk. Vomiting, diarrhoea, hepatomegaly, jaundice, and ascites may appear within one week. Acidosis, hypoglycaemia, dehydration or Gram-negative septicaemia (*E. coli* infection) results in death within days or weeks. In others, manifestations appear gradually during the first three to six months. Failure to thrive and irreversible mental retardation occur in the absence of treatment. Cataract, detectable by slit lamp, may be obvious during the first week of life. Galactosuria can be detected in the urine. Proteinuria, aminoaciduria and phosphaturia due to proximal tubular damage can present as Fanconi's syndrome. The diagnosis may be suspected from the presence of sugar in urine, hypoglycaemia, and raised blood levels of galactose vis-à-vis deficiency of enzyme in red blood cells. Cultured amniotic fluid cells or red blood cells from cord blood may be tested to determine the enzyme content when family history is positive.

Treatment consists of omission of galactose-containing food. Even soyabean preparation contains galactose and should be avoided. All defects regress with institution of appropriate diet. Mothers of babies with galactosaemia should have restricted milk intake in subsequent pregnancies for complete prevention of mental defects.

Galactose Kinase Deficiency

The incidence of this rare disorder is around 1 in 100,000 births. Cataracts are the only clinical manifestation and occur in early childhood. Investigations reveal the presence of a non-glucose reducing substance in urine, high level of galactose in blood and absence or reduced galactokinase in red blood cells. Early introduction of galactose-free diet prevents formation of cataract.

Uridine Diphosphate Glucose Epimerase Deficiency

This asymptomatic disorder can only be recognised by assay of the enzyme in erythrocytes.

INBORN ERRORS OF FRUCTOSE METABOLISM

Fructose is present principally in fruits and honey and as a component of sucrose. After absorption it is metabolised in the following manner-

$$\text{Fructose} + \text{ATP} \xrightarrow{\text{Fructokinase}} \text{Fructose-1-phosphate} + \text{ADP}$$

$$\text{Fructose-1-phosphate} \xrightarrow{\text{Aldolase}} \text{Dihydroxyacetone phosphate} + \text{Glyceraldehyde}$$

Both the above trioses are further metabolised through the glycolytic pathway. The latter may be utilised as a substrate for gluconeogenesis. Deficiency of the above enzymes leads to fructosuria or fructose intolerance.

Essential Fructosuria

This rare form of non-glucose mellituria occurs due to relative or absolute deficiency of hepatic fructokinase. Inherited as autosomal recessive, its incidence is around 1 in 130,000. Renal excretion varies depending on the amount of intake; part of the ingested fructose is utilised by adipose and muscle tissue.

18.3 Lipids and Lipoprotein Metabolism

Soneil Guptha

INTRODUCTION

Cholesterol in our body is generally obtained from dietary (animal) sources or synthesised in the liver. All cells rely on cholesterol as building blocks to create the multiple membranes. Besides helping in regulating membrane fluidity, lipids (cholesterol being one of the lipids) are utilised by living organisms as:

1. Precursor to steroid hormones and bile acids;
2. Major source of energy in the post-absorptive state;
3. Absorption, synthesis and transport of fat soluble vitamins;
4. Maintenance of the cell membrane; and
5. Other biological activities such as production of prostaglandins, leukotrienes, lipoxins, prostanoids, prostacyclines, thromboxanes and gangliosides.

However, in the past 30 years, role of cholesterol as a causal factor for atherosclerotic vascular disease also had a transforming influence in understanding of cardiovascular illness and its treatment strategies.

LIPIDS AND LIPOPROTEINS

Lipids

Fat (Lipid) is insoluble in plasma, and hence, cannot be transported directly through the blood. It is now recognised that lipids (fat/cholesterol) in their various forms are transported by lipoproteins (**Figure 1**).

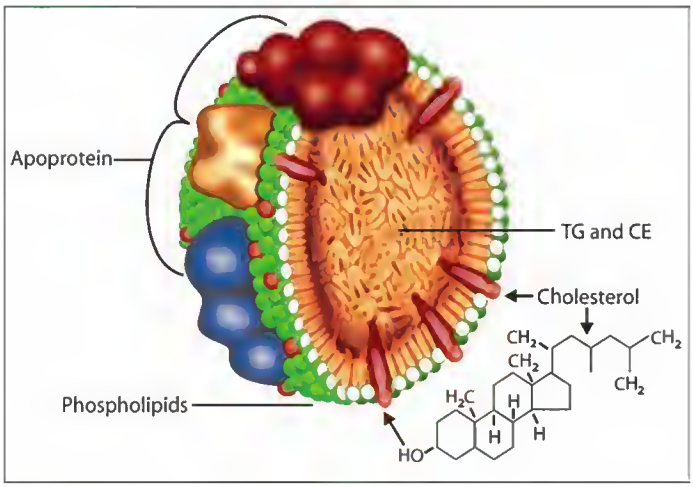

Figure 1: Diagrammatic representation of lipoprotein and cholesterol molecule. *Source: http://www.peprotech.com.*

Lipoproteins

Lipoproteins are a group of heterogenous substances, metabolically active, constantly circulating through the vasculature and existing in a state of dynamic equilibrium between tissues and liver. Triglyceride-fats and cholesterol esters are carried internally in a lipoprotein and shielded from water by the phospholipids monolayer and the apoproteins. Such characteristics make them soluble in the salt water-based blood pool. These lipoprotein particles have hydrophilic groups of phospholipids (PL), cholesterol and apoproteins directed outward. Constitution of the four major classes of lipoproteins is shown in **Table 1**.

Table 1: Compositions of Major Lipoproteins

Class	Protein (%)	Cholesterol (%)	Phospholipid (%)	Triacylglycerol (%)
High density lipoprotein	33	30	29	8
Low density lipoprotein	25	50	21	4
Intermediate density lipoprotein	18	29	22	31
Very low density lipoprotein	10	22	18	50
Chylomicrons	<2	8	7	84

Source: www.lipid-diagnostic.com/toosogie.

The functions of lipoprotein particles includes absorption of dietary fat and transportation of lipids (triglyceride and cholesterol), absorption of and transportation of fat-soluble vitamins; and transportation of cholesterol from peripheral tissues back to the liver.

Chylomicrons

Chylomicrons are produced in the intestinal lumen following the absorption of digested fat. These are the largest lipoproteins and are rich in triglyceride (TG). Because of their particle size, chylomicrons scatter more light and may cause the serum to take on a cloudy appearance after meals or in patients with dyslipidaemia characterised by the inability to catabolise chylomicrons and TG rich lipoproteins. Chylomicrons are transported in the blood to tissues, such as skeletal muscle, fat, and the liver.

Very low density lipoprotein and intermediate density lipoprotein cholesterol

Very low density lipoprotein (VLDL) is a lipoprotein particle similar to chylomicrons, which contains a high concentration of TG. VLDL is synthesised from free-fatty acids formed in the catabolism of chylomicrons in the liver, or from endogenous production of TG. The TG component of VLDL also undergoes hydrolysis by capillary lipoprotein lipase (LPL) to provide fatty acids to adipose and muscle tissue. The remaining lipid portion is called intermediate density lipoprotein (IDL). IDL is then converted to low density lipoprotein (LDL) by enzymatic action of hepatic lipase or is taken up by the liver via the LDL receptor.

Low density lipoprotein cholesterol

In human body, LDL, the products of VLDL and IDL metabolism, are the most cholesterol-rich of all lipoproteins. LDL particles have a plasma life of 3 to 4 days. Each LDL particle contains one molecule of apoprotein B, which is the major protein constituent of LDL. There are two forms of LDL: large buoyant and small, dense LDL. Small, dense LDL is especially rich in cholesterol esters, associated with metabolic disturbances such as hypertriglyceridaemia and insulin resistance; and especially atherogenic. The main role of LDL is to transport cholesterol from the liver to the peripheral tissues, including adrenocortical cells, lymphocytes, muscle cells, and renal cells. About two-thirds to three-fourths of the cholesterol in normal human plasma is contained in LDL particles. LDL is mostly taken up by the liver and other cells via LDL receptors (**Figure 2**) and to a much lesser degree by the LDL-receptor-independent pathway, or scavenger pathway. This scavenger pathway contributes to the deposition of cholesterol in arterial walls and in macrophages of tendons and skin (xanthomas).

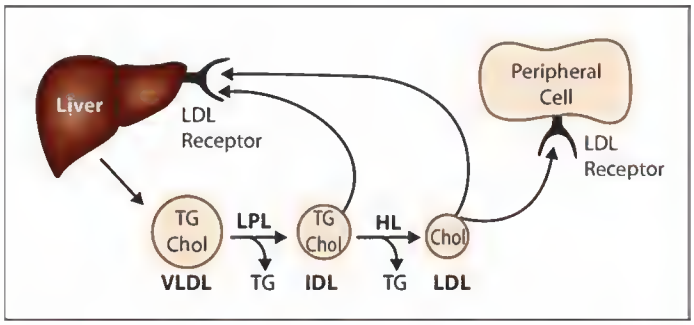

Figure 2: Schematic representation of low density lipoprotein metabolism. *Source: http://ethesis.helsinki.fi.*

LDL= Low density lipoprotein; TG= Triglyceride; Chol= Cholesterol; VLDL= Very low density lipoprotein; LPL= Lipoprotein lipase; IDL= Intermediate density lipoprotein; HL= Hepotic lipose.

High density lipoprotein cholesterol

High density lipoproteins (HDLs) are the smallest and densest of the plasma lipoproteins. These are a heterogenous class of lipoproteins with relatively high protein content (40% to 55%), which is the reason for their high density. HDL-C accounts for approximately 25% of blood cholesterol and is a source of cholesterol for endocrine tissues such as the adrenal glands, ovaries, and testes. HDL-C is an important contributor to reverse cholesterol transport, the process whereby cholesterol from peripheral tissues is transported to the liver, where it can be disposed of in bile. HDL is also reported to have anti-oxidant and anti-inflammatory properties that prevent development of atherosclerotic plaques or atheromas. These effects include the inhibition of apoptosis, the inhibition of thrombosis and the restoration of endothelial function.

Lp(a)

The mechanism and sites of Lp(a) production and catabolism are debated. Kidney has been identified as playing a role in Lp(a). Vegetarians have higher levels of Lp(a) than fish eaters. Lp(a) because of LDL cholesterol content, contributes to atherosclerosis and also has been demonstrated to cross-bind with receptors for LDL. Lp(a) physiological structure is similar to plasminogen and tissue plasminogen activator (t-PA). Thus, it competes with plasminogen for its binding site, leading to reduced fibrinolysis. Also because Lp(a) stimulates secretion of plasminogen activator inhibitor 1 (PAI-1) it leads to thrombogenesis. These unique features of Lp(a) suggest that it causes generation of clots and atherosclerosis.

Apolipoproteins

Apo is a protein moiety associated with lipoprotein. It is responsible for the structural integrity of lipoprotein molecules. Apo activates enzymes that are responsible for lipoprotein production. It also helps in binding of the lipoproteins to the cell surface receptors. The classification of Apo along with its primary source and its association with various lipoproteins is presented in **Table 2**.

Table 2: Different Apoproteins (Apo) and Their Activities

Type	Primary Source	Constituent of Lipoprotein	Role in Lipid Metabolism
Apoprotein AI	Intestine, liver	HDL, CM	Structural protein of HDL, LCAT activator
Apoprotein B48	Intestine	CM	Structural apoprotein of CM
Apoprotein B100	Liver	VLDL, IDL and LDL	Structural apoprotein of these LPs and ligand for binding to LDL receptor
Apoprotein C	Liver	CM, VLDL and remnants	Inhibit binding of LDL receptor related protein
Apoprotein D	Spleen, brain, testes, adrenals	HDL	Unknown
Apoprotein E	Liver	CM, VLDL, IDL and HDL	Structural apoprotein and ligand for binding of these lipoproteins to LDL receptor/ remnant receptor (?)

Source: http://www.peprotech.com/lipoprotein & apoproteins.

LIPID HOMEOSTASIS/TRANSPORT (Cholesterol Balance)

Cholesterol balance is maintained through hepatic and extra-hepatic activity. Depending on the diets, typical daily consumption varies from 300 to 700 mg and three times (approximately 1000 to 2000 mg) of that is secreted in the bile and subsequently into the intestines. Three major lipid transport pathways in the body are described below.

Exogenous Cholesterol Transport

The exogenous pathway of lipoprotein metabolism is responsible for the transport of lipids from the intestine (**Figure 3**). Dietary fats are digested in the stomach and duodenum and converted into monoglycerides (MGs) and free fatty acids (FFAs) by gastric lipase. Dietary cholesterol esters are de-esterified into free cholesterol (FC) by these same mechanisms. MGs, FFAs, and FC are then hydrolysed by the pancreatic cholestryl ester hydrolase, emulsified/solubilised by bile acid into micelles in the intestinal lumen and shuttled to intestinal villi for absorption. After absorption, the FC along with fat soluble

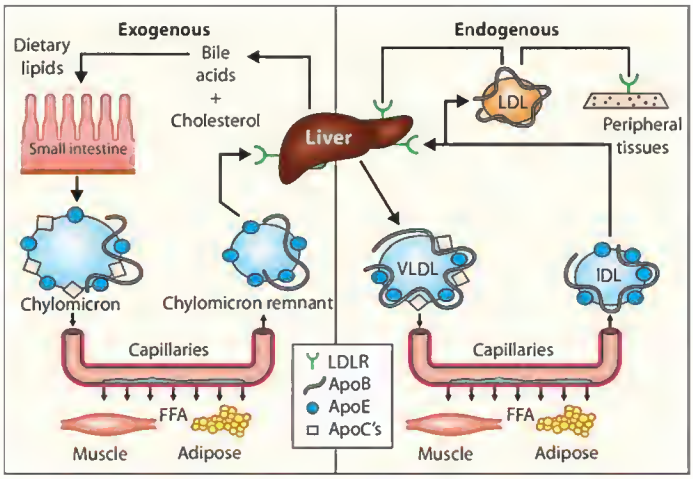

Figure 3: Schematic representation of lipid transport pathways.
Source: Harrisons's Online chapter 350, Transport of Dietary Lipids.

vitamins and retinol combine (re-esterified) with FFAs by acylCoA:cholesterol acyltransferase (ACAT) to form cholesteryl and retinyl esters, respectively. Following this process these esters are packaged with Apo-B48 to form chylomicrons. The chylomicrons are then transported across the enterocytes and released into the lymphatics and through the cisterna – chyle thoracic duct system enter the blood circulation. Unlike other digested nutrients, chylomicrons do not enter the portal blood. While in circulation, chylomicron acquires ApoA and ApoC and binds to endothelial cells of capillaries supplying the skeletal muscles and adipose tissue. At the capillary endothelium tissue interface, the enzyme LPL hydrolyses the chylomicron to release FFAs and MGs and the chylomicrons are reduced to chylomicrons remnants. The FFAs are utilised either for energy purposes or for resynthesis of triglycerides (TGs) in the adipose tissue or in liver combined with glycerol for endogenous TGs synthesis. The chylomicrons remnants which are less and less laden with TGs but are relatively richer in their cholesterol content, can be removed rapidly by the liver with the assistance of hepatic lipase (HL) or if they are small enough may be able to penetrate the endothelial surface of the arterial wall where they may contribute to plaque formation. In the hepatic bed and the chylomicrons, remnants bind to hepatocytes through ApoE receptors. By this exogenous pathway, on an average, 100 g of TGs and 1000 mg of cholesterol are transported every day. The process is brisk with a short half-life of few minutes, and therefore, no chylomicron and chylomicron-remnant is found in the circulation after 10 hours of fasting in a healthy individual.

Endogenous Cholesterol Transport

The circulation and metabolism of VLDL molecules constitute the endogenous lipid transport (**Figure 3**). The liver is a cross road of cholesterol metabolism, regulating and maintaining cholesterol balance by responding to variations in cholesterol uptake and export. Synthesis of cholesterol in liver involves generation of TG and cholesterol ester and packaging into VLDL particles which are released into the circulation. Besides triglycerides and cholesterol derived from liver (endogenous), VLDL contains a very specific apoprotein synthesised by hepatocytes called ApoB100. Over and above ApoB100, the VLDL molecules acquire ApoE and ApoC in circulation. The VLDL is then processed (similar to the chylomicrons from the exogenous pathway, though at a slower rate) by LPL in tissues to release FFAs and MGs. The fatty acids are taken up by muscle cells for energy or by the adipose cells for storage. Once processed by LPL, the VLDL becomes a VLDL remnant or intermediate density lipoproteins (IDL), a smaller, denser lipoprotein than VLDL. These molecules further go on liberating FFAs from their residual TGs content to the peripheral tissues, for the purpose of fuel and ultimately converted to LDL. Thus, LDL is the end-product of VLDL metabolism. The LDL molecules are relatively homogenous having no TGs, rich in cholesterol and contain only ApoB100. The LDL molecule binds to a variety of peripheral tissues like endothelial cells, kidney, adrenal, lymphocyte etc, through ApoB100 – receptors. By the process of receptor mediated endocytosis, the LDL is then taken inside the lysosomes of these cells. Cholesterol liberated from LDL is utilised for cell membrane synthesis of every cell, steroid hormone synthesis by appropriate cells and inhibition of ApoB100 receptors synthesis so as to prevent excess deposition of cholesterol in the peripheral cells. Over and above this, some quantity of LDL and IDL are taken up by liver through the ApoB100 receptors present on hepatocytes or are hydrolysed in the liver by hepatic-triglyceride lipase to form LDL, a smaller, denser particle than IDL. As LDL is taken up by receptors, free cholesterol is released and accumulates within the cells. LDL receptor activity and uptake of LDL regulate plasma LDL concentration by several mechanisms, including decreasing the synthesis of hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase that controls the rate of cholesterol synthesis, suppressing the synthesis of new LDL receptors in the cells, and activating the enzyme, acyl-coenzyme A cholesterol acyltransferase, which esterifies free cholesterol into cholesterol ester, storing cholesterol in the cell. Scavenger cells also engulf excess of LDL in circulation so as to maintain homeostasis in health. Approximately 70% of the cholesterol in the body remains in the form of LDL. Liver is responsible for clearing 70% of the LDL circulating in the body.

Reverse Cholesterol Transport

The cholesterol produced by the peripheral cells is transported back to the liver through HDL-mediated pathway called the reverse cholesterol transport (**Figure 4**). Liver and the intestine synthesise nascent HDL particles that contain ApoA-I and phospholipids (mainly lecithin). These molecules contain ApoA, -C and -E but give off ApoC during the course of metabolism ApoA interacts with a molecular complex known as the ATP-

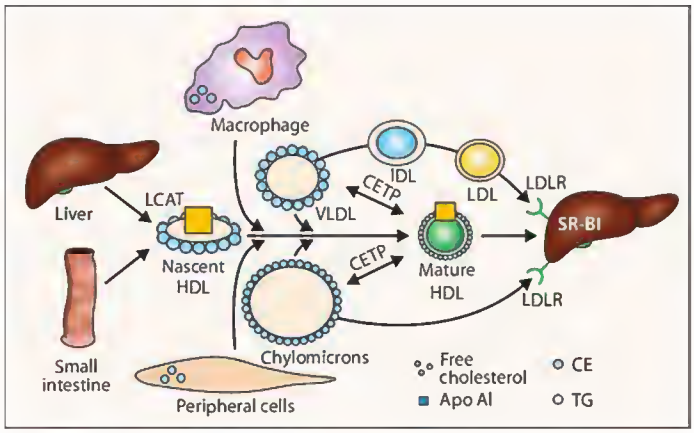

Figure 4: Schematic representation of reverse cholesterol transportation pathways.
Source: http://www.fracp.bigpondhosting.com/images/hdlmetabolism.jpg.

binding cassette transporter 1 (ABCA1) in the hepatocyte, and is then secreted into the plasma as a lipid-poor particle. Through further interactions with ABCA1 expressed on the surfaces of macrophages in the arterial wall, the circulating lipid-poor apoA removes excess cholesterol from these macrophages, forming what is known as nascent pre-beta HDL particles. The enzyme lecithin-cholesterol acyltransferase (LCAT) converts free cholesterol to cholesteryl ester, thereby moving the esterified cholesterol inside the HDL particles, causing the nascent HDL to swell up into a round, "mature" HDL particle. Both the pre-beta HDL molecules and alpha-HDL are then returned to the liver for excretion in the bile through 1 of 2 pathways. This process of mobilising cholesterol from peripheral tissue to liver, which is reverse to both endogenous and exogenous lipid transport and is called, 'reverse cholesterol transport'.

DYSLIPIDAEMIA: CLASSIFICATION OF LIPID DISORDERS

Definition

Dyslipidaemia is a disorder of lipoprotein metabolism, which can include overproduction or deficiency of lipoproteins or both. The disorder can manifest as an elevation of plasma cholesterol, TGs, or both, or a low high density lipoprotein level or all three together that contributes to the development of atherosclerosis.

Classification of Dyslipidaemia

Conventionally, dyslipidaemia is classified based on patterns of elevation in lipids and lipoproteins (Fredrickson phenotype classification) (**Table 3**).

Table 3: Fredrickson Classification (Phenotypic) of Hyperlipidaemias

Phenotype	Lipoprotein Elevated	Lipid Elevated	Atherogenecity
I	CM	TG ↑↑↑ Chol N to ↑	Not known
II-a	LDL	TG N Chol ↑↑	Very high
II-b	VLDL and LDL	TG ↑↑ Chol ↑↑	Very high
III	IDL(Remnants)	TG ↑↑↑ Chol ↑↑	Very high
IV	VLDL	TG ↑↑ Chol N to ↑	High
V	VLDL and CM	TG ↑↑↑↑ Chol ↑ / ↑↑	Higher

CM = Chylomicrons; LDL = Low density lipoprotein; VLDL = Very low density lipoprotein; IDL = Intermediote density lipoprotein; TG = Triglyceride; N = Normol level; ↑ Mildly roised; ↑↑ = Moderotely roised; ↑↑↑ = Severely roised; ↑↑↑↑ = Very severely roised; Chol = Cholesterol.

Source: Fredrickson DS et ol. Circulotion 1965:35:321-327.

This classification does not consider specific dyslipidaemia where there is low HDL that may contribute to the disease despite normal cholesterol and TG levels. A more practical system classifies dyslipidaemia due to the aetiological factors (**Table 4**: Aetiological classification); categorised as primary (genetic) and secondary (lifestyle and other).

Table 4: Aetiological Classification of Dyslipidaemia

Primary Hyperlipidaemia

Hypercholesterolaemia
- Monogenic
  - Familial hypercholesterolaemia due to decreased clearance of LDL
  - Familial combined hyperlipidaemia-excess of TG and apoprotein B 100 production
  - Familial monogenic hypercholesterolaemia due to over production of apoprotein B 100
- Polygenic hypercholesterolaemia

Hypertriglyceridaemia
- Over production of VLDL-TG
  - Familial endogenous hypertriglyceridaemia without excess of apoprotein
  - B 100 production
  - Familial combined hyperlipidaemia (as above)
- Peripheral clearance defect of TG-rich Lipoproteins
  - Familial lipoprotein: deficiency (Fredrickson Type-1)
  - Familial apoprotein C-II deficiency
- Primary clearance defects
  - Familial endogenous hypertriglyceridaemia
  - Familial Type V hyperlipoproteinaemia
  - Familial combined hyperlipidaemia-clearance defect with excess apoprotein
  - B 48 production
- Primary clearance defect combined with secondary excess production of TG

Secondary Hyperlipidaemia

A. Hypercholesterolaemia
- Hypothyroidism
- Diabetes mellitus
- Cushing's syndrome
- Oral contraceptives (OCP)
- Diets rich in saturated fat
- Nephrotic syndrome
- Chronic liver disease
- Anorexia nervosa
- Acute intermittent porphyria
- Cholestasis
- Dysglobulinaemia

B. Hypertriglyceridaemia
- Diabetes mellitus
- Obesity
- Hypothyroidism
- Diets rich in carbohydrates
- Excessive alcohol consumption
- Chronic renal failure
- Cushing's syndrome
- Beta-blockers and diuretics
- Glucocorticoid and oestrogen use
- Dysglobulinaemia

C. Glycogen storage disease
- Systemic lupus erythematosus
- Bulimia
- Pregnancy
- Hypopituitarism

Source: http://secure.pharmacytimes.com/

Clinically subjects can be diagnosed to have dyslipidaemia on the basis of the following factors (Clinical classification).

1. Increase in cholesterol only (pure or isolated hypercholesterolaemia)
2. Increase in TGs only (pure or isolated hypertriglyceridaemia)
3. Increase in both cholesterol and TGs (mixed or combined hyperlipidaemias)
4. Decrease in HDL-C (isolated low HDL-C)
5. Atherogenic dyslipidaemia (increase small dense LDL-C; increase TG, Low HDL-C and increased Lp(a)

Diagnosis of Dyslipidaemia

Irrespective of the underlying mechanism or classification of dyslipidaemia, the biochemical abnormalities will manifest either as hypertriglyceridaemia or hypercholesterolaemia or a combination of both, with or without low HDL-C. Lipoprotein levels associated with various conditions are depicted in **Table 5**.

Raised triglyceride levels suggest an increase in VLDL and/or chylomicron levels while an isolated rise in cholesterol indicates a rise in LDL levels. Combination of both is often due to poor metabolic clearance of IDL, VLDL or chylomicron-remnants.

Several important studies have suggested a linear relationship between lipid levels and the risk of atherosclerotic vascular diseases or fatal and non-fatal events. Hence, there is no numeric definition for diagnosis of dyslipidaemia. The diagnosis is made/applied to subjects who have lipid levels for which treatment has proven beneficial. From the management point of view, estimation of plasma levels of TGs and total cholesterol and HDL-C are necessary as they offer a guide to detect and monitor dyslipidaemia. Further breakdown of cholesterol into LDL, HDL and VLDL cholesterol is also useful clinically. However, a detailed analysis of the TG and apoprotein content of each lipoprotein molecule is at present mainly of academic/research interest. Direct estimation of LDL cholesterol although expensive and usually vital as the calculated value of LDL-C may not correlate quite well with the actual LDL-C especially in South-East Asians due to the common dyslipidaemia characterised by elevated serum TGs with normal to mildly elevated total cholesterol/LDL-C, low HDL-C levels. If direct estimation of LDL-C is not available, then LDL-C can be mathematically derived using the Friedewald formula as given below

Table 5: Lipoprotein Abnormalities Observed with Various Conditions

Cause	VLDL	LDL	HDL
Type 1 diabetes	↑	– or ↓	– or ↑
Type 2 diabetes	↑↑	↑	↓
Hypothyroidism	↑	↑↑	↑
Pregnancy	↑	↑	– or ↑
Obesity	↑	– or ↑	– or ↑
Alcohol	↑	– or ↑	↑
Nephrotic syndrome	↑	↑↑	– or ↓
Chronic renal failure	↑	—	↓
Cholestasis	—	↑↑ (LpX)	↓
Hepatocellular disease	(IDL)	—	↓
Hyperuricaemia	↑	—	↓

VLDL = Very low density lipoprotein; LDL = Low density lipoprotein; HDL = High density lipoprotein; IDL = Intermediate density lipoprotein; LpX = Lipoprotein X.

$$\text{LDL cholesterol} = \text{Total cholesterol} - (\text{HDL cholesterol} + \text{Triglycerides}/5)$$

For example, if the total cholesterol is 200 mg/dL and HDL cholesterol is 40 mg/dL and TG is 300 mg/dL then LDL level = 200 – (40 + 300/5), i.e. = 100 mg/dL. However, this formula is only valid if levels of TGs are 400 mg. An increase in TG level from 44 mg/dL to 398 mg/dL is associated with a 73 mg/dL increase in VLDL. This, in turn, results in a spurious 73 mg/dL decrease in LDL, disqualifying many patients from necessary treatment based on LDL criteria from current guidelines.

Epidemiology of Dyslipidaemia

Epidemiological studies have established a strong correlation between premature coronary artery disease (CAD)/cardiovascular disease (CVD) and serum cholesterol levels. World Health Organization (WHO) in 2002 reported that high cholesterol level is one of the main non-communicable disease-related risk factors in India. Though there is no consistent national protocol to collect the incidence of dyslipidaemia demonstrates various lipid levels reported in different Indian studies.

The Indian Council of Medical Research (ICMR) surveillance project reported a prevalence of dyslipidaemia (defined as a ratio of total to HDL cholesterol >4.5) of 37.5% among adults aged between 15 to 64 years, with an even higher prevalence of dyslipidaemia (62%) among young male industrial workers. The INTERHEART investigators reported that the prevalence of dyslipidaemia (abnormal apolipoprotein ApoB/ApoA1 ratio) among controls without acute myocardial infarction was higher among studied participants living in the 5 South Asian countries (45%) compared with participants from the other 47 countries represented in the study (35%). Abnormal ApoB/ApoA1 ratio was the single largest contributor to the population attributable risk for acute myocardial infarction in South Asian countries. In Indian context lower lipid levels have been seen in rural population. In urban India the high triglycerides are low HDL-C and marginally elevated LDL-C is usually observed. The impact of dyslipidaemia on the burden of congestive heart disease (CHD) has been otherwise understudied at a population level in native South Asians, despite its large contribution to CHD in other world populations. The excess burden of CAD among Indian subcontinent appears to be primarily due to dyslipidaemia with a low prevalence of non-lipid factors (hypertension, smoking and obesity). Diabetes and metabolic syndrome are particularly common among Indo-Asians but do not fully explain the excess burden of CAD in this population. National Commission on Macroeconomics and Health (NCMH) in India has estimated that by 2015 approximately 62 million Indian patients will develop CAD; out of this 23 million will be less than 40 years of age. Studies have shown that the increased prevalence of dyslipidaemia was evident in males aged between 31 to 40 years. In Asian Indian subjects, the prevalence of multiple cardiovascular risk factor increase between the age group of 20 and 29 years with a rapid escalation between 30 and 39 years of age. Hence, screening for risk factors and appropriate interventions should target men and women at around 30 years of age.

Approach to Management of Dyslipidaemia

Irrespective of the cause of hyperlipidaemia/dyslipidaemia, there is uniformity and agreement regarding the management of these disorders as suggested by NCEP/ATP III, Joint European/ Joint British and Canadian guidelines. Current pharmacological therapies for the management of dyslipidaemias are outlined in **Table 6**.

Table 6: Pharmacological Agents for the Management of Dyslipidaemia

Hypertriglyceridaemias	
Fibrates	Management after diet restriction
Fibrates + Low dose resins	Required when LDL rises while on fibrates *vis-à-vis* lowered TG
Fibrates + Omega 3 fatty acids	If TG >1000 mg/dL (Type IV and IIb hyperlipidaemia)
Niacin and niacin analogue	Appropriate drug but compliance poor
Combined hyperlipidaemias triglycerides and cholesterol	
Statin	When hypocholesterolaemia is predominant
Niacin and niacin analogue	Lowers LDL and TG
Niacin + Resins	May be useful
Fibrates	When hypertriglyceridaemia is predominant
Fibrates + Resins/Niacin	If LDL rises above normal while on fibrates
Hypercholesterolaemia	
Statin	Low dose often adequate except in familial type where resins have to be added
Resin	Same as above
Fibrates	Useful in moderate rise in cholesterol
Niacin and niacin analogue	Very useful (see above)
Oestrogen replacement	Useful in postmenopausal women with moderate rise in cholesterol

LDL = Low density lipoprotein; TG = Triglyceride.

Key points in treatment of dyslipidaemia

Unlike, diagnosis of hypertension or diabetes mellitus, the diagnosis of dyslipidaemia can only be made on the basis of lipid normograms for the population under consideration. Although no consensus data is available on lipid normogram for the Indian population, considering that the projection of an epidemic of cardiovascular morbidity in coming years, the algorithm can be fairly relied upon to consider a diagnosis of dyslipidaemia and the basic approach towards its treatment (**Figure 5**).

This algorithm is suggested based upon

1. that evidences for clinical benefit for statins are robust and undisputable and yet to be confirmed for newer fibrates, cholesterol absorption inhibitors, fish oils and newer niacin formulations;
2. that much controversy remains as to what the targets of therapy should be but most agree to (a) keep the TGs to below 150 mg/dL, (b) HDL-C to more than 50 mg/dL, (c) LDL-C values being below 100 mg/dL, and (d) optional to keep the LDL-C to <70 mg/dL in patients with diabetes mellitus or vascular complications;
3. that absolute indications for intensive dietary and pharmacotherapy are: vascular diseases whether CAD, peripheral vascular disease (PVD) or cerebrovascular disease (CVD); genetic hyperlipoproteinaemias, viz. familial hyperlipidaemia and type III; and diabetes mellitus.
4. that for other patients the decision to treat and the target for therapy are based on total risk of the disease. In diabetics the targets are lower than the non-diabetics. Estimation of risk should be broadly based and include family history of CAD/CVD, age, gender, blood pressure, smoking history, alcohol intake, lipid levels (type of dyslipidaemia) and existing co-morbid conditions.

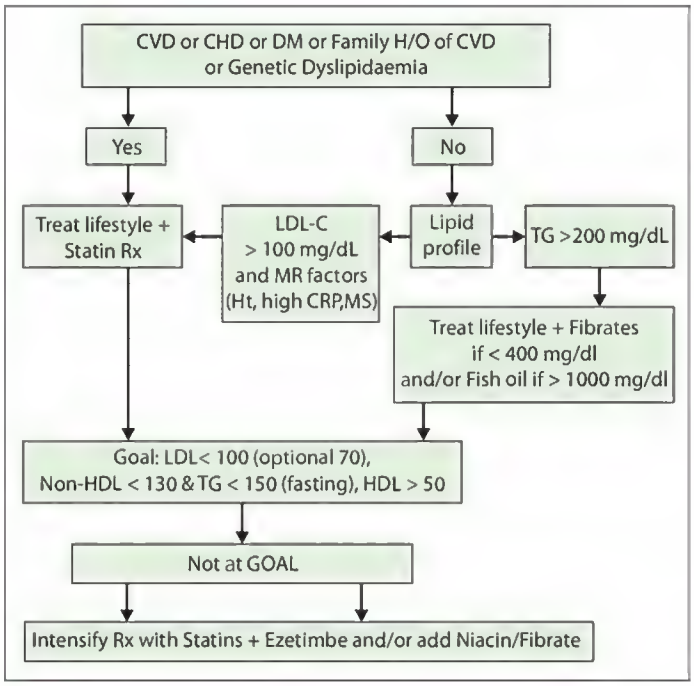

Figure 5: Suggested algorithm for the diagnosis and management of dyslipidaemia. *(Adapted from Endocrine Practice 2009; 15: 370-376).*

THERAPEUTIC CHOICES FOR DYSLIPIDAEMIA

Dietary and Lifestyle Intervention

Modification of lifestyle includes food habits, cessation of smoking, cutting-down alcohol intake, weight reduction if appropriate and regular exercises are not only very much necessary to attain normal lipid levels but are indeed the first step and cornerstone in the management of hyperlipidaemia/dyslipidaemia. Junk food rich in fat as well as refined carbohydrates, frequent snacks and consuming canned or commercially available pre-cooked food, are behavioural habits that are amenable to counselling and reinforced counselling. Alcohol supplies, empty calories and its intake in any case should not exceed 30 g per day. Aggressive weight reduction is often not feasible, so gradual reduction, attainment and maintenance of ideal body weight improves dyslipidaemia, especially TG and HDL-C. Dietary modification is initiated by reduction of saturated fat content to 10% of total calories and reduction of cholesterol intake to <300 mg per day (Step I diet) for 2 to 3 months. The saturated fat content should then be reduced to <7% of total calories and cholesterol intake to <200 mg per day (Step II diet) for up to 6 months.

Accordingly, butter, ghee, hydrogenated oil and palm oil should be eliminated from the diet. Similarly refined carbohydrates like *maida* and *maida*-based preparation can be substituted with carbohydrates with high fibre content. Dietary protein with low fat content could be selected, e.g. dried beans, peas and pulses, chicken-breast, lean meat and

low-fat dairy products. The diet should contain adequate amounts of natural fibres derived from green leafy vegetables and salads. Dietary management of dyslipidaemia in children especially in those without familial hypercholesterolaemia remains controversial. Patients who already have CAD or in the obese and dyslipidaemic subjects, weight loss is the key strategy as is eating less. Exercise is more helpful in maintaining weight loss rather than achieving it.

Pharmacological Interventions

Five groups of drugs have been recommended by the International Lipid Information Board (ILIB) to be categorised as lipid-lowering drugs (**Table 7**). Besides, the pharmacological agents mentioned in the table, fish oil supplements when used with therapeutic intention and oral oestrogen replacement therapy in menopausal women, surgical resection and probucol are tabulated in the **Table 7** and text is discussed before **Table 7**.

Table 7: Pharmacological Agents for the Management of Dyslipidaemia

Class of Drugs	Molecules	Available Strengths of pill (mg)	Dosage and Administration	Indications	Contraindications	Warnings and Precautions
Statins	Atorvastatin	10, 20, 40, 80	10 to 20 mg once daily	Hypercholesterolaemia Elevated total-cholesterol, LDL-C Prevention of stroke, Myocardial infarction (MI)	Active liver disease Pregnancy Nursing mothers Hypersensitivity	Myopathy Rhabdomyolysis Hypothyroidism Renal impairment Hepatic impairment
	Rosuvastatin	5, 10, 20, 40	5 mg to 40 mg Once daily	Hyperlipidaemia Mixed dyslipidaemia Hypertriglyceridaemia Primary dysbetalipoproteinaemia Atherosclerosis	Active liver disease Pregnancy Nursing mothers Hypersensitivity	Myopathy Rhabdomyolysis Hepatic impairment
	Simvastatin	5, 10, 20, 40, 80	5 mg to 80 mg Once daily	Prevention of stroke, MI Hypercholesterolaemia Hyperlipidaemia Hypertriglyceridaemia	Active liver disease Pregnancy Nursing mothers Hypersensitivity	Myopathy Rhabdomyolysis Hepatic impairment
Fibrates	Fenofibrate	145	160 mg to 200 mg Once daily	Hypertriglyceridaemia	Hypersensitivity Hepatic or severe renal dysfunction, Primary biliary cirrhosis Pre-existing gallbladder disease Pregnancy	Liver impairment Myopathy Pancreatitis Renal impairment
	Gemfibrozil	300, 600	1200 mg Once daily	Hypertriglyceridaemia	Active liver disease Pregnancy Nursing mothers Hypersensitivity	Liver disease Kidney disease Gallbladder disease Pregnancy
	Bezafibrate	200		Hyperlipidaemia Hypertriglyceridaemia	Hypersensitivity Hepatic or renal dysfunction Pregnancy Breast-feeding	Liver disease Kidney disease Gallbladder disease Pregnancy
Niacin (nicotinic acid)	Niaspan	500, 750, 1000	500 mg to 2000 mg Once daily	Hypertriglyceridaemia	Active liver disease Active peptic ulcer disease Arterial bleeding Hypersensitivity	Liver disease Kidney disease Pregnancy Diabetes
Bile acid sequestrants	Cholestagel	625	2.6 g to 3.8 g Divided in two or three doses	Hypercholesterolaemia Hyperlipidaemia	Hypersensitivity Bowel or biliary obstruction	Diabetes mellitus Hypothyroidism Nephrotic syndrome Obstructive liver disease Constipation
	Colesevelam	625	2.6 g to 3.8 g Twice daily with meals	Hypercholesterolaemia Hyperlipidaemia	Hypersensitivity Bowel obstruction Hypertriglyceridaemia -induced pancreatitis	Chronic liver disease Severe gout Diabetes Hyperuricaemia Peptic ulcer disease
Inhibitor of intestinal cholesterol absorption	Ezetimibe	10	10 mg Once daily	Primary hyperlipidaemia Homozygous Familial hypercholesterolaemia Homozygous sitosterolaemia	Active liver disease Pregnancy Nursing mothers	Myopathy Rhabdomyolysis Hepatic impairment

Probucol

This drug has dominant effect on lowering LDL-C and is best used as an alternate remedy in patients who had failed to respond or cannot tolerate statins. It can be administered in a dose of 500 mg twice daily. Probucol has no effect on TG levels and may even lower HDL-C levels, but surprisingly it reduces tendon xanthomas effectively, the mechanism of which is still not clearly understood and has proven even point reduction in the CRST trial. Probucol has antioxidant effects and can be used in combination with resins or statins in resistant patients. The drug is lipophilic and tends to get deposited in the adipose tissue, and hence, is not advisable to be administered to women of child bearing potential. Side effects are pre-dominantly gastrointestinal and are usually infrequent. However, prolongation of QT interval and dangerous arrhythmias can occur in occasional cases. Therefore, it is contraindicated in patient with myocardial damage, unexplained syncope (Adam-Stoke attack) or ventricular arrhythmias. As a matter of caution, electrocardiogram has to be done in every patient before and periodically after probucol therapy.

Oestrogen replacement therapy

This therapy is limited to postmenopausal women with dyslipidaemia. Oestrogen replacement therapy (ERT) is instituted only after weighing the risks for CHD and cancer. Although moderate fall in plasma levels of LDL-C and rise in HDL-C occurs, the therapy has no effect on TG levels or may even rise, especially in patients with hypertriglyceridaemia. ERT has no proven end-point reduction trial. Monitoring for gynaecological (especially breast) malignancies have to be done periodically and in women who have not undergone hysterectomy have to be given concomitant progestin therapy along with ERT. Conjugated oestrogen 0.625 mg per day and micronised oestradiol 2 mg per day is an adequate dose for treating dyslipidaemia with ERT.

Omega-3 fatty acids (omega-3FA)

The role of omega-3FA with long chain, i.e. eicosapentaenic acid (EPA) and decosahepaenoic acid (DHA) in reducing plasma TG levels by enhancing peripheral clearance of VLDL as well as lowering TG production by liver is now well documented. There may also be a modest decrease in cholesterol levels along with TG levels in plasma. Fish and other marine oils contain EPA and DHA. Currently, these are available as capsules in combination of 180 mg of EPA and 120 mg of DHA. The therapeutic dose varies from 3 to 12 capsules per day with meals, while 3 capsules per day is adequate as maintenance therapy. A trial in Japanese patients is ongoing to explore the impact of omega-3FA on cardiovascular events.

Surgical Resection of Ileum

POSCH study was the only prospective, randomised, secondary prevention trial to use partial ileal bypass as the method of reducing cholesterol levels. The trial ended after a mean follow-up of 9.7 years (range 7.0 to 14.8 years). Five years after randomisation, total cholesterol levels in the surgery group were 23.3% lower than in the control group, LDL levels 37.7% lower, HDL levels 4.3% higher, VLDL levels 8.3% higher, and TG levels 19.8% higher. Surgery reduced total mortality by 21.7% and CHD mortality by 28.0% compared with controls, but this was not statistically significant. However, patients in the surgery group had significantly lower rates of CHD mortality and non-fatal myocardial infarction combined, PVD, coronary artery bypass grafting, percutaneous transluminal coronary angiography, and disease progression as determined by coronary arteriography. Patients in the surgery group also had more adverse events, such as diarrhoea, kidney stones, gallstones, and bowel obstruction. The authors calculated a gain of 2.7 years in life expectancy in the surgery group. The follow-up study to POSCH after patients had been followed up, for a mean of 18 years (range 15.5 to 23.0 years) confirmed that lipid-lowering therapy decreased overall mortality and increased life expectancy.

CONCLUSIONS

It is well established that reducing total cholesterol and LDL cholesterol levels can significantly reduce the risk of CHD morbidity (including the need for invasive interventions) and mortality. Dyslipidaemia associated with increased CHD risk may be managed either by an individual post-event approach (secondary prevention strategy for intensive intervention and prevention of future events) or by a clusters who are at increased risk (primary prevention strategy for controlling the risk in high risk) or population-based approach (primordial prevention strategy preventing development of risk factors) with changes in diet, smoking habits and physical activity. Targeted LDL cholesterol, HDL cholesterol and TG levels as well as the multiplicative effects of other CHD risk factors should be considered when deciding on a management strategy for an individual patient. Finally, it is important to know that despite the availability of treatment guidelines, many patients do not receive adequate therapy especially in our country due to socio-economic and other reasons. Aggressive therapy of hyper-lipidaemia/dyslipidaemia can help to reduce the epidemic of premature CAD seen in Indians and people from other countries.

18.4 Disorders of Purine and Pyrimidine Metabolism

RV Jayakumar

INTRODUCTION

Purines (adenine and guanine) and pyrimidines (cytosine, thymine, uracil) serve fundamental roles in the replication of genetic material, gene transcription, protein synthesis and cellular metabolism. Purine as well as pyrimidine triphosphates constitute the monomeric precursors of ribonucleic acid (RNA) and deoxyribonucleic acid (DNA). Purines and pyrimidines are required for transcription, translation and protein synthesis.

PURINE METABOLISM

Liver is the major site of *de novo* synthesis of purines in the body, the other source being from the diet. Inside the cells, purine nucleotides are sequentially degraded by specific enzymes, with uric acid as the end product of this pathway. The steps involved in the formation of uric acid include the removal of amino acid group from the adenosine monophosphate (AMP) to produce inosine 5'-monophosphate (IMP), or from adenosine to produce inosine by adenosine deaminase. Then the IMP and guanosine 5'-monophosphate (GMP) are converted into their nucleoside forms, inosine or guanosine, by the action of 5'-nucleotidase. The next step is by the action of purine nucleoside phosphorylase which converts inosine and guanosine into their respective purine bases, hypoxanthine and guanine. Then guanine is deaminated to form xanthine, and hypoxanthine is oxidised by xanthine oxidase to xanthine, which is further oxidised to uric acid, the final product of purine degradation. The inborn errors of purine metabolism are shown in **Table 1**.

HYPERURICAEMIA AND GOUT

Hyperuricaemia is defined as a serum or plasma urate concentration greater than 7 mg/dL in males and 6 mg/dL in females. Gout is an inflammatory response to the monosodium urate monohydrate (MSUM) crystals formed secondary to hyperuricaemia. Major clinical manifestations include acute synovitis, chronic erosive and deforming arthritis, tophi, nephrolithiasis, interstitial nephritis and hypertension.

Three prerequisites for the development of gout are the development of hyperuricaemia leading to urate saturation, formation of monosodium urate (MSU) crystals and interactions between MSU crystals and leukocytes.

Epidemiology of hyperuricaemia is different from that of gout. Mean urate concentrations are age and sex related. Prepubertal in males, the mean concentration is around 3.5 mg/dL with a steep rise to 5.2 mg/dL at puberty. In females , the rise is appreciated only after menopause (up to 4.7 mg/dL). Only 10% of the patients with hyperuricaemia exhibit gout. The incidence of gout varies in population from 0.2 to 3.5 per 1000. Gout is rare in children and in pre-menopausal women. The peak age of onset in males is between 40 and 50 years. Serum uric acid concentration is the single-most determinant of the risk of developing gout. With normal renal function, its blood concentration depends mainly on breakdown of nuclear proteins and dietary purine load. Provocative factors include diuretics, alcohol, dietary excess, surgery, trauma, sepsis, stress, starvation and dehydration.

Hyperuricaemia and gout may be classified as primary and secondary. Increased overproduction of uric acid as a cause of gout is seen in only 10% to 15% of the patients (over-producers) and in 80% to 90%, uric acid excretion is impaired (under-excretors). Obesity, hypertension and dyslipidaemia are important associated disorders. A negative association exists between gout and rheumatoid arthritis.

Table 1: Inborn Errors of Purine Metabolism

Enzyme Activity	Inheritance	Clinical Features
HGPRT–deficiency (complete)	X–linked (fully expressed in males of 2-16 years)	Hyperuricaemia, gout, choreoathetosis, spasticity, mental deficiency Self-mutilation i.e., Lesch-Nyhan syndrome
HGPRT–deficiency (partial)	X-linked	Hyperuricaemia, gout, convulsion, mental retardation, spino-cerebellar syndrome
PRPPS–over-activity	X-linked	Hyperuricaemia, gout, deafness, mental retardation, polyneuropathy, dysmorphic facial features
APRT–deficiency	Autosomal recessive	Renal colic (due to calculi of 2, 8-dihydroxyadenine)
XO–deficiency	Autosomal recessive	Hypouricaemia, excessive urinary excretion of xanthine and hypoxanthine, renal colic (due to xanthine calculi)
ASL–deficiency	Autosomal recessive	Autism psychomotor retardation, axial hypotonia
AD–deficiency	Autosomal recessive	Muscular weakness and muscle cramps after exercise
PNP–deficiency	Autosomal recessive	Isolated T-cell immune deficiency
ADA–deficiency	Autosomal recessive	Severe combined immunodeficiency (T- and B-cell)

HGPRT = Hypoxanthine-guanine phosphoribosyltransferase; PRPPS = Phosphoribosylpyrophosphate synthetase; APRT = Adenine phosphoribosyltransferase; XO = Xanthine oxidase; ASL = Adenylosuccinate lyase deficiency; PNP = Purine nucleoside phosphorylase; ADA = Adenosine deaminase deficiency.

CLINICAL FEATURES

Hyperuricaemia and gout can occur in the following four phases.

Asymptomatic Hyperuricaemia

Hyperuricaemia may be an incidental finding and may never lead to gout. Conversely, during acute gouty arthritis, serum uric acid levels may not be elevated. Acute over-production of urate may occur with cytotoxic chemotherapy which is associated with a high risk of acute renal failure. Asymptomatic hyperuricaemia needs close observation but no active treatment.

Acute Gouty Arthritis

The big toe (first metatarsophalangeal joint) is the classic site for urate gout. One-third of the patients may get their first attack at another site, such as the in-step of the foot, ankle, knee or hand joints. The attack is acute, it starts in the night, the joint and surrounding tissues are swollen, red, hot, shiny, and extremely painful. There is mild fever with chills. Resolution is usual within a week even without treatment. As acute gout tends to be recurrent, a history of previous self-limiting episodes is a helpful pointer. A positive family history can be obtained from such patients.

Recurrent Gouty Arthritis

The frequency of subsequent acute attacks of gout usually increases over time. Approximately 60% of the patients have a second attack within the first year, and 78% have a second attack within 2 years. Only 7% of the patients do not have a recurrence within a 10-year period.

Chronic Tophaceous Gout

The symptom-free interval between acute episodes may last a few days to several years. In some patients, asymptomatic periods progressively shorten and in about 10 years from the first episode, chronic tophaceous phase develops. Tophi are chalky deposits of sodium urate that are large enough to be seen on radiographs and may occur at virtually any site. The most common sites include the joints of hand and feet. The helix of the ear, olecranon bursa and the Achilles tendon are the classic locations for tophi. Articular tophaceous gout can result in a destructive arthropathy and chronic secondary osteoarthritis. The duration of time between the first gouty attack and recognisable tophaceous disease is highly variable and may range from 3 to 42 years. Tophaceous disease is more likely to occur in patients with the following: a polyarticular presentation, a serum urate level higher than 9 mg/dL and a younger age at onset (i.e. 40 years or younger).

DIAGNOSIS

A definitive diagnosis requires aspiration and examination of synovial fluid to confirm the presence of monosodium urate crystals. Urate crystals are needle shaped and are negatively birefringent on polarising microscopy. The presence of crystals does not prove that gout is acute.

Serum urate concentrations are often normal during acute gout and many patients with hyperuricaemia never develop acute gout. Thus, a raised serum urate concentration favours gout, but is not diagnostic. Plain radiographs are unhelpful in patients with acute gout and might show only soft-tissue swelling. In patients with recurrent episodes, there is likely to be evidence of osseous destruction or erosive changes in the joints.

Plain radiographs are helpful to differentiate chronic tophaceous gout from rheumatoid arthritis. Erosions in gout are characteristically punched-out with overhanging sclerotic margins and are situated away from joint margins, sometimes outside the joint capsule. Rheumatoid arthritis causes marginal erosions, always within the limit of joint capsule. The absence of periarticular osteopaenia and preservation of joint space in gout also helps to differentiate the two conditions. Septic arthritis is the important differential diagnosis as the consequences of not treating it can be disastrous. The clinical features of acute gout and septic arthritis are often indistinguishable and sometimes coexist. Other conditions that can cause acute onset arthritis include reactive arthritis, pseudogout (characterised by elderly onset, predilection for knees or wrists, radiological chondrocalcinosis, and synovial fluid pyrophosphate crystals) and rheumatoid arthritis (with polyarticular presentation).

TREATMENT

Acute gout is a self-limiting condition typically lasting 7 to 10 days, but treatment ensures pain relief and speedy recovery.

Therapeutic options include non-steroidal anti-inflammatory drugs (NSAIDs), colchicine, intra-articular corticosteroids and systemic corticosteroids.

The drug of choice in most patient would be a NSAID, provided there are no contraindications (renal impairment, active peptic ulcer disease, congestive cardiac failure, known hypersensitivity, or anticoagulant therapy). The NSAID is usually continued for at least 5 to 7 days or longer if pain takes longer to resolve. To reduce gastrointestinal toxicity, the dose of NSAID should be gradually tapered as soon as improvement occurs. Parenteral preparations or suppositories are available for patients who cannot swallow tablets.

The second drug of choice is colchicine. It works by inhibiting urate crystal phagocytosis by neutrophils. Colchicine is most effective when started shortly after the onset of acute episodes, before phagocytosis establishes itself. The dose should be gradually tapered when improvement occurs and then stopped after pain completely resolves. Colchicine should be used in lower doses in patients with renal impairment.

In gout affecting medium or large joints and in those with the absence of septic arthritis, intra-articular corticosteroids are useful, especially if patients cannot take NSAIDs or colchicine. Methylprednisolone is the preparation most commonly used. The dose is typically 80 mg for large joints and 40 mg for medium joints. Pain relief can be expected in 24 to 48 hours.

In patients with polyarticular gout in whom other treatments are difficult, systemic corticosteroid is an option.

PREVENTION OF RECURRENT ATTACKS

Uricosuric Drugs

These agents decrease the serum uric acid level by increasing renal excretion. Probenecid and sulphinpyrazone are used in patients who are considered under-excretors of uric acid. Uricosuric drugs should not be given to patients with urine output of less than 1 mL per minute, creatinine clearance of less than 50 mL per minute or history of renal calculi. The physiologic decline in renal function that occurs with ageing frequently limits the use of uricosuric agents.

Probenecid

Probenecid in a dosage of 1 to 2 g per day, achieves satisfactory control in 60% to 85% of the patients. It is important to note that the drug also blocks the tubular secretion of other organic acids. This may result in increased plasma concentrations of penicillin, cephalosporins, sulphonamides and indomethacin.

Sulphinpyrazone

The dosage is 100 to 200 mg twice a day and increase it to 800 mg/day. It is a uricosuric agent that is related to phenylbutazone. Because it can act as an antiplatelet drug, it should be used cautiously in patients who are anticoagulated or have bleeding problems. Sulphinpyrazone can also cause gastrointestinal problems. Thus, caution should also be excercised in giving this drug to patients with peptic ulcer disease.

Allopurinol

Allopurinol is a xanthine oxidase inhibitor, impairs conversion of hypoxanthine to xanthine and the conversion of xanthine to uric acid. The effect of the drug depends on the dosage. Allopurinol in a dosage of 300 mg per day has been reported to reduce serum urate concentrations to less than 7 mg/dL in 70% of the patients.

Allopurinol is the drug of choice in patients with severe tophaceous deposits and in patients with a history of impaired renal function (creatinine clearance of less than 50 mL per minute) uric acid nephropathy or nephrolithiasis. The drug is also preferred as a pre-treatment agent to protect against uric acid nephropathy in patients with lymphoproliferative or myeloproliferative disorders. The initiation of allopurinol therapy can also precipitate an acute gout attack. The dosage of allopurinol should be adjusted in patients with renal impairment. Common side effects are gastrointestinal intolerance and skin rashes. Other serious events include hypersensitivity reactions, hepatitis, toxic epidermal necrolysis, vasculitis and bone marrow suppression.

Febuxostat

Febuxostat is a novel, orally administered non-purine analogue inhibitor of xanthine oxidase, used in the management of hyperuricaemia. The daily dose is 80 to 120 mg per day. It is metabolised by glucornide formation and oxidation in the liver. Adverse events include abnormal liver function test, diarrhoea, and musculoskeletal symptoms.

HYPOURICAEMIA

Hypouricaemia, defined as serum urate concentration <2 mg/per day, can result from decreased production of urate, increased excretion of uric acid, or a combination of both. Important causes are uricosuric agents such as aspirin (at doses >2 g/day), X-ray contrast materials, neoplastic diseases, hepatic cirrhosis, inappropriate secretion of vasopressin, defects in renal tubular transport such as primary Fanconi syndrome and Fanconi syndromes associated with Wilson's disease, cystinosis, multiple myeloma and heavy metal toxicity. Hypouricaemia causes no symptoms or pathology, and therefore, requires no treatment.

PYRIMIDINE METABOLISM

There are three major pathways for pyrimidine metabolism in man, *de novo* synthesis, salvage and degradation. The *de novo* pyrimidine synthesis involves series of six enzymatic reactions leading to the formation of orotic acid, orotidine monophosphate and uridine monophosphate, from which thymidine and cytidine monophosphates are formed. The pyrimidine nucleotide monophosphates are degraded to the nucleosides cystidine, uridine and thymidine by 5'-nucleotidase. Further catabolism leads to the formation of beta alanine and beta aminoisobutyrate and metabolic incorporation in the citric acid cycle.

18.5 Iron Metabolism and Iron Overload Syndrome

Mukesh Desai

INTRODUCTION

Iron is an important element necessary for electron transport. Besides being an essential element of haemoglobin it is also an important component of several enzymes, which are necessary for several metabolic functions as shown in **Table 1**.

Table 1: Metabolic Functions of Iron

Iron Haem Proteins	Function
Haemoglobin	Oxygen carrier
Myoglobin	Oxygen storage
Cytochromes a, b, c	Energy production; converts NADH, $FADH_2$ into ATP energy
Cytochrome P450	Drug metabolism
Catalase	Degrades H_2O_2
NADPH oxidase (phagocytes)	Respiratory burst required to kill pathogen

NADH = Nicatinamide adenine dinucleotide dehydrogenase; FADH = Flavin adenine dinucleatide dehydragenase; ATP = Adenosine triphosphate; NADPH = Nicatinamide adenine dinucleatide phosphate dehydragenase; H_2O_2 = Hydrogen peraxide.

Iron must be maintained in soluble form to prevent toxicity and specialised transport systems and membrane carriers have evolved in humans to maintain iron in a 'soluble' state suitable for circulation in the bloodstream, e.g. bound to serum transferrin.

IRON METABOLISM

Since there is no mechanism for deliberate excretion of iron through the liver or kidneys, iron homeostasis is maintained primarily by the tight regulation of iron absorption in the intestine and the high degree of conservation of body iron stores.

Iron Loss and Intake

Daily excretion of iron is about 1.2 mg (faeces 0.8 mg, urine 0.2 mg, sweat 0.2 mg, hair and nails negligible amount). Iron loss through menstrual blood flow in woman is about 1 mg per day. Therefore, daily requirement of dietary iron is 1 to 3 mg and is more during periods of growth, menstruation, pregnancy and lactation.

During pregnancy, a total of 1250 mg extra iron is required: increase in packed cell volume (500 mg), foetus and placenta (500 mg), loss during labour (250 mg) and loss in breast milk (200 mg) minus 250 mg, since there is no menstrual blood loss. Therefore, during the second and third trimesters of pregnancy and while breast-feeding, an additional 4 to 5 mg of iron is required daily. Ferrous sulphate iron tablets (anhydrous, 200 mg) contain 67 mg iron, of which only 8% to 10% is absorbed. Hence, one tablet is given daily during pregnancy.

Two major sources of iron are foods containing iron and recycling of iron from senescent red cells. Most of the iron found in the plasma derives from the continuous breakdown of haemoglobin in senescent red cells by reticuloendothelial (RE) macrophages. The remaining body iron is stored, primarily in hepatocytes.

The amount of iron obtained from the diet should compensate the daily iron loss. The average Western diet contains 10-15 mg iron from which only 5% to 10% is normally absorbed. The daily requirement depends on the type of diet. A non-vegetarian diet of red meat, liver, egg-yolk is a rich source of iron. For a vegetarian, sources of iron are green leafy vegetables, dry fruits, jaggery, beans, and outer layers of cereals (which are normally discarded during refinement). Milk is a poor source of iron. Four cells play an important role in an iron metabolism as shown in **Figure 1** while the daily iron cycle is shown in **Figure 2**.

Mechanism of Iron Absorption

Dietary iron is absorbed mainly through the duodenum and upper small intestine. The absorption is regulated as per the needs of the body, i.e. increased in iron deficiency and decreased in iron overload.

Body iron status is sensed by the duodenal crypt cells through a complex mechanism involving circulating transferrin-bound iron and the transferrin receptor and iron proteins secretion is regulated by iron responsive elements (IREs) and iron binding proteins (IRPs) (**Figure 3**). Lower the intracellular iron higher the IRP secretion, the IRP binds to IRE present on 5' or 3' region of the genes of proteins involved in iron metabolism having different effect on them. Binding of IRP occur on 5' region of ferritin gene preventing translation of ferritin. Similar effect is seen on ferroportin and delta amino levulinic acid gene with their decreased production.

While binding on 3' region of transferrin and divalent metal transporter-1 (DMT-1) genes stabilises the gene and increases its expression and thus absorption of iron from gastrointestinal tract.

High intracellular iron decreases IRP, thus decreased binding to IRE on 5' region of ferritin gene allowing transcription of ferritin necessary for iron storage while decreased binding to 3' region of transferrin gene will prevent stabilisation of mRNA and allow its degradation thus decreasing transferrin production.

When body iron status is low, there is decreased iron concentration within the crypt cells. This causes an increase in mRNA expression for DMT-1.

The crypt cells migrate up the villus and mature into absorptive villus enterocytes, the DMT-1 is increased at the apical surface, increasing iron absorption from the intestinal lumen. Absorbed iron is released into the circulation via the iron export proteins.

Factors affecting iron absorption are outlined in **Table 2**.

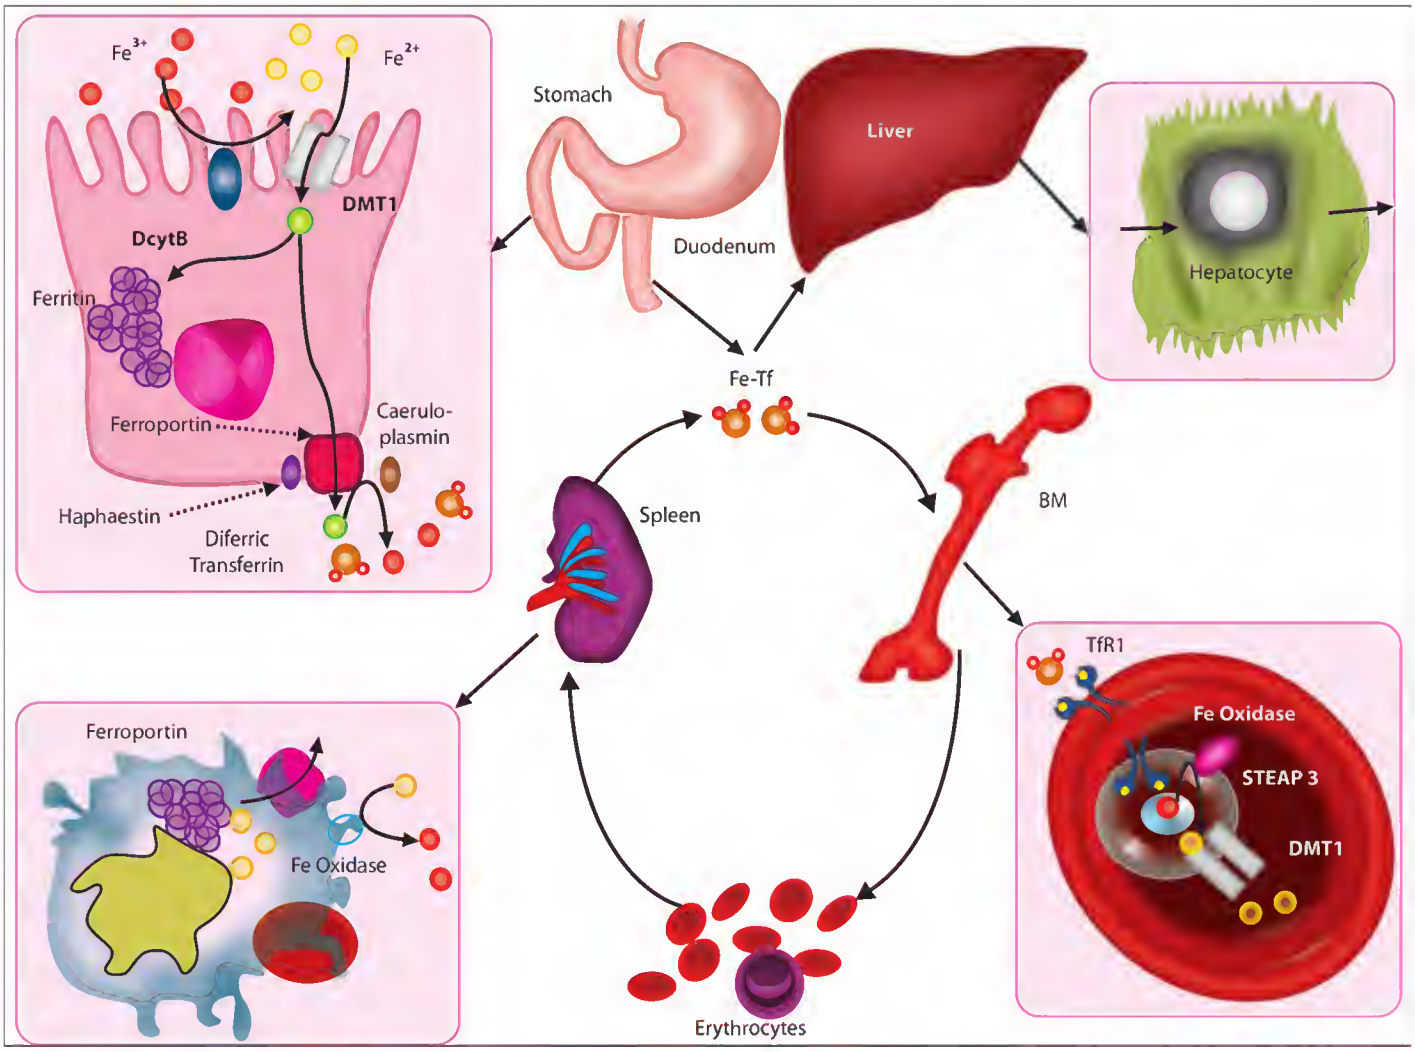

Figure 1: Overview of iron metabolism. Four cells play an important role in iron metabolism. Duodenal crypt cell for iron absorption; on brush border are enzymes DcytB (ferric reductase) which convert ferric iron to ferrous form and the DMT1 (divalent metal transporter1) which will allow absorption of iron along with other divalent metal iron like Zn, Cu and Ca. Hence co-administration of Ca^{++} with oral iron decreases absorption of iron. Once absorbed iron is released by ferroportin on the basolateral surface of crypt cell. Haphaestin acts as ferric oxidase and convert ferrous to ferric form before export. Plasma Caeruloplasmin also act as ferric oxidase and help in conversion of ferrous to Ferric form of iron. Transferrin is the carrier protein in plasma and binds two atoms of ferric iron to form diferric transferrin. Erythroblast is the major site for utilisation of iron. Only 1 mg of elemental Fe is absorbed per day. Iron thus released from duodenal enterocyte is transported as diferric soluble form bound to transferrin. Liver is the major site for storage of iron and production of Hepcidin the major regulator of Iron. Macrophages recycle senescent RBCs and very little iron is lost.

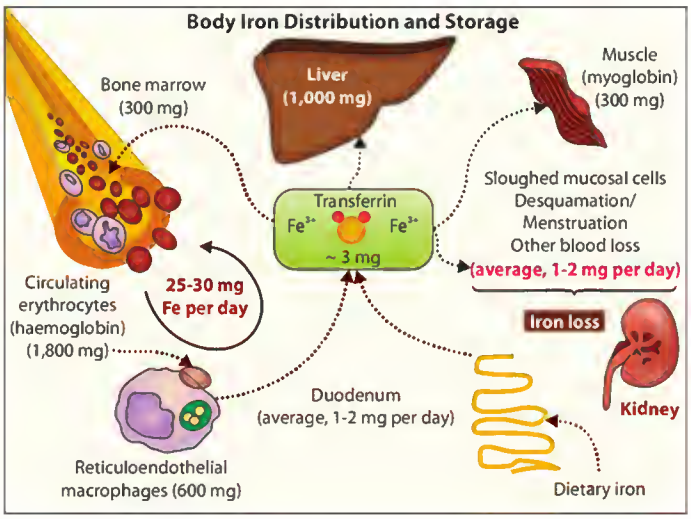

Figure 2: Body Iron distribution and storage; only 1 to 3 mg of Fe is bound to transferrin; Iron deficiency only develops once body iron stores are exhausted. Major store and distribution of Iron is in the circulating erythrocytes approximately (1,800 mg), Liver (1000 mg), RES (400 mg) and muscle (300 mg). Most of the iron is utilised to form haemoglobin.

Table 2: Factors Affecting Iron Absorption

Factors Which Increase Iron Absorption	Factors Which Decrease Iron Absorption
Haem iron	Inorganic iron
Ferrous iron (Fe^{2+})	Ferric iron (Fe^{+++})
Acids (ascorbic acid, citric acid, vitamin C, hydrochloric acid, gastric secretions)	Alkalis (antacids, pancreatic secretions)
Solubilising agents (sugars, amino acids)	Precipitating agents (phytates like bran, oats, rye, fibre and phosphates)
Iron deficiency	Iron excess
Increased erythropoiesis	Decreased erythropoiesis
Pregnancy	Infection
Hereditary haemochromatosis	Polyphenol (tea, cereals)
Protein-rich diet	Dietary calcium, milk

Specific Proteins Involved in Iron Metabolism and their Functions

Since free iron is toxic, iron must be maintained in soluble form to prevent toxicity and in human specialised transport systems

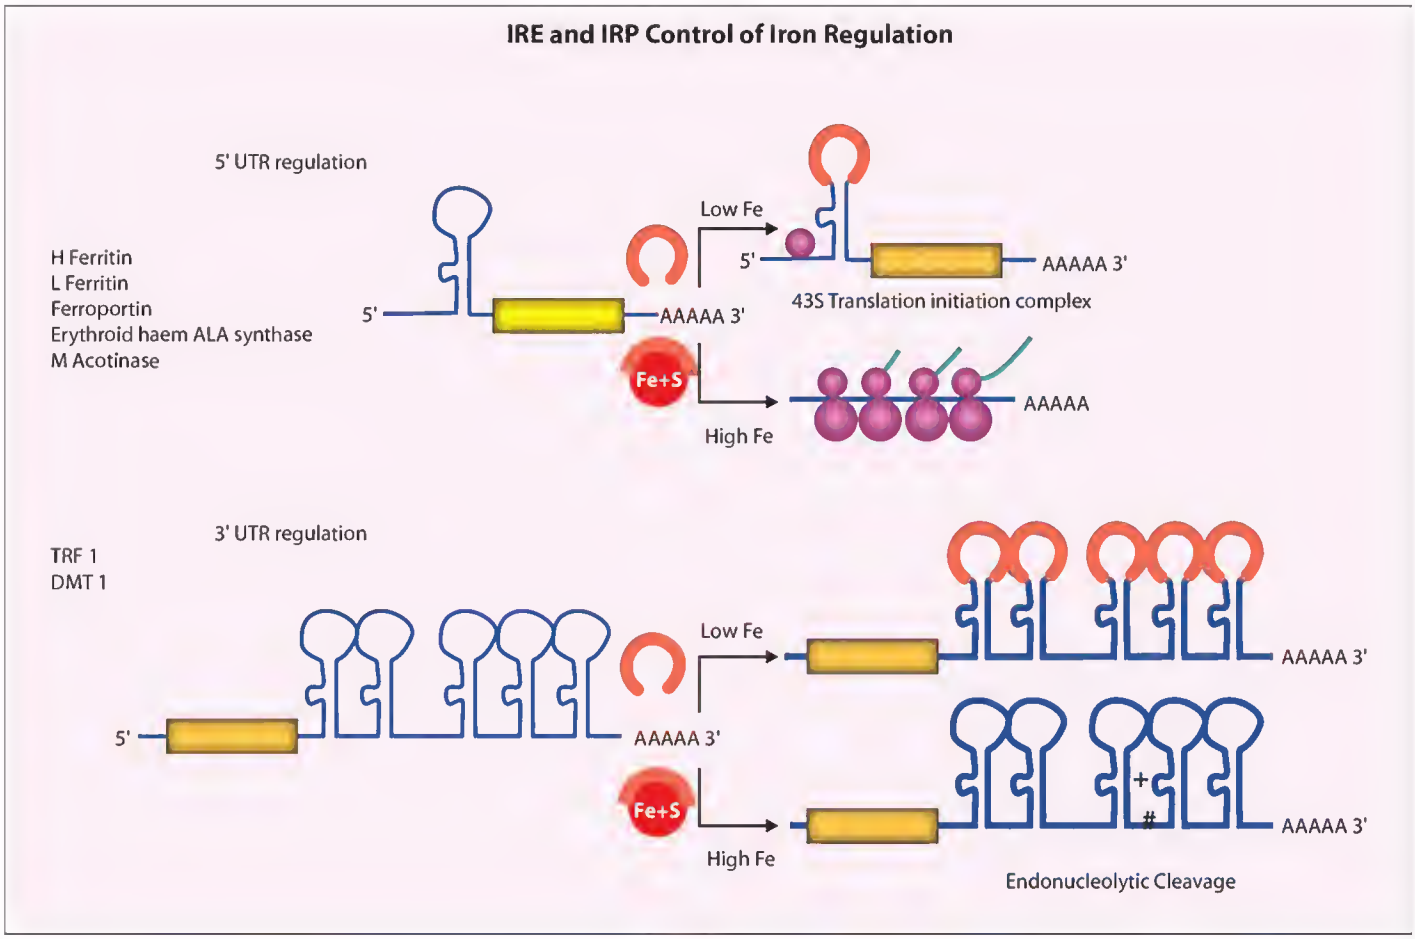

Figure 3: Intracellular regulation of Iron. Iron is regulated at both intracellular and systemic level. IRP1 and IRP2 (Iron Responsive Protein) act as cell sensor to iron availability and regulate the cellular iron by binding to IREs. The IREs are present at either the 5' UTR or 3' UTR region of mRNA of proteins important in Iron metabolism as shown in fig. In case of excess or deficiency of intracellular iron they either block or allow translation of these proteins. As for example if there is excess of iron, the IRP which is also an acotinase; an enzyme important in formation of iron sulphur cluster, rather than IRE of Ferritin mRNA. Thus allowing translation of ferritin and promoting storage of excess iron as ferritin. IRP2 disruption leads to hypochromic microcytic anaemia with late onset neurodegenerative disorder. Disruption of IRE in L ferritin gene result in hyperferritinemia with cataract syndrome, while disruption in H ferritin result in iron overload syndrome. Disruption of IRE in the ferroportin gene results in a complex disorder of iron homeostasis.

and membrane carriers have evolved to maintain iron in a 'soluble' state. **Table 3** lists the various proteins involved in iron metabolism and their functions. Rapid advances have taken place and this is an evolving field. Hepcidin is considered to be the master hormone regulating availability of iron.

Steps in the absorption of iron are outlined in **Figure 4**.

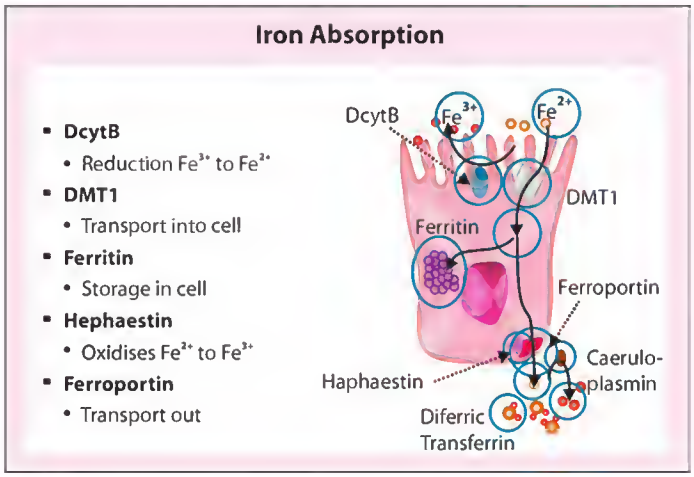

Figure 4: Duodenal crypt cell, and the steps in iron absorption and the proteins involved.

Oral ferric iron is converted to ferrous iron on the luminal surface of enterocyte brush border by DcytB ferric reductase.

Transluminal transport of ferrous iron is done by DMT-1 present in the enterocyte brush border. This step is regulated by the iron status of the body. Inside the enterocyte depending on iron status it may be sequestered in enterocyte as ferritin or transported across the basolateral membrane of enterocyte into the circulation for utilisation. Ferroportin helps export ferrous iron into circulation while reconversion of ferrous iron to ferric iron takes place with the help of hephaestin. Ferroportin is present besides on the macrophages and other RE cells and the hepatocyte and its function is regulated by hepcidin.

Distribution of Iron in Blood

Upon its release from the basolateral surface into circulation, the ferrous iron is oxidised to the ferric form and loaded onto transferrin. The aggregate binding sites of all the transferrin in the circulation comprise the total iron binding capacity (TIBC) of plasma. Normally 20% to 45% of iron-binding sites are filled (transferrin saturation). About 80% of iron passing through the transferrin compartment is from the red cells. Immature erythroid cells acquire iron from transferrin through specific transferrin receptors located on the cell surface membrane (**Figures 5 and 6**).

Table 3: Specific Proteins Involved in Iron Metabolism and Their Function

Protein	Function	Expression
Transferrin	Iron binding transfer protein fluid	Plasma
Ft (H and L subunits) (IREs 5'UTR)	Iron storage	Most cells
Transferrin receptor-1 (IREs 3'UTR)	Iron uptake receptor-mediated endocytosis of ferric transferrin	Erythroid cells, epithelial cells rapidly growing (intestinal crypt cells). Other cells including macrophages
Transferrin receptor-2	Iron uptake	Hepatocyte, circulating monocytes. Possibly senses iron status may have a role in iron regulation by controlling expression of hepcidin
DMT1 (Nramp2/DCT1) (IREs 3'UTR)	Iron import; iron release from endosome to cytoplasm	Brush border of epithelial cell of the intestinal villus. Endosomal vesicles in erythroid cells and other cell types
FP1/IR1/MTP1 (IREs 5'UTR) ferroportin	Iron export	Basolateral membrane of epithelial cell of the intestinal villus; placenta; other cell types
Duodenal cytochrome b	Ferric reductase	Brush border of enterocytes of the intestinal villus
Hephaestin	Ferroxidase	Basolateral membrane and vesicles of enterocytes of the intestinal villus
Caeruloplasmin	Ferric oxidase	Plasma
HFE (No IREs)	Uncertain. The HFE protein-β2-microglobulin heterodimer binds TfR1, reducing its affinity for transferrin	Intestinal crypt cells and tissue macrophages
Hepcidin (No IREs)	Antibacterial activity; master regulator of iron homeostasis, regulates activity of ferroportin and thus iron release from mucosal cells and macrophages	Liver, blood, urine, Iron hormone responsible for anaemia of chronic disease
Haemojuvelin	Unknown; possibly regulator of hepcidin release	Highly expressed in hepatocytes
IRP1 AND IRP2	Post-transcriptional control of target mRNAs (Ft, TfR1, DMT1, FP1/IR1/MTP1, mitochondrial aconitase, erythroid aminolevulinate synthase)	Mainly: liver, spleen, kidney, heart. Occasionally: duodenum, brain

Steps in iron transport are given below and depicted in **Figure 6**.

1. Fe^{2+}Tf bind to TfR1on RBC.
2. Fe^{2+}Tf/TfR1 complex localise to clathrin-coated pits which invaginate to form endosomes.
3. A proton pump decreases pH leading to iron release.
4. DMT1 moves iron across endosomal membrane to cytoplasm.
5. Apo-Tf and TfRl are recycled to the cell surface for further use.
6. In red blood cells most of the iron is incorporated into proto-porphyrin to make haem (mitochondria).

Reutilisation of Iron

Aged erythrocytes are phagocytosed by specialised macrophages in the spleen, bone marrow and liver. Within macrophages, the haem-oxygenase I catabolises haem, releasing ferrous iron, which may be responsible for intracellular transmembrane iron transport. Macrophages return most of the catabolised erythroid iron into the transferrin compartment of the blood stream, and the cycle recommences. Ferroportin plays an important role in the release of macrophage iron into blood and is in turn controlled by hepcidin. Thus, hepcidin is a master regulator of iron availability (**Figure 1**).

Iron Storage

Excess iron is stored in the body as ferritin or haemosiderin. The iron in ferritin is enclosed within a protein shell, apoferritin. This can take up ferrous iron and oxidise it to ferric iron, which is deposited within the iron core. In due course, ferritin is engulfed by lysosomes and catabolised to haemosiderin. Iron enters and leaves the ferritin molecule in a controlled fashion, making it available for normal physiologic functions of the cells. Minute quantities of ferritin are found in the serum, which correlate closely with the body iron stores. One microgram per litre of serum ferritin is approximately equivalent to 10 mg of storage iron.

Hepcidin

A 25 aa peptide was identified in the year 2000 with antimicrobial activity. Since it was produced by the liver it was named hepcidin *(hepatic bactericidal protein)*. It was subsequently discovered to be a master iron regulatory hormone. Factors regulating intestinal iron absorption also regulate the expression of hepcidin. Decreased iron stores, increased erythropoietic activity, anaemia and hypoxia negatively regulate hepcidin expression. Cellular targets of hepcidin are villous enterocytes, RE macrophages and hepatocytes. Iron homeostasis is dependent on regulatory feedback between body iron needs and intestinal iron absorption. Intestinal iron absorption varies inversely with liver hepcidin expression. Hepcidin decreases the functional activity of ferroportin by directly binding to it and causing it to be internalised from the cell surface and deregulated; decreases basolateral iron transfer and thus dietary iron absorption; decrease in iron export by hepatocyte and macrophage and a resultant increase in stored iron (**Figures 7 and 8**).

Hepcidin response

Transferrin receptor-2 may serve as a sensor of circulating transferrin-bound iron, thereby influencing expression of the iron regulatory hormone hepcidin. The hepcidin response is also modulated by HFE and haemojuvelin. Inflammatory cytokines including interleukin (IL)-6 and LPS increase hepcidin secretion (**Figure 9**).

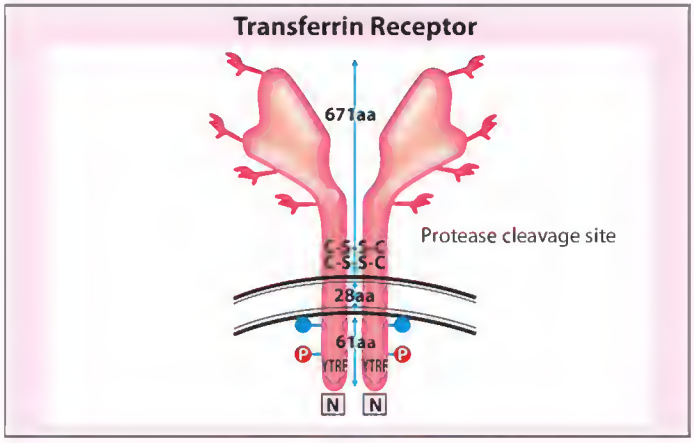

Figure 5: Transferrin receptor 1 (TfR1) which is important for the cellular uptake of Iron. TfR1 expression increases from 300,000 per pronormoblast to 800,000 per basophilic normoblast at the height if Hb synthesis. There is a precise correlation between TfR1 number and iron requirement of the body. There are 2 types of transferrin receptors. Transferrin receptor 1(TfR1) is important for absorption of iron while TfR2 is important for sensing total body iron and is important for regulation of iron. The extracellular part of TfR is shed and this sTfR can be measured. sTfR is elevated in IDA while it is normal in anaemia of inflammation (AOI). A better diagnosis of IDA in setting of AOI can be made by calculating sTfR per Log ferritin ratio. A ratio of less than 1 suggests AOI, while ratio of >2 suggest IDA. Ratio between 1 and 2 suggest IDA with AOI.

Hepcidin deficiency

It results in hereditary haemochromatosis as patient absorbs excessive iron relative to body stores implying the 'set-point' for the 'stores regulator' is altered. Ineffective erythropoiesis with increased destruction of erythroid precursors (e.g. thalassaemias) but this is coupled to increased iron absorption.

Hepcidin excess

It results in anaemia of chronic disease. Infection/inflammation induces iron sequestration in macrophages and decreases intestinal absorption. Hepcidin is a negative regulator of iron absorption in duodenum and of iron release from macrophage.

Iron Overload

Iron overload is the pathological state in which total body stores of iron are increased often with organ dysfunction because of iron deposition (**Table 4**). The iron-replete state is characterised by increased production of ferritin and decreased production of the transferrin receptor. These responses are mediated by the iron-responsive elements binding protein (IRE-BP). As the body content of iron increases, the iron saturation of

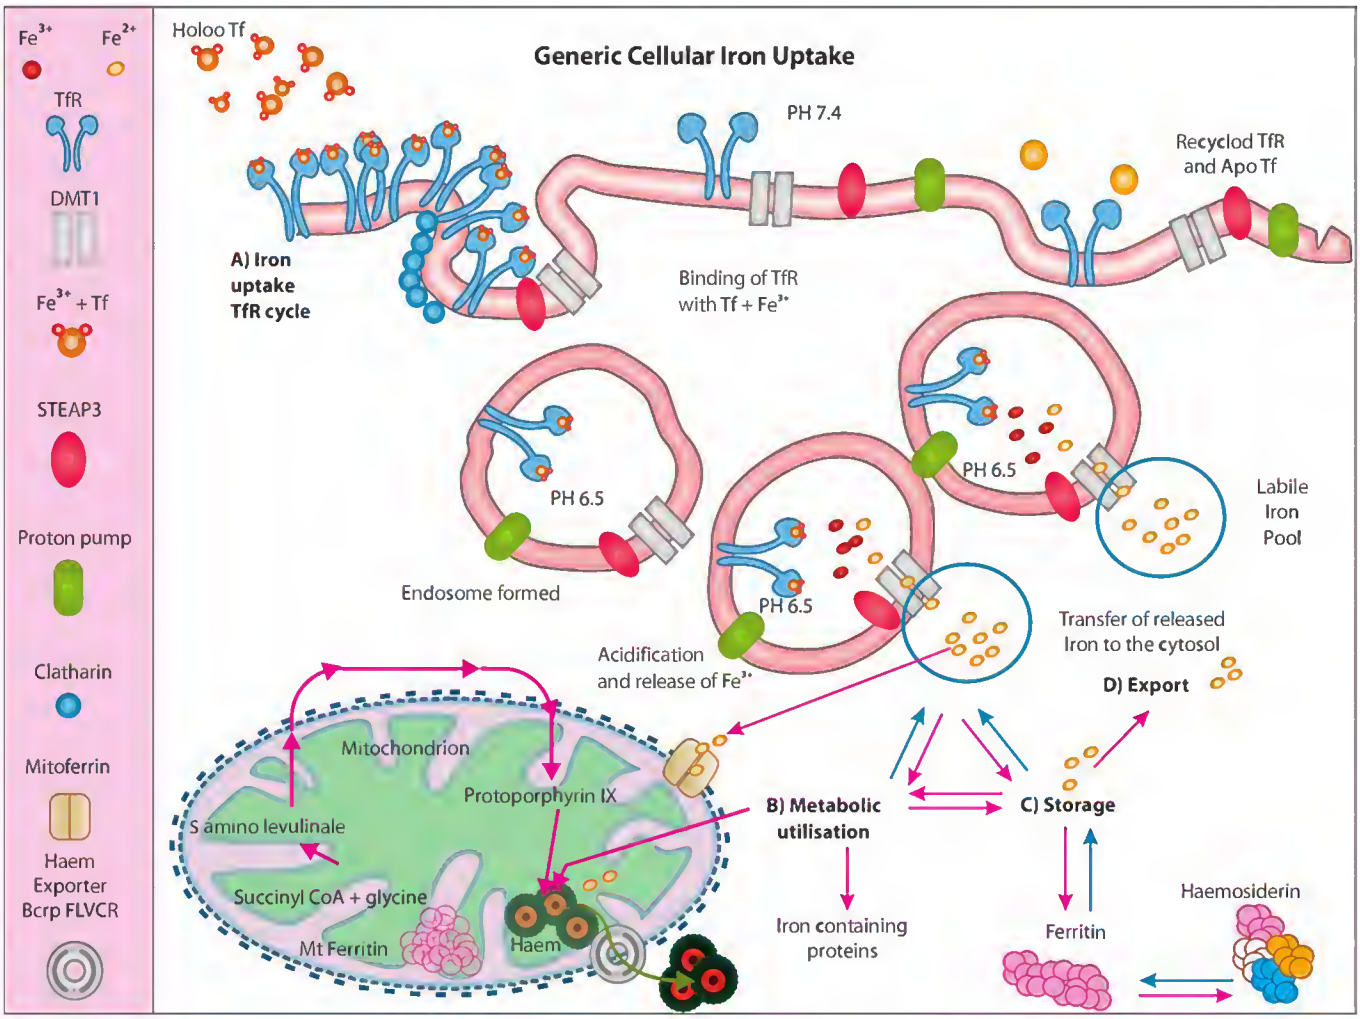

Figure 6: Cellular Iron uptake begins by holotransferrin with diferric iron atoms binding the TfR and their internalisation to form the endocytic vesicle. With progressive acidification of the vesicle by the proton pump ferric iron is released and converted to ferrous form with help of STEAP3 and exported out of the vesicle into the cytosol via DMT1. This iron in cytoplasm is called labile iron pool and available to be removed by chelation. This iron finds its way to the mitochondria, how we do not precisely know; for formation of Haem and other iron containing enzymes. The endocytic vesicle rejoins the surface of cell and the apotransferrin is released into circulation to bind diferric iron while the TfR will bind other holotransferrin to reenter the endocytic cycle. In DMT1 deficiency, there is poor iron absorption at duodenal level but iron that enters the erythroblast cannot be released from the endocyte into the circulation resulting in IDA.

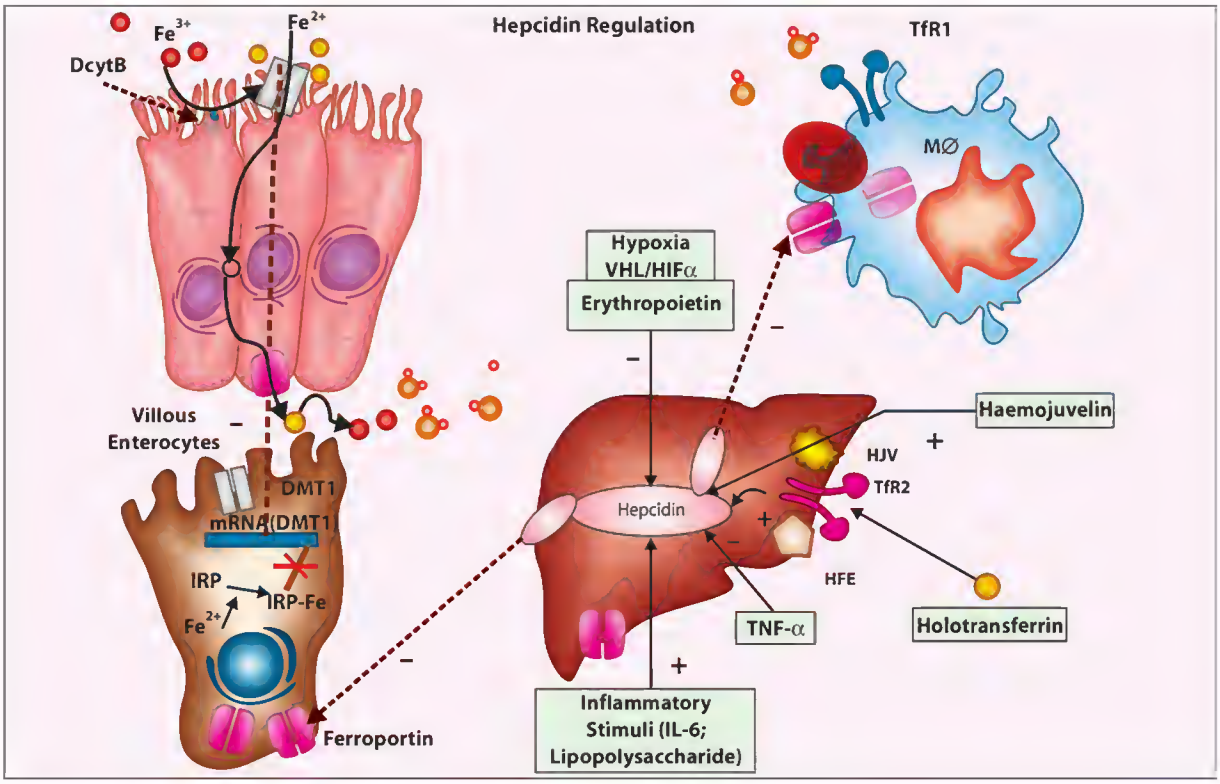

Figure 7: Hepcidin a 25 AA protein is the master regulator of iron. It is a systemic regulator and regulates body's need for iron. Hepcidin regulates iron by binding ferroportin and tagging it for ubiquitination and proteosomal degradation. This prevents export of iron from the cells like duodenal enterocyte, Macrophages and Hepatocytes. Hepcidin levels are decreased in IDA, Hypoxia and are increased by inflammatory stimuli like IL6 and LPS. Erythropoietin and TNF α negatively regulate, while HFE and HJV positively regulate Hepcidin production.

Table 4: Classification of Iron Overload

Severe iron overload

- Excess iron absorption
  - Hereditary haemochromatosis (HH)
  - Massive ineffective erythropoiesis (e.g. thalassaemia intermedia, sideroblastic anaemia, congenital dyserythropoietic anaemia)
- Increased iron intake
  - Sub-Saharan dietary iron overload
  - Excess parenteral iron therapy
- Repeated red cell transfusions
  - Congenital anaemias (e.g. thalassaemia major, sickle cell anaemia, red cell aplasia)
  - Acquired refractory anaemias (e.g. myelodysplastic syndromes, aplastic anaemia)
  - Rare genetic disorders of iron metabolism (e.g. atransferrinaemia, acaeruloplasminaemia)

Modest iron overload

- Chronic liver disease (e.g. alcoholic cirrhosis)
- Porphyria cutanea tarda
- Rare genetic disorders of iron metabolism (e.g. atransferrinaemia, acaeruloplasminaemia)

Focal iron overload

- Pulmonary haemorrhage (e.g. idiopathic pulmonary haemosiderosis)
- Chronic haemoglobinuria
- Friedreich's ataxia
- Hereditary hyperferritinaemia with autosomal dominant congenital cataract

circulating transferrin increases, the fasting transferrin saturation (serum iron, iron binding capacity) increases resulting in the off-loading of iron, particularly to cells with high levels of transferrin- receptors e.g. heart, liver, thyroid, gonads and pancreatic islets.

HEREDITARY HAEMOCHROMATOSIS

Hereditary haemochromatosis (HH) is an autosomal recessive inherited disorder with a frequency of 1 in 300 in the Caucasian population. In HH there is a gradual accumulation of iron leading to tissue damage. HH becomes symptomatic later in females (due to extra iron loss associated with menses, pregnancy and lactation) than in males. Types of hereditary haemochromatosis are outlined in **Table 5**.

Genetic Defect

The HFE protein is synthesised by the HH gene and is similar to the major histocompatibility complex (MHC) Class I protein. The role of this HFE protein and the means whereby mutations result in iron overload are still unknown, but a number of observations have been made. In the endoplasmic reticulum, newly synthesised HFE forms a 1:1 complex with β_2-microglobulin and this heterodimer is targeted to the plasma membrane. At neutral pH, the HFE/ β_2-microglobulin heterodimers form a stable complex with the transferrin receptor and decrease the affinity of the transferrin receptor for transferrin. HFE is abundantly expressed in the crypts of duodenal mucosa. This homoeostatic mechanism is disrupted when the HFE gene is mutated in HH giving a false signal that body iron stores are low resulting in increased iron uptake. There are two pathogenetic models of HFE related hereditary haemochromatosis, the crypt programming model and the HFE models as shown in **Figures 10 and 11**. The common mutations are C282Y, H63D and S65C in the HFE gene on chromosome 6.

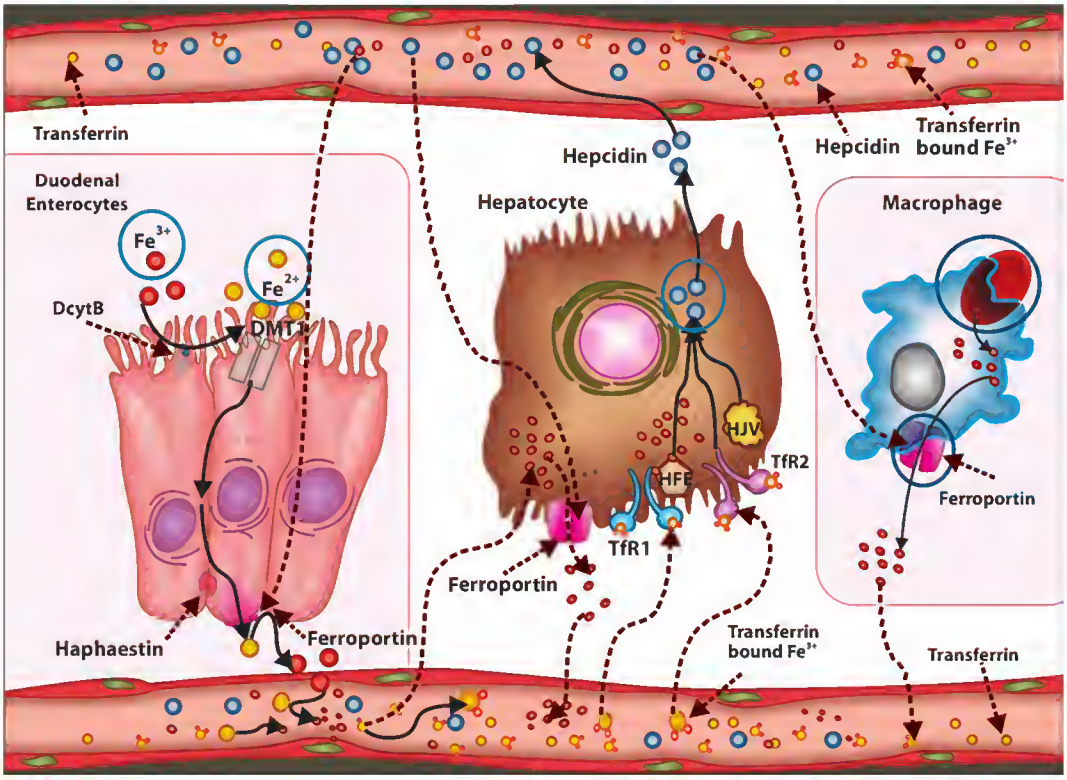

Figure 8: Overall iron regulation and iron homeostasis in the human body and the amount of investment nature has done in iron.

Table 5: Comparative Overview of the Primary Iron-Overload Disorders Classified as Hereditary Haemochromatosis in the OMIM Database

Feature	HFE-Related Hereditary Haemochromatosis	Juvenile Hereditary Haemochromatosis		TfR2-Related Hereditary Haemochromatosis	Ferroportin-Related Iron Overload
OMIM Classification	Type 1	Type 2, subtype A	Type 2, subtype B	Type 3	Type 4
Implicated gene and its chromosomal location	*HFE*, 6p21.3	*HJV* (originally called *HFE2*), 1q21	*HAMP*, 19q13.1	*TfR2*, 7q22	*SLC40A1*, 2q32
Gene product					
Name	HFE	Haemojuvelin	Hepcidin	Transferin receptor 2	Ferroportin (also iron-regulatory protein, or metal-transporter protein)
Known or postulated function	Interaction with transferrin receptor 1, probably facilitating uptake of transferrin-bound iron; possibly modulation of hepcidin expression	Unknown: possibly modulation of hepcidin expression	Down-regulation of iron relase by enterocytes, macrophages, or placental cells	Possible uptake of iron by hepatocytes	Export of iron from enterocytes, macrophages, placental cells
Pattern of inheritance	Autosomal recessive	Autosomal recessive	Autosomal recessive	Autosomal recessive	Autosomal dominant
Evidence of expanded plasma iron compartment (high transferrin saturation	Earliest detectable biochemical anomaly	Earliest detectable biochemical anomaly	Earliest detectable biochemical anomaly	Earliest detectable biochemical anomaly	Only in advanced stages
Main organs accumulating iron	Liver, endocrine glands, heart	Liver, endocrine glands, heart	Liver, endocrine glands, heart	Liver, endocrine glands, heart	Liver, spleen
Predominant cell distribution of iron accumulation	Parenchymal	Parenchymal	Parenchymal	Parenchymal	Reticuloendothelial
Potential for organ damage	Variable	High	High	Variable	Low
Anaemia	No	No	No	No	Maybe seen in mensturating women or after phlebotomy
Resoponse to therapeutic phlebotomy	Excellent: decrease in serum ferritin in parallel with transferrin saturation; no risk of anaemia	Excellent: decrease in serum ferritin in parallel with transferrin saturation; no risk of anaemia	Excellent: decrease in serum ferritin in parallel with transferrin saturation; no risk of anaemia	Excellent: decrease in serum ferritin in parallel with transferrin saturation; no risk of anaemia	Fair: rapid decrease in saturation with persistently high serum ferritin; substantial risk of anaemia with aggressive phlebotomy regimen
Decade of onset of symptomatic organ disease	4th or 5th	2nd or 3rd	2nd or 3rd	4th or 5th	4th or 5th

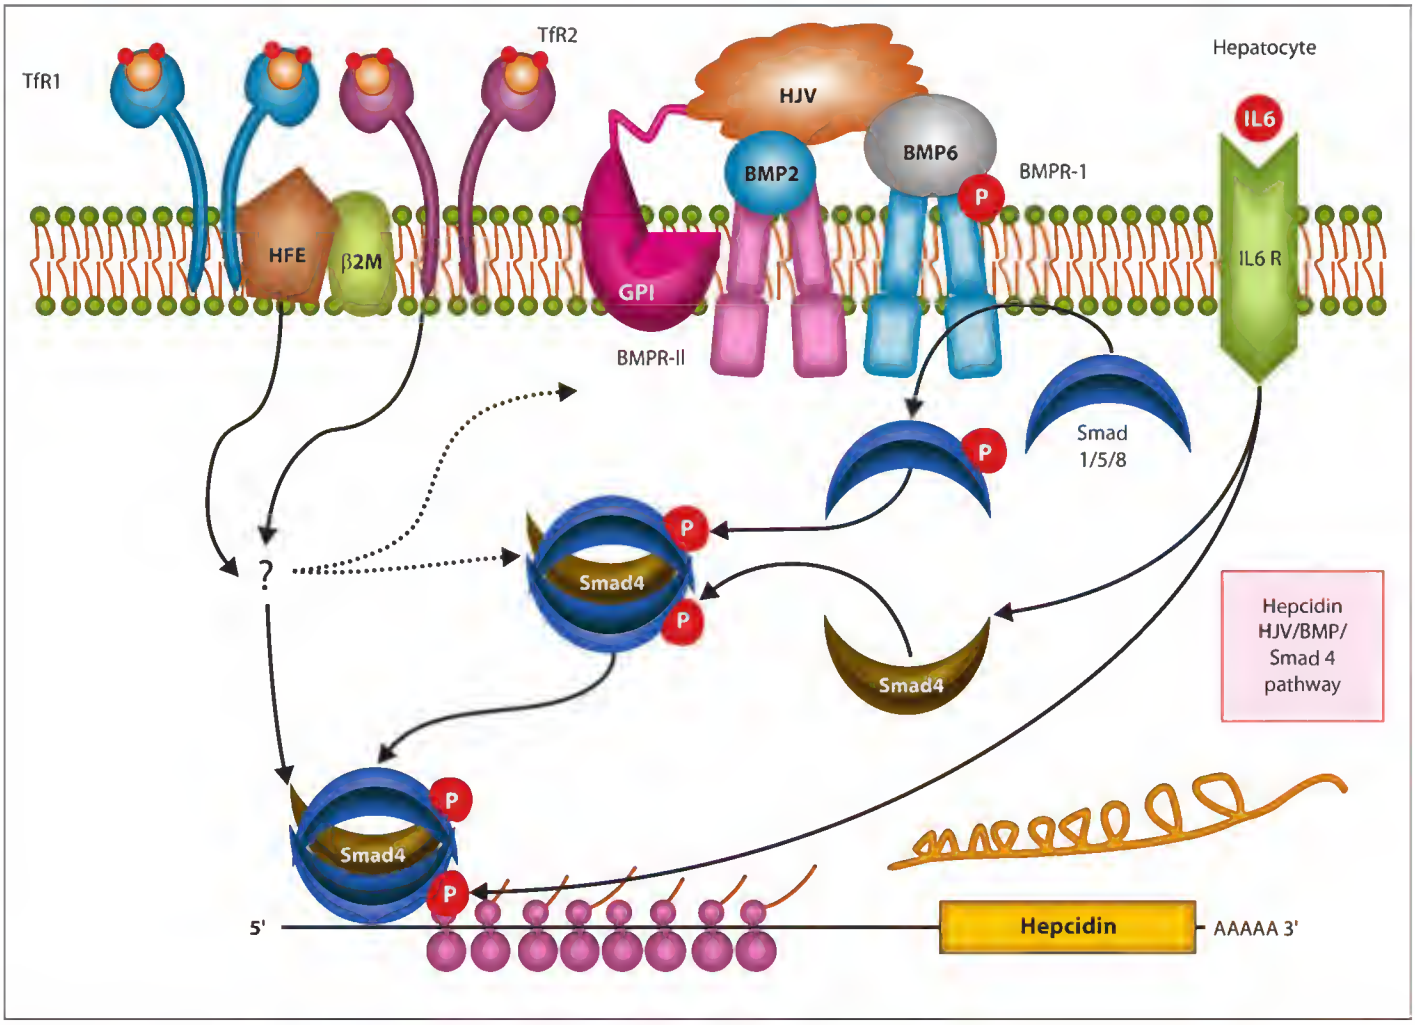

Figure 9: Regulation of Hepcidin transcription by TfR2, HFE, HJV, BMP (bone morphogenetic protein) and Smad 4. Disruption in this regulation is very often responsible for iron overload and haemochromatosis.

Clinical Features

These are mainly caused by iron deposition in various organs, as shown in **Table 6**.

The classical triad of HH is a middle-aged man presenting with diffuse hyperpigmentation, hepatomegaly and diabetes mellitus requiring insulin. The presentation occurs only when complications are irreversible and prognosis is poor. This stage is far too late and must be considered as a clinical diagnosis failure.

Signs and symptoms that may allow an earlier diagnosis include asthenia (unexplained chronic fatigue), arthralgia (most characteristically affecting second and third metacarpophalangeal joints - painful handshake) and aminotransferase elevation (especially in the absence of alcohol, NASH, viral infection, autoimmunity).

Table 6: Clinical Features of Iron Overload

Heart	Cardiomyopathy, dysrrhythmias, congestive heart failure
Endocrine organs	Growth and sexual developments are delayed in children Delayed puberty Diabetes mellitus Hypothyroidism and hypoparathyroidism Hypopituitarism
Skin	Excessive melanin skin pigmentation (bronze diabetes)
Liver	Haemosiderosis, cirrhosis, risk of hepatocellular carcinoma.
Joints	Arthropathy caused by pyrophosphate deposition
Excessive infections	Listeria, *Yersinia enterocolitica, Vibrio vulnifcus,* by ingesting uncooked seafood

Laboratory Findings

Raised serum iron and transferrin saturation (>45%, especially >60% in males and >50% in females), raised serum ferritin, lowered serum soluble transferrin receptor levels and increased iron in liver and bone marrow (Perls' Prussian blue staining) are found. Hepatic iron content of >40 µmol/g on dry weight indicates definite increase in liver iron; >71 µmol/g dry weight is highly suggestive of HH. Hepatic iron index is the ratio of µmol iron/g dry weight divided by age in years. Ratio >2 generally separates patients with homozygous HH from heterozygotes or those with alcoholic liver disease. Increased urinary iron excretion in response to iron chelator therapy are abnormal, and liver function tests, endocrine abnormalities e.g. raised blood sugar, abnormal thyroid

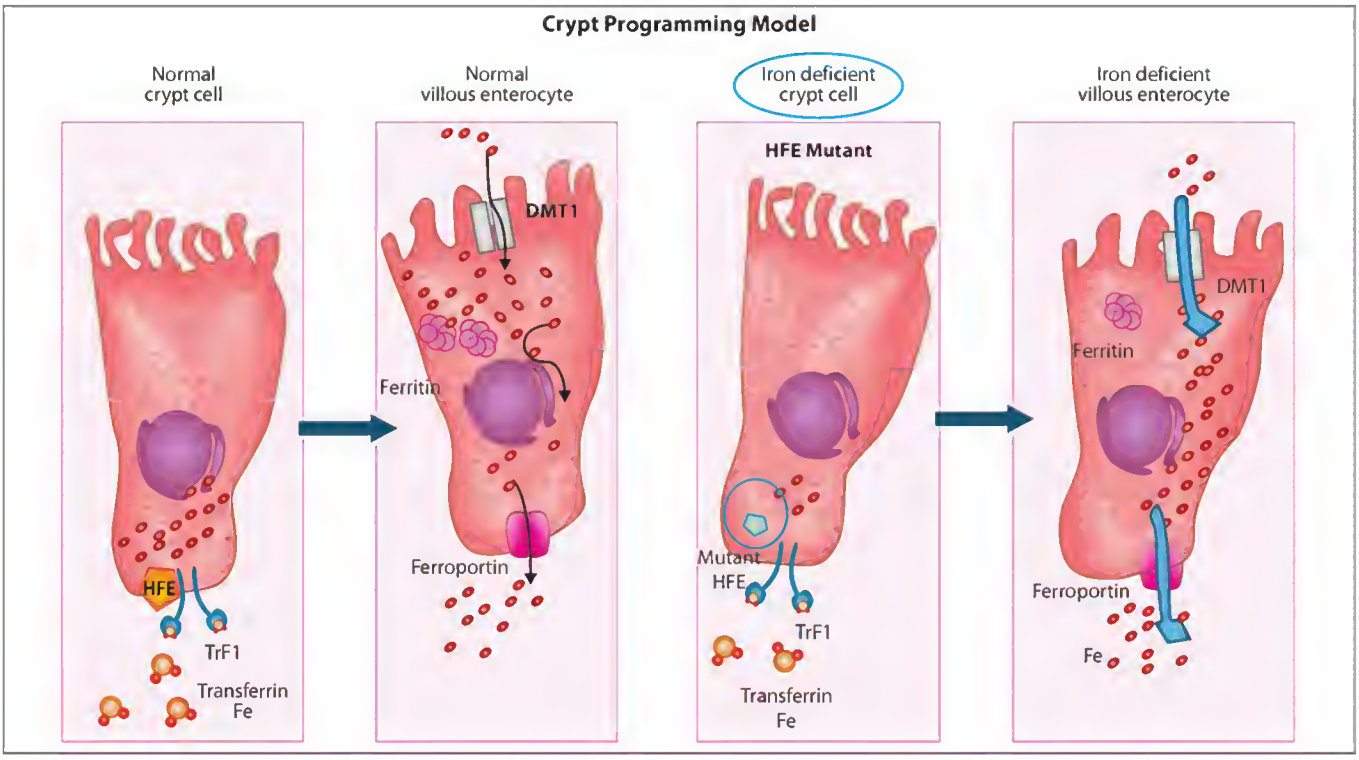

Figure 10: Crypt programming Model of HFE-Related Hereditary Haemochromatosis. Cryptprogramming model, undifferentiated duodenal crypt cells, take up iron from the bloodstream by transferrin receptor 1 (TfR1), which is located on their basolateral membranes. Interaction of TfR1 with normal HFE senses the iron status. The cellular pool of iron will programme the mature absorptive enterocytes that will be derived from these cells by modulating the activity of specialised luminal iron transporters [e.g. divalent metal transporter 1, (DMT1)] and basolateral iron transporters (e.g. ferroportin). Due to presence of C282Y mutation, HFE is unable to interact with TfR1, leading to iron-deficient crypt cells, these cells are programmed to iron starvation, hence persistently absorbing iron from the intestinal lumen and transfer virtually all of it into the bloodstream, regardless of actual erythropoietic needs.

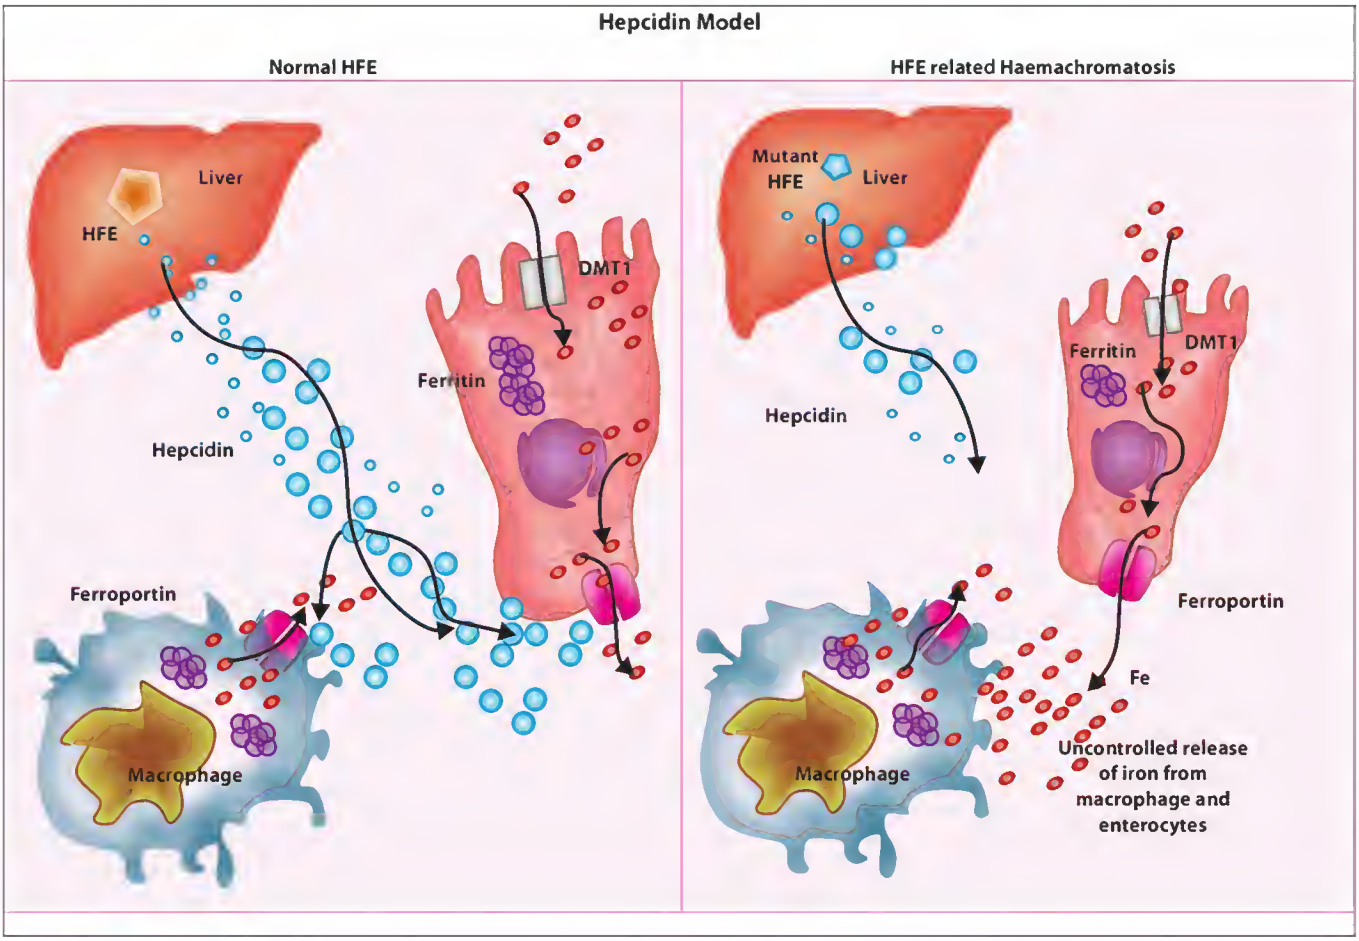

Figure 11: Hepcidin Model of *HFE*-Related Hereditary Hemochromatosis. Mutant HFE might alter signals or factors for appropriate synthesis or up-regulation of Hepcidin by hepatocytes, resulting in uncontrolled release of iron from macrophages and duodenal enterocytes.

function tests are seen. ECG and echocardiogram are abnormal. Genetic testing for HFE gene mutation C282Y (incidence >80% in HH) can be done.

Treatment

Phlebotomy greatly reduces mortality from cardiac and hepatic failure. This should be at the rate of 350 mL of blood each week or more often if the haemoglobin concentration can be maintained greater than 12 g/dL. Treatment can be measured by monitoring serum ferritin and the phlebotomy may need to be continued for over 2 years. The aim is to maintain normal transferrin saturation and serum ferritin in the low normal range, ideal is to achieve a serum ferritin around 50 ug/dL as shown in **Figure 12**. Desferrioxamine as a continuous intravenous infusion may have a limited role to treat life-threatening cardiac failure. Treatment of endo-crinopathies and infections is required. Screening for hepato-cellular carcinoma should be done.

All first-degree relatives over the age of 10 years should be tested for increase in transferrin saturation and ferritin and screened for HFE genotype.

ATRANSFERRINAEMIA

It is a rare autosomal recessive hereditary disorder. There is iron overload and hypochromic anaemia. There is reduced delivery of iron to bone marrow and reduced haemoglobin synthesis. Two mutations that have been identified are a deletion creating a frameshift resulting in a null transferrin allele and Ala 477Pro.

ACAERULOPLASMINAEMIA

It is an autosomal recessive disorder of iron overload. There is loss of function mutation in caeruloplasmin gene 3q23- q24. Caeruloplasmin has ferroxidative activity involved in the release of iron from cells. Patients have accumulation of iron in neural and glial cells of the brain, hepatocytes and pancreatic islet cells.

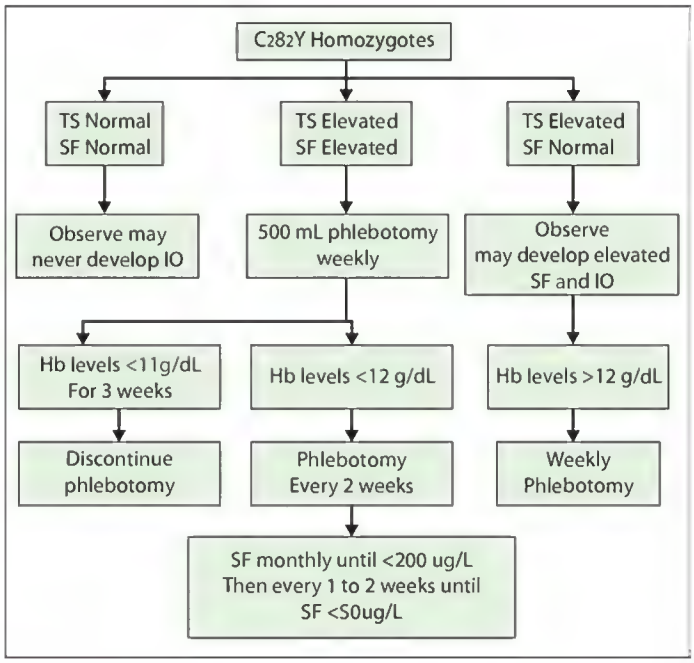

Figure 12: Strategic algorithm for C282Y Homozygous patients with hemochromatosis and the desired serum ferritin values after phlebotomy. SF (serum ferritin), TS (transferrin saturation) and IO (iron overload).

Treatment

Treatment consists of aggressive chelation with desferrioxamine and replacement of plasma or caeruloplasmin concentrate. Phlebotomy may exacerbate microcytic hypochromic anaemia and hence should be avoided.

18.6 The Porphyrias

Dhanpat Kumar Kochar, Abhishek Kochar

INTRODUCTION

Porphyrias are metabolic disorders resulting from the deficiency of a specific enzyme in the haem biosynthetic pathway. There are eight enzymatic steps in the conversion of glycine and succinyl-CoA to haem. The first and last three enzymes are located in the mitochondria whereas the other four are in the cytosol (**Figure 1**). Depending on the primary site of over production and accumulation of their respective porphyrin precursors or porphyrins, the porphyrias are classified as either hepatic or erythropoietic. Based on their clinical manifestations, porphyrias can be labelled as acute or cutaneous, but some of them have overlapping features. A definitive diagnosis requires demonstration of specific enzyme deficiency or gene defect. The important aspect including inheritance, enzyme deficiency, gene defect and excretion of precursors are shown in **Table 1**.

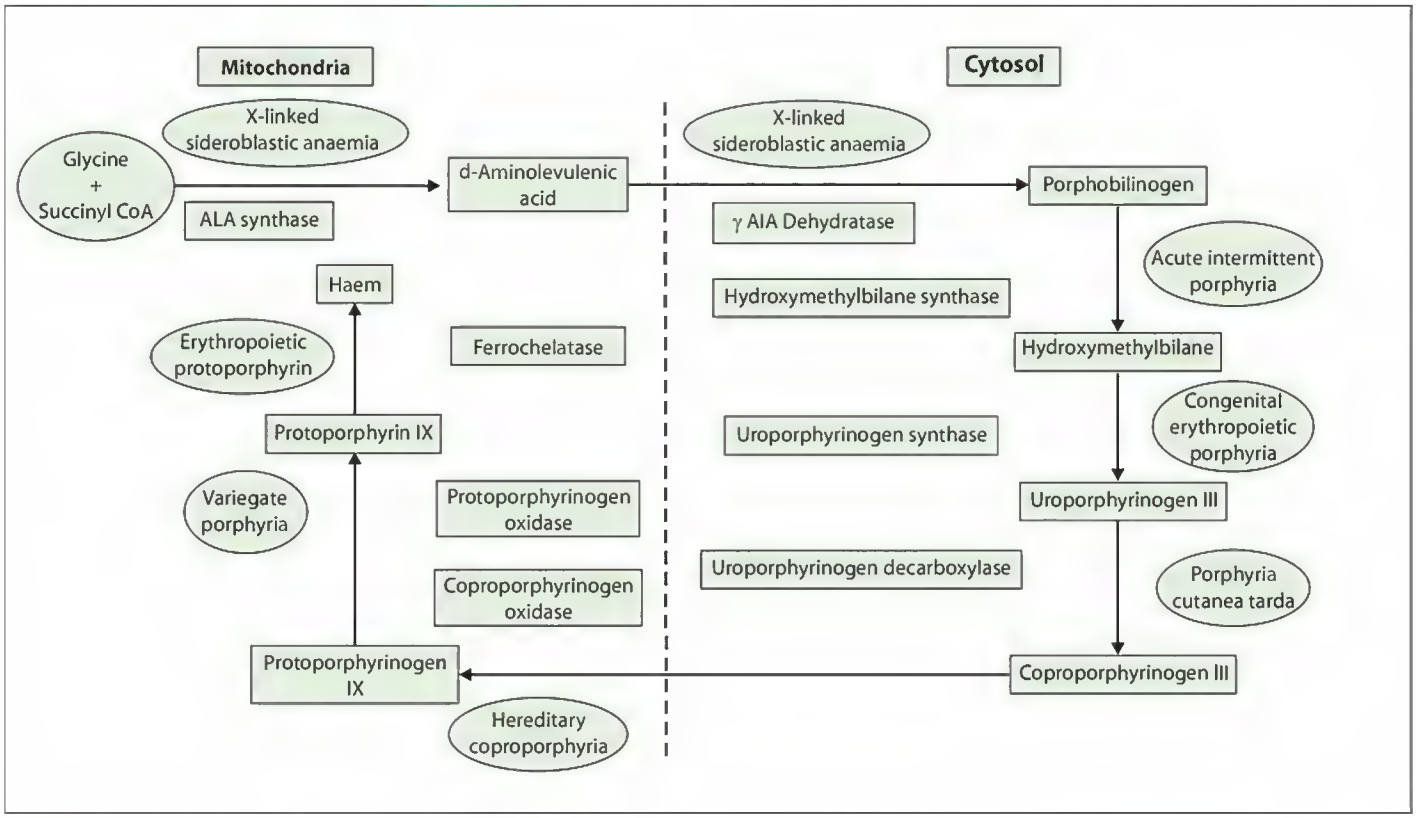

Figure 1: Haem-biosynthesis pathway with enzymes (in boxes) of each step and its associated disease (in ovals).

PORPHYRIA IN INDIA

The occurrence of acute intermittent porphyria (AIP) in India is mostly concentrated to *Maheshwari* and *Kumhar* communities of North West Rajasthan in and around Bikaner. In India, first case was reported by Wig and Malhotra in 1959. Estimated prevalence in India is 1 in 4.4 million but in Bikaner district it is around 1:12500 and around 1:400 to 1:600 in the specified communities, respectively. This prevalence is much higher than what has been described in many parts of the World. The disease has a female predilection (2:1). In their study, Wig and Malhotra have described a novel gene mutation in AIP in this region.

HEPATIC PORPHYRIAS

Acute Intermittent Porphyria

This is an autosomal dominant inherited disease resulting from the half normal level of hydroxymethylbilane synthase (HMBS) activity. In the classic form of AIP, both the 'non-erythroid' housekeeping HMBS isoform and the 'erythroid' HMBS isoform are deficient. The disease manifestation occurs due to induction of this rate limiting hepatic enzyme in heterozygotes. It remains latent or asymptomatic in majority of heterozygous having HMBS mutations and almost always before puberty. The pre-pubertal latency of the disease signifies the role of steroid hormones in clinical expression of the disease and increased frequency in women suggest a role of oestrogens or progestins. Common precipitating factors are infection, porphyrinogenic drugs (**Table 2**), steroids, alcohol, low calorie diet and occasionally pregnancy, which is usually well tolerated.

Clinical features

AIP is characterised clinically by acute episodes of a variety of gastrointestinal and neurologic symptoms and between these

episodes, the patient remains asymptomatic. Abdominal pain is constant, poorly localised and may be cramping in nature but sometimes it may be very severe and is associated with passage of red coloured (port wine) urine. Patient may have nausea, vomiting and severe constipation mimicking picture similar to intestinal obstruction. Fever, tenderness and leukocytosis are usually absent or mild because the symptoms are neurologic rather than inflammatory. Mental symptoms ranging from anxiety, insomnia, depression to disorientation, hallucination and paranoia can occur in acute attacks. Patients may have severe disabling pain all over the body, especially in lower limbs. Peripheral neuropathy is due to axonal degeneration and is primarily motor neuropathy affecting the proximal muscles of upper and lower limbs. Deep tendon reflexes are decreased or absent as neuropathy advances, however, ankle reflex may remain intact up to late in the course of illness. Sometimes 7th, 10th and 11th cranial nerves may also

Table 1: Important Features of Different Porphyrias

Disease Name	Deficient Enzyme (Activity % of Normal)	Gene Locus and Number of Mutations	Principal Symptoms (NV or P)	Increased Porphyrin Precursors and/or Porphyrins			
				Erythrocytes	Urine	Stool	Inheritance
Hepatic Porphyrias							
5 ALA dehydratase deficient porphyria (ADP)	ALA dehydratase (~ 5)	9q34 7 mutations	Neurovisceral	Zn protoporphyrin	ALA Coproporphyrin III	—	AR
Acute intermittent porphyria (AIP)	HMB synthase (~ 50)	11q23.3 272 mutations	Neurovisceral	—	ALA, PBG Uroporphyrin	—	AD
Porphyria cutanea tarda (PCT)	URO decarboxylase (~ 20)	1q34 60 mutations	Photosensitivity	—	Uroporphyrin 7-carboxylate porphyrin	Isocoprop-orphyrin	AD
Hereditary corpo-porphyria (HCP)	Coproporphyrinogen oxidase (~ 50)	3q12 36 mutations	Neurovisceral and Photosensitivity	—	ALA, PBG, Coproporphyrin III	Coproporp-hyrin III	AD
Variegate porphyria (VP)	Protoporphyrinogen oxidase (~ 50)	1q22 121 mutations	Neurovisceral and Photosensitivity	—	ALA, PBG, Coproporphyrin III	Coproporp-hyrin III Protoporphyrin	AD
Erythropoietic Porphyrias							
Congenital erythropoietic porphyria (CEP)	Uroporphyrinogen synthase (~ 1-5)	10q25.2-6.3 35 mutations	Photosensitivity	Uroporphyrin I Coproporphyrin I	Uroporphyrin I Coproporphyrin I	Coproporphyrin I	AR
Erythropoietic proto porphyria (EPP)	Ferrochelatase (~ 20-30)	18q21.3 74 mutations	Photosensitivity	Protoporphyrin	—	Protoporphyrin	AD

AD = Autosomol dominant; ALA = 5' aminolevulinic ocid; AR = Autosomal recessive; HMB = Hydroxymethylbilane; PBG = Porphobilinogen.

Table 2: List of Safe and Unsafe Drugs in Porphyria

Safe Drugs			Unsafe Drugs	
ACE inhibitors	Furosemide	Naproxen	Antidepressants	Macrolides
Acetylsalicylic acid	Gabapentin	Octreotide	Artemether	Methyldopa
Adenosine	Haloperidol	Olanzapine	Amiodarone	Nandrolone
Aminoglycosides	Hydrocortisone	Ondansetron	Azole antifungals	Phenytoin
Amphotericin B	Isoflurane	Orlistat	Barbiturates	Progesterones
Anti-D immunoglobulin	Insulin	Oxazepam	Chloroquine	Quinine (lesser than Chloroquine)
Cefotaxime	Immunoglobulins	Paracetamol	CCB's	Rabeprazole,
Ceftriaxone	Ibuprofen	Propranolol	Chlorzoxazone	Rifampicin
Chlorpromazine	Ipratropium	Propofol	Coxibs	Spironolactone
Codeine	Lactulose	Propylthiouracil	Carbamazepine	Oral contraceptive pills
Clonazepam	Lamivudine	Quinolones	(Cisapride)	Simvastatin
Clozapine	Levothyroxin	Ranitidine	(Clopidogrel)	(Sibutramine)
Dalteparin	Lithium	Rosuvastatin	Oestrogen	Testosterones
Desmopressin	Loperamide	Salbutamol	Hydralazine	Thiopental
Dexamethasone	Meropenem	Streptokinase	Isoniazid	Valproic acid
Didanosine	Metformin	Suxamethonium	IV lidocaine	(glimepride)
Estradiol patch or vaginal tablet	Morphine	Vaccines	Ketamine	(methylprednisolone)
Ethambutol	Multivitamin + iron	Vigabatrin	Metronidazole	(lamotrigine)
Enoxaparin	Nitrates		Metoclopramide

be involved. Patient may have generalised convulsion which may be secondary to hypertension, syndrome of inappropriate antidiuretic hormone hypersecretion leading to hyponatraemia apart from the disease itself. Patients may have urinary retention and rarely sensory loss. Progression to respiratory and bulbar paralysis and death may occur, especially when diagnosis and treatment are delayed. Patient may have postural hypotension, severe tachycardia and hypertension due to autonomic neuropathy. The disease can be disabling but is rarely fatal.

A rare homozygous dominant form of AIP occurs when patients inherit HMBS mutations from each heterozygous parent leading to very low (<2%) enzyme activity. The disease presents in infancy with failure to thrive, developmental delay and bilateral cataracts.

Diagnosis

During the acute attack, along with other features, urine is characteristically red or becomes red after keeping in sunlight for 30 minutes. The essential biochemical finding in acute attacks of AIP is increased urinary excretion of delta-aminolevulinic acid (ALA) and porphobilinogen (PBG), which can be estimated qualitatively by Watson-Schwartz test. Levels are substantially increased in plasma and urine during an acute attack and can be measured quantitatively in blood and 24 hours urine. Study of specific HMBS gene mutation is helpful in the diagnosis of symptomatic and asymptomatic persons.

Treatment

An acute attack of AIP is treated with carbohydrate loading as intravenous glucose 300 g per day and/or intravenous hematin. The use of narcotic analgesics for abdominal pain and phenothiazines for nausea, vomiting, anxiety and restlessness are very helpful. Low-dose benzodiazepines are safe as tranquilisers. Intravenous hematin should be used in case of a severe attack or in those milder cases which do not respond within 1 to 2 days, in the dose of 3 to 4 mg/kg daily for 4 days in forms of lyophilised hematin, haem albumin or haem arginate. Rapid recovery occurs if treatment is started early. However, recovery may take months or years in patients having severe motor neuropathy. Recurrent attacks can occur during luteal phase of menstrual cycle and Gonadotropin-releasing hormone analogues are useful in such cases. Patients should not receive drugs which are likely to precipitate acute attack (**Table 2**). Hypertension may be treated by propranalol and convulsion requires use of oral gabapantine. Long-term risk of hypertension, chronic renal disease and hepatocellular carcinoma is increased in these patients and yearly hepatic imaging may be helpful. Liver transplant is being tried as a new modality of treatment.

Porphyria Cutanea Tarda (PCT)

PCT, the most common type of porphyria is due to deficiency of hepatic Uroporphyrinogen decarboxylase. It may be either sporadic (type 1) which is more common or familial (type 2 and 3). The enzyme deficiency must be substantial (~20%) for disease manifestation.

Clinical features

Blistering skin lesions appearing most commonly on the back of the hands are the major clinical features and they leave areas of atrophy and scarring when they rupture or crust. Lesions may also occur on the forearms, face, legs and feet. Skin friability and small white papules, hypertrichosis and hyperpigmentation are seen specially on face. Neurologic features are absent. The important precipitating factors include hepatitis C, human immunodeficiency virus (HIV), excess alcohol, elevated iron levels and oestrogens. The association of increased evidence of haemochromatosis gene (HFE) mutation, C282Y and H63D, in patients with type 1 and 2 PCT reflects the role of excess hepatic iron as precipitating factor. Patients of PCT characteristically have chronic liver disease and sometimes cirrhosis and have an increased risk of hepatocellular carcinoma. Hexachlorobenzene, di- and tri-chlorophenols and dioxin can precipitate the disease.

Diagnosis

Porphyrins are increased in the liver, plasma, urine and stool. The urinary ALA level may be slightly increased but the PBG level is normal. Increased isocoproporphyrins in faeces and sometimes in plasma and urine are diagnostic.

Treatment

Standard treatment is repeated phlebotomy to reduce hepatic iron load. One unit of blood can be removed every 1 to 2 weeks till serum ferittin reaches the lower limits of normal. Close monitoring of haemoglobin levels and ferritin levels is required to prevent development of iron deficiency and anaemia. Continued phlebotomy may not be needed after remission. An alternative to phlebotomy is low-dose regimen of chloroquine (e.g. 125 mg chloroquine phosphate twice a week) or hydroxy-chloroquine.

Hereditary Coproporphyria (HCP)

This Autosomal dominant porphyria results from half normal activity of coproporphyrinogen oxidase and patients may have acute attacks and cutaneous photosensitivity together or separately. An acute attack is identical but less severe than that of AIP, while the blistering skin lesions are like that seen in PCT. The diagnosis of HCP is readily confirmed by increased levels of coproporphyrinogen III in faeces, which distinguishes it from other porphyrias. An increase in the faecal coproporphyrinogen III/coproporphyrinogen I ratio is very useful for detecting latent cases. The treatment of acute attack is similar to that of AIP and PCT.

Variegate Porphyria (VP)

VP is an autosomal dominant hepatic porphyria due to deficient activity of protoporphyrinogen oxidase and can present with skin photosensitivity, acute neurovisceral crises, or both. Acute attacks are identical to those in AIP and are precipitated by the same factors as AIP whereas blistering skin manifestations are similar to those in PCT. Increased urinary ALA, PBG with coproporphyrinogen III and increased faecal protoporphyrin and coproporphyrinogen III help in diagnoses. The latter also help to distinguish VP from AIP. Plasma of the patient shows a unique fluorescence peak at neutral pH. Acute attacks are treated like that of AIP along with avoiding the exposure to sunlight.

ALA Dehydratase Deficient Porphyria (ADP)

ADP is an acute, hepatic porphyria caused due to severe deficiency of ALA-dehydratase activity (<10%). It is very rare and the clinical presentations vary according to the level of enzyme, however, neuropathy and abdominal pain

are common. There is a significant increase in urinary excretion of coproporphyrin III and ALA. The treatment of acute attack is similar to AIP.

THE ERYTHROPOIETIC PORPHYRIAS

In the erythropoietic porphyria, the excess porphyrins produced in bone marrow erythrocyte precursors are transported via plasma to the skin, where it causes cutaneous photosensitivity.

X-Linked Sideroblastic Anaemia (XLSA)

XLSA results from the deficient activity of the erythroid form of ALA synthase. These patients develop weakness since infancy and a refractory form of haemolytic anaemia. Patients have secondary hypersplenism and hypercellular bone marrow with megaloblastic erythropoiesis. The condition may respond to pyridoxine supplementation; however, blood transfusion may be needed in non-responsive patients.

Congenital Erythropoietic Porphyria (Gunther's Disease)

An autosomal recessive disorder occurring due to the deficient (not absent) activity of uroprophyrinogen III synthase causing accumulation of uroporphyrin I and coproporphyrin I isomers. Severe cutaneous photosensitivity begins in early infancy. Sunlight exposed skin becomes friable with formation of bullae and vesicles which are prone to rupture. Skin thickening, focal hypo/hyperpigmentation, and hypertrichosis of the face may occur. Haemolysis occurs due to increased levels of erythropoeitic porphyrins in blood. Increased levels of Uroporphyrin and coproporphyrin in erythrocytes, plasma, urine and faeces help in the diagnosis. The predominant porphyrin in faeces is coproporphyrin I.

Apart from supplementation of β-carotene, protection from sunlight and minor skin trauma are important preventive measures. Severe cases often require blood transfusion for anaemia. Splenectomy may reduce haemolysis and decrease transfusion requirements. Bone marrow and cord blood transplantation have proven effective in several transfusion dependent children. Recently, stem cell therapy is also being tried.

Erythropoietic Protoporphyria (EPP)

EPP is the most common erythropoeitic porphyria in children and occurs due to partial deficiency of ferrochelatase activity (<35%). Skin photosensitivity begins in childhood with pain, redness and itching occurring within minutes of sunlight exposure. It is non-blistering and is associated with elevations in erythrocyte protoporphyrin. Chronically skin may develop lichenification. About 5% of these patients may develop chronic liver disease.

The hallmark of this disease is an increase in erythrocyte protoporphyrin which is not complexed with zinc, in contrast to conditions such as lead poisoning, iron deficiency, haemolytic disorders in which zinc complexed protoporphyrin is seen. RBC's exhibit red fluorescence at 620 nm. Urinary levels of porphyrins and porphyrin precursors are normal. Avoiding sunlight exposure and wearing clothes designed for specific protection is helpful. Oral β-carotene to maintain serum level at 600 to 800 mg/dL may be very useful.

18.7 Wilson's Disease

Sanjib Sinha, AB Taly

INTRODUCTION

Wilson's disease (WD) is an autosomal recessive disease involving a defect of copper transport by the hepatic lysosomes. It leads to excess copper deposition in liver, brain, kidneys and skeletal system, commonly affects children or young adults and runs an invariably fatal course if not adequately treated by de-coppering therapy. Among the various inborn errors of metabolism, WD is of specific interest to physicians due to availability of effective treatment. *Wilson SAK* provided detailed description of clinical and pathological changes in WD way back in 1912, but major advances in our understanding of the pathogenesis, cellular biology, and molecular genetics of the disease have occurred in the past three decades.

EPIDEMIOLOGY

The prevalence rate of WD is varied and has been reported as 12 to 29 per million in European populations. The prevalence of WD in other Asian countries has been between 33 and 68 per million but, there are no epidemiological surveys in India till date. At National Institute of Mental Health and Neurosciences (NIMHANS), we record 15 to 20 new cases of WD annually.

PATHOGENESIS

The major breakthrough regarding pathophysiology of WD came in 1948 when Cumings demonstrated excess of copper in brain and liver in these patients. It is now known that mutations in ATP-7B, a copper transporting protein, leads to abnormal accumulation of copper in hepatocytes that later spills into the circulation and eventually gets deposited in other organs. How does a copper deposition lead to tissue damage largely remains speculative?

GENETICS

Genetically WD is an autosomal recessive disorder of hepatocyte copper trafficking caused by impaired function of P-type adenosine triphosphatase (ATPase), encoded by ATP-7B gene located on chromosome 13q14 and consists of 21 exons. The ATP-7B transporter has dual synthetic and excretory roles, functioning in the transport of copper into the trans-Golgi compartment, for incorporation into the plasma protein caeruloplasmin, and into the bile, for excretion of excess stores. Defective ATP7B function results in hepatic copper accumulation and leads to hepatic and neurological manifestations of Wilson's disease. More than 400 mutations, documented from various countries including India, perhaps account for its clinical heterogeneity.

PATHOLOGY

Liver

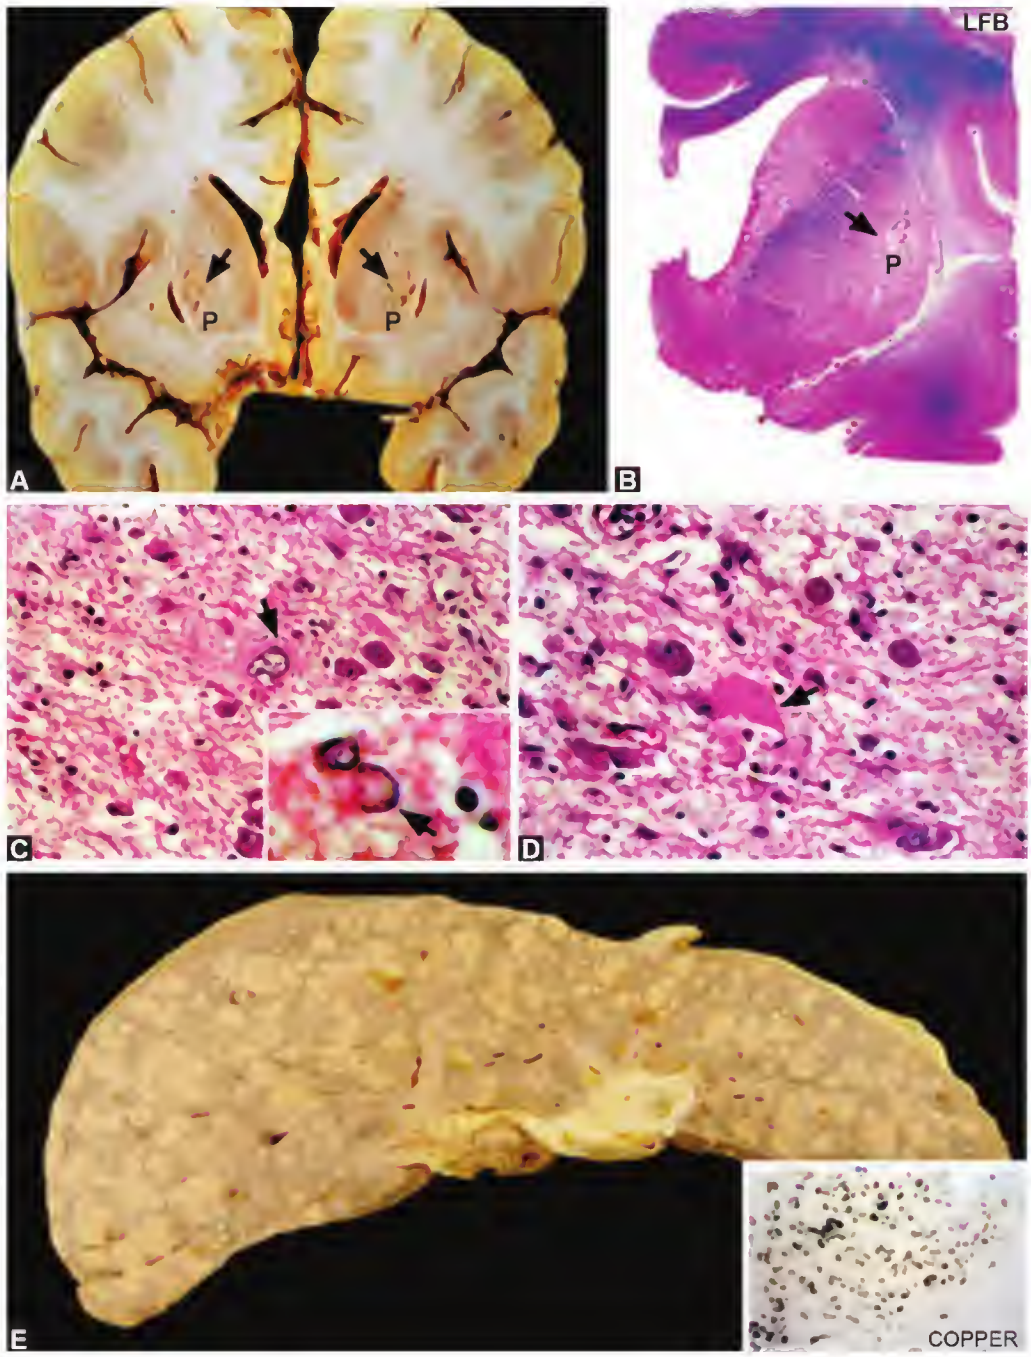
In the early stages of the disease, diffuse cytoplasmic copper accumulation can be detected in liver by special immunohistochemical stains. Thereafter it progresses to an inter-mediate stage characterised by periportal inflammation, mononuclear cellular infiltrates, erosion of the limiting plate, lobular necrosis, and bridging fibrosis that suggests hepatitis. Cirrhosis almost invariably follows with either a micronodular or a mixed macronodular-micronodular pattern. In patients with fulminant hepatic failure, parenchymal apoptosis, necrosis and collapse might predominate, often with a background of cirrhosis (**Figures 1A and E**).

Brain

Brain shows evidence of putaminal softening, ventricular dilatation and atrophy, white matter cavitations, and central pontine myelinolysis like changes. Histological features include spongiform degeneration, astrocytosis, neuronal loss, gliosis and presence of characteristic fairly large Opalski cells, which exhibit fine granular cytoplasm and slightly abnormal nuclei (**Figure 1**).

CLINICAL PROFILE

Walshe has aptly stated that no two patients of WD may have similar clinical characteristics even among the common sib-ship, stressing its diverse manifestations. The phenotypic variability often leads to delay in diagnosis and treatment unless there is a high index of suspicion.



Majority of patients manifest with hepatic or neuropsychiatric symptoms (**Table 1, Figures 2A to D**). While hepatic involvement occurs early in the course of WD, it may go unrecognised and may not be the first symptom for seeking medical attention. Hepatic presentation, predominantly noted at a younger age, ranges from acute fulminant hepatitis to sub-clinical chronic liver disease. Most of these patients may not undergo investigation for WD due to its rarity in the community and low index of suspicion. Some of these patients succumb to illness while others develop neurological symptoms later in the course of disease.

Psychiatric presentation of WD includes bipolar affective disorder, schizophrenia, and psychosis with cognitive decline. A small number of patients predominantly exhibit renal dysfunction (e.g. renal tubular acidosis), and haematological symptoms (e.g. low counts, bleeding, etc.).

DIAGNOSIS

Slit lamp evaluation of Kayser-Fleischer (KF) ring forms corner-stone of clinical diagnosis. The KF ring is invariably present in all patients with neuropsychiatric form of WD but detection rate depends on the experience of clinician and ophthalmologist. In hepatic and other forms, KF ring may not be detected, and therefore, heavy reliance on this sign may lead to under recognition of the disease (**Figures 2A to D**).

The key biochemical diagnostic test includes low serum total copper, low serum caeruloplasmin and elevated 24-hour urinary

Figures 1A to E: Coronal slice of the brain from a case of Wilson's disease (WD) shows (A) bilaterally symmetrical putaminal (P) softening (arrows) extending laterally up to the external capsule; (B) whole mount preparation stained with Luxol Fast Blue (LFB) shows relative preservation of internal capsule and pale and softened neuropil in the putamen (P, arrow); (C) softened area in the putamen has bizarre astrocytes with vesicular lobulated nuclei (arrow) with inset showing Alzheimer type 2 astrocytes in the neuropil (arrow) (haematoxylin and eosin stain x 240 [Inset: H & E x 300]); (D) large opalski cell characteristic of WD has irregular eosinophilic cytoplasm and small peripherally placed pyknotic nucleus (H & E x 240); (E) slice of enlarged liver shows micro- and macro-nodular cirrhosis with inset demonstrates copper deposits within hepatocytes on rubanic acid stains (Inset: Rubanic acid x 240).

copper. It should be noted that caeruloplasmin being an acute phase reactant might be falsely normal in patients with acute presentation, especially of hepatic form. Therefore, high index of suspicion in this group of patients is required for accurate diagnosis.

One needs to carry out liver function tests, renal function tests, and haematological parameters, abdominal ultrasound, endoscopic examination, among others to assess status of various other organs involved in the disease.

Therapeutic monitoring for effective treatment can be done by 24-hour urinary copper excretion.

IMAGING

Introduction of magnetic resonance imaging (MRI) has made dramatic inroads into the pathological and anatomical correlates of clinical manifestations and has replaced computed tomography (CT) in the evaluation of WD. MRI of brain can assist in the diagnosis as well as prognosis. The MRI changes are varied in severity and topography, however, presence of central pontine myelinolysis, like changes, mid-brain tectal plate signal changes and giant Panda sign distinguishes WD from other extra-pyramidal disorders (**Table 2, Figures 3A to F**). The changes are dynamic and a significant proportion of the patients may

Table 1: Clinical Manifestations of Wilson's Disease

Hepatic
- Acute hepatitis (similar to self-limiting viral hepatitis)
- Persistently elevated serum liver enzymes
- Chronic hepatitis
- Cirrhosis (decompensated or compensated)
- Fulminant hepatic failure

Neurological
- Dystonia
- Tremor
- Dysarthria
- Drooling
- Parkinsonism or akinetic rigid syndrome
- Gait disturbances ataxia
- Pseudobulbar palsy
- Chorea
- Seizures
- Cognitive impairment
- Metabolic myopathy

Psychiatric
- Bipolar affective disorder
- Depression
- Neuroses
- Personality changes
- Schizophreniform psychosis
- Mental retardation

Haematological
- Hypersplenism and related issues
- Bleeding gums
- Haematemesis
- Pallor

Ophthalmic
- Kayser-Fleischer ring
- Sunflower cataract

Other Systems (uncommon)
- Renal tubular acidosis
- Menstrual irregularities
- Recurrent abortion
- Hyperpigmentation

show variable reversibility of MRI features following treatment. MR spectroscopy has provided insight into the ongoing biochemical changes.

Radiographic evaluation has documented following skeletal abnormalities osteoporosis, fractures, and arthritis and milkman pseudo fractures.

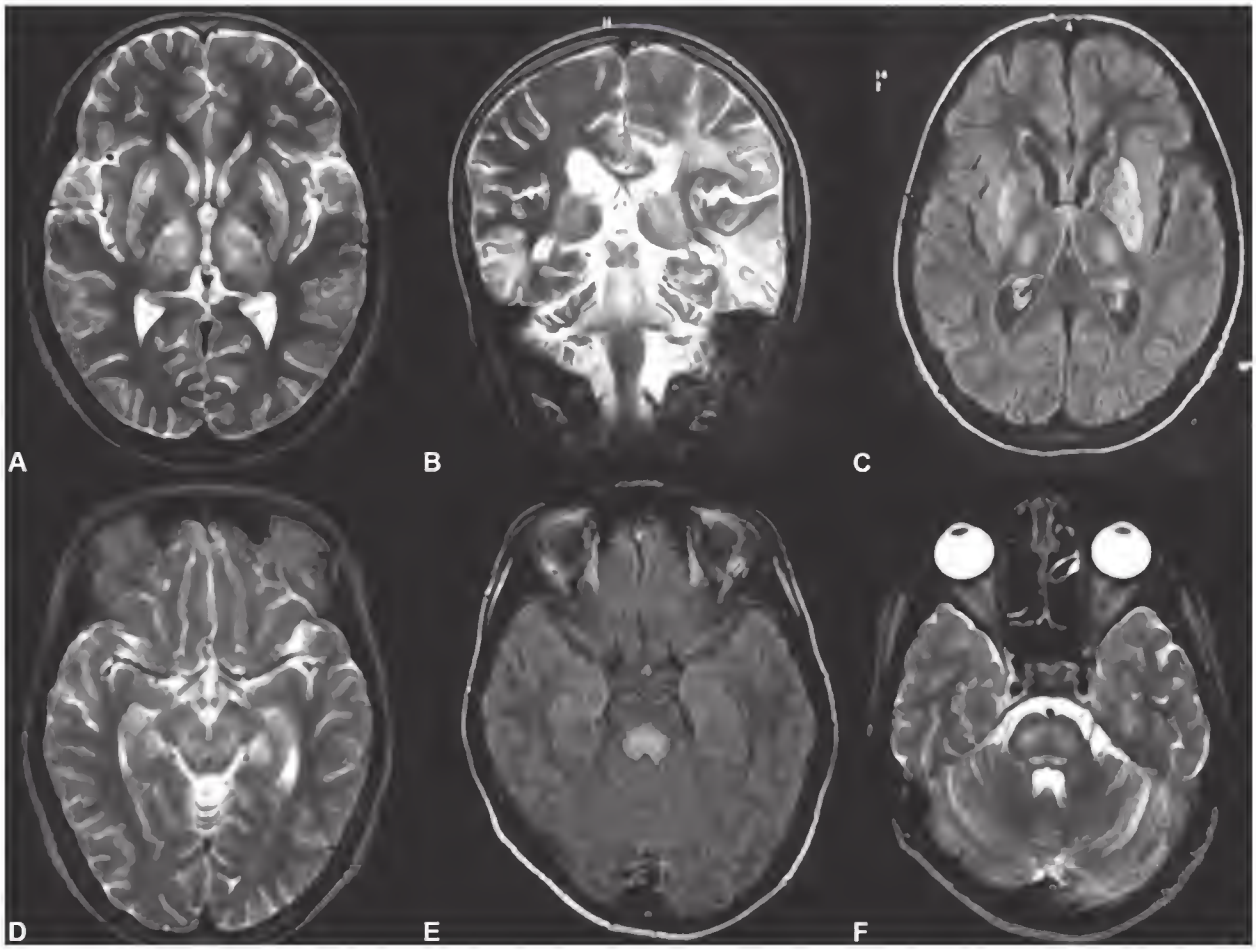
MANAGEMENT

Therapeutic Aspects

The outcome of WD was rather gloomy until 1948 when Cuming suggested use of Dimercaprol (BAL) for chelating the copper. This breakthrough in the management of WD was followed by introduction of penicillamine as de-coppering therapy in 1955 by Walshe. A number of drugs, such as zinc, trientine and ammonium tetrathiomolybdate, have been shown to have beneficial effect and frequently recommended in the management. Liver transplantation, the most definitive treatment for WD has been successfully carried out since 1982. Most patients need close monitoring and life-long supervised care. A general approach to diagnosis and management of WD is provided in **Figure 4**.

Penicillamine is the most commonly used de-coppering agent in India. A significant and paradoxical worsening, reported by few authors, can be largely reduced if penicillamine is started in a low dose and built up to the required dosage slowly (250 to 1000 mg per day). Zinc, introduced in early 1960s, is an effective agent with minimal side effects and forms an essential component of treatment in vast majority of patients. Unlike penicillamine and other de-coppering agents, zinc is cheap, easily available, has better compliance rate and can be used as an effective maintenance therapy in Indian population (150-300 mg elemental zinc per day). The experience in Indian literature on trientine dihydrochloride

Figures 2A to D: (A) Typical "Wilsonian" dystonic smile; (B) dystonia of upper and lower extremities in a young boy with Wilson's disease; (C) Kayser-Fleischer ring – naked eye appearance; (D) sunflower cataract.



and ammonium tetrathio-molybdate in WD is rather sparse, largely due to non-availability of these drugs and their prohibitive cost.

Symptomatic treatment for hepatic dysfunction, portal hypertension, osseous changes, drooling, extra-pyramidal and psychiatric manifestations, hypersplenism is required in many patients. Surgical interventions like thalamotomy for disabling and resistant tremor in WD have been reported.

PROGNOSIS

WD has come off from the shadow of being an untreatable fatal disorder to potentially treatable disorder. It is believed that most of the patients with the currently available medications might lead a normal life. However, outcome of WD is as varied as its clinical manifestations and there are no consistent clinical imaging or laboratory parameters that can dictate prognosis.

A rapid progressive course is usually noted in the hepatic form of the disease, e.g. acute fulminant hepatic failure. In non-hepatic forms, the clinical course is usually indolent and relentlessly progressive if not treated. Most of the neurological patients do respond to therapy, even when present with severe form of the disease. Some patients have very stable initial course with dramatic response to de-coppering agents but later show

Source: Modified from Taly et al. Neurology India 2009; 57: 527-40.

sudden deterioration, usually precipitated by poor drug compliance and sometimes by infections and stress. The exact reason for this delayed worsening remains a challenge. These patients probably have very delicately maintained internal milieu and any factor which tends to change the balance leads to vicious cycle of deterioration. Thus, therapeutic outcomes can be broadly classified into three categories:

1. Patients who have been diagnosed, treated and have normal life or are clinically stabilised, but still have problems with "Quality of Life".

2. Patients who have relentlessly progressive course despite specific treatment.
3. Patient who dramatically worsen and progress after long-term stable clinical course.

CONCLUSION

WD is perhaps more common than reported from India. There is a need to have epidemiological and genetic studies taking into consideration its variable presentation and high degree of consanguinity in south Indian populations. A nation-wide registry may improve awareness among medical communities and lead to early diagnosis and prompt treatment. Once diagnosis is established the patient and the care-giver need to be educated regarding compliance and long-term follow-up.

18.8 Lysosomal Storage Disorders

Prasanta Kumar Bhattacharya

DEFINITION AND EPIDEMIOLOGY

Lysosomes are a group of subcellular organelles of diverse size and shapes, which contain numerous acid hydrolases, each of which is responsible for degradation of specific biological macromolecules derived either endogenously from metabolism or cellular structures or from breakdown of exogenous materials.

Lysosomal storage disorders (LSDs) represent a group of more than 40 distinct genetic diseases, each one resulting from a deficiency of a particular lysosomal protein or, in a few cases, from non-lysosomal proteins, that are involved in lysosomal biogenesis.

Although the incidence of LSDs in the general population is rare, it is about 1 in 5,000 live-born infants, their prevalence in certain selected populations is considerably high. Gaucher's disease and Tay-Sachs disease, for example, are reported to be 1 per 855 and 1 per 3,900, respectively in the Ashkenazi Jewish population; aspartylglucosaminuria is prevalent in 1 per 18,500 in the Finnish population and mucopolysaccharides (MPS) type III is about 1 per 24,000 in the Netherlands.

AETIOPATHOGENESIS

Most LSDs are inherited in an autosomal recessive manner, with the exception of Fabry's disease and MPS type II, which show X-linked recessive inheritance. Since lysosomes are found in most cells of the body, these disorders tend to be multi-systemic and are always progressive, although the rate of progression may vary. Organ damage arises from progressive accumulation of the substrates for the missing enzyme. There are several potential ways in which accumulated substrate might cause disease. The most obvious is enlargement of the affected cell, resulting in enlargement of the respective organ. The accumulation of undegraded substrate leads to a number of secondary biochemical and structural events, which individually or in combination, leads to the pathophysiology and clinical manifestations of these disorders. These secondary events include secondary lysosomal hypertrophy, neuronal changes, macrophage activation and cytokine release.

CLINICAL FEATURES

The clinical manifestations of the different disorders are diverse and it is not within the scope of this chapter to discuss each one in detail. Some clinical features are common for all of them. These include:

1. The symptoms arising from these disorders may start early in infancy or late in life, are usually permanent and progressive, and are unrelated with food intake or inter-current illnesses.
2. These disorders are usually associated with connective tissue diseases, skeletal abnormalities and neurological symptoms including deafness and progressive mental deterioration.
3. Visceral syndromes affecting the spleen, liver, lungs, kidneys and the heart are common.
4. Ocular disease occurs especially in mucopolysaccharidoses and neurosphingolipidoses with corneal opacities, retinal changes and macular cherry-red spots.
5. Recurrent non-immune hydrops foetalis is an uncommon but important presentation of several LSDs including Farber's disease, GMI gangliosidosis, galactosialidosis, Niemann-Pick disease type C, etc.

MODALITIES OF DIAGNOSIS

It is important to make an early diagnosis of these disorders for various reasons:

1. These being inherited genetic disorders, genetic counseling of other members of the family can be done and unexplained symptoms in relatives can be clarified.
2. Definitive treatment modalities, like enzyme-replacement therapy, bone marrow transplantation or even substrate-reduction therapies, although costly, are available for these disorders. These new treatments may halt or even reverse progressive organ damage. The substantial morbidity and premature mortality of these disorders may be preventable.
3. Several of these disorders respond to palliative treatment including renal and hepatic transplant.

Diagnostic Work-up

Early diagnosis of these disorders is critical, because those patients, who are treated before significant symptom development, have the best chance for a positive outcome. The most vital point in the diagnostic work-up is the suspicion about LSD-based on clinical clues. The LSDs can be suspected in any individual experiencing developmental delay, loss of learned skills, ataxia, seizures, weakness and dementia, more so, if the individual is regressing after a period of relatively normal development and the disorder seems progressive. Suspected patients should be referred to special laboratories for histochemical staining of biopsy material and examination of urine metabolites, including lipids and oligosaccharides, so as to narrow down the diagnostic possibilities. However, specific enzymatic assays on leukocytes isolated from fresh heparinised blood samples or on fibroblasts cultured from small skin biopsies yields better results than biopsy. These immuno-chemical tests help in patient management, especially in early detection of the disorder, prediction of clinical severity, determining the most appropriate therapeutic regimen, and for monitoring of patients who are on therapy. Molecular analysis of genes, which encode for lysosomal enzymes, especially deoxyribonucleic acid (DNA) based studies, are now available, which not only support the enzymatic diagnoses of LSD but they further help in the detection of phenotype. At present, specific enzymatic and genetic diagnoses are preferred to histopathological studies on light microscopy. Electron microscopy of biopsy material is also considered helpful in arriving at a correct diagnosis.

SELECTED DISORDERS

Table 1 summarises various enzyme deficiencies and the clinical features. The important ones are discussed in subsequent paragraphs.

Gaucher's Disease

This is the most common LSD and is also the most prevalent genetic disease among Ashkenazi Jews. It results from the deficiency of enzyme glucocerebrosidase, which normally splits glucosylceramide, to produce glucose, leading to glucosylceramide accumulation in the reticuloendothelial system.

Clinical features

Gaucher's disease is a multi-system disorder with haematological problems, organomegaly and skeletal involvement with bone pain and pathological fractures. There is hepato-splenomegaly with features of hypersplenism. The marrow cavity is widened due to deposition of Gaucher's cells (cerebroside laden macrophage with eccentric nuclei and "crumpled silk" like PAS-positive cytoplasm due to intra-cytoplasmic substrate inclusions) along with expansion of the bones, especially the lower ends of femur and humerus. Based on the presence or absence of severe neurological involvement three clinical variants are described:

1. *Type 1 Gaucher's disease (non-neuronopathic):* It is a chronic disease presenting both in young and in older persons as a slowly to rapidly progressive visceral disease characterised by hepatosplenomegaly. Younger patients have a greater degree of hepatosplenomegaly and peripheral blood cytopaenias while chronic bone disease is commoner in the older group.
2. *Type 2 Gaucher's disease (acute-neuronopathic):* It is rare, with rapidly progressive neurodegenerative course with extensive visceral involvement and death within the first 2 years of life.
3. *Type 3 Gaucher's disease (chronic-neuronopathic):* It may present with clinical manifestations that are intermediate to those seen in type 1 and 2 with presentation in childhood and death by the age of 12 to 15 years.

Tay-Sachs' Disease

It is common in Ashkenazi Jews. A history of consanguinity is usually present. There is deficiency of β-hexosaminidase A, which leads to accumulation of GM_2 gangliosides within the central nervous system (CNS) ganglion cells along with degeneration of myelin. It is clinically characterised by mental apathy, early mental retardation and visual defects leading to progressive spasticity, blindness and dementia. There are macular cherry-red spots on fundoscopy. The infantile form of the disease manifests by 6 months of age and death occurs within 3 to 4 years. The juvenile-onset type presents with ataxia and dementia with death by about 15 years. The adult-onset form starts in childhood with clumsiness, with motor and spinocerebellar signs developing in adolescence and progressing into adulthood with psychosis and dementia.

Sandhoff Disease

It is similar to Tay-Sachs' disease with additional hepato-splenomegaly and bony dysplasia.

Fabry's Disease

It is an X-linked disorder due to α-galactosidase deficiency and characterised by angiokeratomas, small vessel disease of kidneys, heart and brain, corneal and lenticular opacities. Proteinuria and progressive renal dysfunction occur in 2nd to 4th decades. Hypertension, left ventricular hypertrophy, myocardial ischaemia and infarctions and heart failure occur in the 3rd to 4th decades. Death usually results from renal failure or cardiovascular or cerebrovascular diseases in untreated patients.

Table 1: Enzyme Deficiencies and Salient Clinical Features of Few Common Lysosomal Storage Disorders

Disorder	Enzyme Deficiency	Stored Material	Clinical Manifestations				
			Clinical Types	Neurological Involvement	Visceromegaly (Liver/Spleen)	Skeletal Disease	Ophthalmic Lesions
Gaucher's disease	Glucocerebrosidase	Glucosylceramide	Type 1	–	+	+	–
			Type 2	+	+	+	Eye movement
			Type 3	+	+	+	
Tay-Sachs' disease	β-hexosaminidase A	GM2 gangliosides	Infantile Juvenile	MR, Seizures	–	–	Cherry red spot
Sandhoff disease	β-hexosaminidase A and B	GM2 gangliosides	Infantile	MR, Seizures	+	±	Cherry red spot
Fabry's disease	α-galactosidase A	Globotriao sylceramide	Childhood	Painful acroparesthesias	–	–	Corneal dystrophy
Niemann-Pick disease A and B	Acid sphingomyelinase	Sphingomyelin	Type A, neuronopathic; Type B, non-neuronopathic	MR, Seizures	+	–	Cherry-red spot
Metachromatic Leukodystrophy	Arylsulphatase A	Cerebroside sulphate	Infantile Juvenile Adult	MR, Dementia, Psychosis	–	–	Optic atrophy

MR = Mental retardation; (+) = present; (–) = absent.

Niemann-Pick Disease

It is an autosomal recessive disorder due to defects in acid sphingomyelinase. Type A is characterised by early onset progressive CNS disease with massive hepatosplenomegaly. Type B has a late and variable onset with hepatosplenomegaly and progressive hepatic cirrhosis and pulmonary disease with the presence of foamy cells in both liver and lungs. Death results in adolescence or early adulthood due to progressive lung or hepatic disease.

TREATMENT

A variety of non-specific therapeutic measures are available for most disorders. Specific therapy can be broadly divided into enzyme-based therapies and non-enzyme-based therapies.

Enzyme-Based Therapy

The enzyme-based therapies currently available are bone marrow transplantation (BMT) and enzyme replacement therapy (ERT). In BMT, which is used in at least 20 known types of LSDs, the donor bone marrow provides a constant and permanent endogenous supply of enzyme-producing cells. Unfortunately, while BMT results in varying degrees of clinical improvement, it rarely, if ever, results in complete reversal of the clinical phenotype because of: (i) inadequate tissue penetration in skeletal and neuronal tissues, and (ii) presence of extensive disease prior to commencement of BMT. Response to ERT varies considerably from disease to disease, depending on the age of onset, rapidity of disease progression and the presence or absence of neurological involvement. Within each disease too, there is considerable variation. Mildly affected patients are the most likely to respond.

Non-Enzyme-Based Therapy

Substrate reduction therapy (SRT) is a novel approach in the treatment of certain types of LSD. The imino-sugar N-butyl-deoxynojirimycin (NB-DNJ) has been shown to inhibit ceramide-specific glucosyltransferase, which catalyses the first step in glycosphingolipids biosynthesis. This results in the inhibition of biosynthesis of all glucosylceramide-based glycosphingolipids.

Future Directions of Therapy

The CNS-directed gene therapy and Chaperone therapy (also known as enzyme enhancement therapy), that have the potential to cross the blood-brain barrier are newer modes of therapy directed towards CNS manifestations of LSDs.

CONCLUSION

Increased awareness by healthcare professionals, with early diagnosis and referral to specialist centres, is increasingly important, as new treatment modalities that are now available may halt or even reverse progressive organ damage. The substantial morbidity and premature mortality of these disorders may be preventable.

18.9 Inherited Disorders of Membrane Transport

SK Singh

INTRODUCTION

Correct localisation of substances within the cell is membrane transport. Molecular transportation takes place at the cell surface or at intracellular cell organelles. The former is responsible for localisation of various substances inside the cell against or along the concentration gradient whereas latter one prevents mixing of various proteins inside the cell organelles. While both abnormalities of membrane transport are related to disease conditions, genetically inherited only membrane transport and their relevance in disease states are described due to space constraints in the present chapter. Transportation of substance across the cell membrane is mediated by the transporters. Classes of substance that need transportation are amino acids, sugars, ions (cations, anions), vitamins and water. Defects in transportation of one or more compounds may be autosomal dominant or recessive in inheritance and these points toward genetic locus that involves alteration in membrane protein.

Pathology of many diseases have not been understood till very recently when defect in membrane transport of molecules and their role in causation of disease was recognised. Mutation in transporter molecules has been demonstrated in disorders of heart, muscle, brain, endocrine and sensory organs. Sometimes mutation of different gene that encodes interacting protein can present similar disease phenotype. In case of allelic heterogeneity, mutation of single gene leads to different diseases depending on functional inactivation, activation or presence of dominant negative effects. The number of inherited membrane transport disorders are increasing with identification of newer molecular basis of these disordes.

The defects in membrane transport that cause diseases are classified as;

1. Disorder of amino acid transport,
2. Disorder of hexose transport,
3. Disorder of anion transport.

DISORDER OF AMINO ACID TRANSPORT

In this disorder two variants are described. One involves group specific membrane receptor or carrier and the other involves substrate specific transport system. In the first variant, 5 amino acids transport disorders, cystinuria, dibasic aminoaciduria, Hartnup disease, iminoglycinuria, and dicarboxylic amino-aciduria have been described and in the second variant, the transport of only one amino acid is impaired due to existence of substrate-specific transport systems. Each of these conditions affects transport of amino acids in the kidney, gut, or both but not in other tissues.

Cystinuria

It is a common inborn error, characterised by impaired renal tubular and intestinal mucosal reabsorption, because of defective transport at brush border and excessive urinary excretion of the dibasic amino acids lysine, arginine, ornithine, and cystine. Cystine is sulphur containing non-essential amino acid that is synthesised from methionine. Because cystine is less soluble its overexcretion predisposes to the formation of renal, ureteral, and bladder stones. Such stones are responsible for the signs and symptoms of the cystinuria.

The disorder is transmitted as an autosomal recessive trait and with a frequency of 1 in 10,000 to 1 in 15,000 in many ethnic groups. There are two genetic variants of cystinuria: type 1 and non-type 1. Homozygotes for both variants have high urinary excretion of dibasic amino acids lysine, arginine, ornithine, and cystine. While heterozygote Type 1 has normal urinary level of these amino acids, non-type 1 has moderately high excretion of these amino acids (non-type 1 was previously known as type II,III). The gene for type 1 cystinuria (SLC3A1) encodes solute carrier family 3 and maps to chromosome 2p16.3. The other types of cystinuria (non-type 1) are caused by mutations in SLC7A9, which maps to chromosome 19q13 and encodes the light subunit needed for the correct processing of SLC3A1.

Clinical manifestations

Increase in urinary excretion of cystine and the other disbasic amino acids leads to cystine renal stones that account for 1% to 2% of all urinary tract calculi and it is most common cause of stones in children. Renal stone formation usually occurs in the second or third decade but may occur in the first year of life and occasionally may present as bladder calculi at birth. In the homozygous patients urinary excretion of cystine usually exceeds 500 mg per day, and stone formation occur at an early age, but heterozygotes excrete usually 100 to 300 mg per day and typically do not have urolithiasis. Clinical presentation, symptoms and signs are those of urolithiasis, haematuria, flank pain, renal colic, obstructive uropathy, infection and these complications can lead to progressive renal insufficiency.

Diagnosis

The cystine stone is pathognomonic of cystinuria. Urinary nitroprusside test should be performed on all patients with urolithiasis to exclude this diagnosis. Half the stones in cystinuric individuals are of mixed composition and the cystine core may not be detected in 10%, therefore, nitroprusside test is reliable for the diagnosis. Nitroprusside test (appearance of a cherry red colour) may be false positive in some heterozygotes for cystinuria and in patients with hypercystinuria, homocystinuria, and mercaptolactate-cysteine disulphiduria. When cystine content exceeds 1000 µmol/L (250 mg/L), cystine crystals are seen in the sediment of acidified, concentrated chilled urine. These hexagonal crystals are pathognomonic of cystine overexcretion in patients not taking sulphonamides. Qualitative urine amino acid analysis helps confirming the diagnosis of cystinuria, while quantitative chromatography can be useful for

differentiating heterozygotes from homozygotes and for following free cystine excretion during therapy. The sulphur content of cystine gives these stones their faint radiopaque appearance.

Treatment

The treatment is essentially targeted to reduce urinary concentration of cystine and to make the pH of urine alkaline as cystine crystals are soluble in alkaline but precipitate in acidic environment. These are accomplished by increasing water and fluid intake to 5 to 7 litres in 24 hours. Water is good for treatment and its intake should be distributed throughout the day and night. Alkanisation of urine to a pH of 7.5 makes the cystine stone soluble and this can be achieved by sodium bicarbonate, acetazolamide, and polycitrates. Long-term use of the alkaliser may lead to the formation of calcium oxalate, phosphate or calcium ammonium phosphate stone or nephrocalcinosis.

If the above measures fail, the alternative treatment is D-penicillamine that makes disulphide of penicillamine and cystine. Such compound is more soluble and it reduces cystine concentration in urine. The dose of penicillamine is 1 to 3 g per day. The side effects include serum sickness, pancytopaenia, agranulocytosis, immune glomerulonephritis and Goodpasture's syndrome. These side effects limit the use of penicillamine in cystinuria and is used as a reserve drug. The other drug is tiopronin (alpha mercaptopropionylglycine) given in dose of 800 to 1200 mg per day in four divided doses as safer and effective alternative. Cystine stone of less than 1.5 cm can be treated by extracorporeal shock wave lithotripsy.

Dibasic Aminoaciduria

It is characterised by a defect in reabsorption of the 3 dibasic amino acids (lysine, arginine, ornithine) but not cystine from renal tubules. It is transmitted as autosomal recessive traits. The common form (type II) is known as lysinuric protein intolerance that show defective intestinal transport of dibasic amino acids as well as exaggerated renal losses. It is associated with impairment of the urea cycle. The defective gene (SLC7A7) is mapped to chromosome 14q11.2. Multiple genes are required in the formation of this dimeric transporter that explains part of the intrafamilial variability observed in lysinuric protein intolerance.

Manifestations are related to deficiency of ornithine, arginine, and lysine. Affected patients present with hepatosplenomegaly, protein intolerance, and episodic ammonia intoxication in childhood. While adults may present with severe osteoporosis, impairment of kidney function or interstitial changes in the lungs. Plasma concentrations of lysine, arginine, and ornithine are reduced, whereas urinary excretion of lysine and orotic acid are increased. The clinical features are due to hyper-ammonaemia and insufficient amounts of lysine to support protein synthesis during growth. Patients with lysinuric protein intolerance are at increased risk during pregnancy and child birth due to bleeding tendency, and pre-eclampsia.

Type I dibasic aminoaciduria has been described, though rare in occurrence. These patients have mental retardation without hyperammonaemia and protein intolerance. Type I disease involves the same transport system as that impaired in the more common type II dibasic aminoaciduria.

Treatment

Dietary protein should be restricted in conjunction with supplementation of citrulline (2 to 8 g per day), a neutral amino acid that facilitate the urea cycle when metabolised to arginine and ornithine. Carnitine supplements improve growth by sparing lysine and by enhancing fatty acid oxidation. Pulmonary disease responds to glycocorticoids.

Hartnup Disease

Hartnup disease was named after the first reported family. There is a defect in the transport of monoamino-monocarboxylic amino acid (neutral amino acids) by the intestinal mucosa and renal tubules and this leads to neutral or aromatic aminoaciduria. Alanine, serine, threonine, valine, leucine, isoleucine, phenylalanine, tyrosine, tryptophan, glutamine, asparagine, and histidine are excreted in urine in quantities 5 to 10 times normal. This is inherited as an autosomal recessive trait, and the gene has been mapped to chromosome 5p15. Homozygotes occur with a frequency of about 1 in 24,000 births. Heterozygotes exhibit no clinical or chemical abnormalities system for neutral amino acids.

Clinical manifestations

Most of the patients remain asymptomatic but rarely those who are symptomatic present with cutaneous photo sensitivity. The skin becomes rough and red after moderate exposure to the sun, and with greater exposure, pellagra like skin rash may develop. This rash may be pruritic and a chronic eczema may appear. Skin changes have been reported in affected infants as young as 10 days of age. Some patients are also characterised by variable neurologic manifestations like intermittent ataxia and unsteady or wide-based gait. Ataxia may last a few days. It often improves spontaneously. Mental development is usually normal but episodic behavioural changes in the form of irritability, emotional instability, depression have been observed. Few patients may present with short stature and atrophic glossitis. Nutritional deficiency of tryptophan results into clinical manifestations. The manifestations is episodic and related in part to metabolic demands for tryptophan. Tryptophan metabolism leads to the synthesis of niacin and nicotinamide-adenine dinucleotide and supplies about half the daily niacin needs and renal and intestinal transport defect for tryptophan leads to niacin deficiency. Only a small fraction of patients with the chemical findings of this disorder develop a pellagra-like syndrome, implying that manifestations depend on other factors in addition to the transport defect.

Diagnosis

The diagnosis of Hartnup disease should be suspected in any patient with clinical features of pellagra without a history of dietary niacin deficiency with neurologic and psychiatric manifestations which may range from attacks of cerebellar ataxia to mild emotional lability to frank delirium accompanied by exacerbations of the skin rash. Fever, sunlight, stress, and sulphonamide therapy provoke clinical relapses.

Main laboratory finding is amino aciduria, which is restricted to neutral amino acids (alanine, serine, threonine, valine, leucine, isoleucine, phenylalanine, tyrosine, tryptophan, glutamine, asparagine, and histidine) does not occur in dietary niacin deficiency. Plasma concentration of neutral amino acids are usually normal. This is quite an unexpected finding and an

explanation for it is that these amino acids are absorbed as dipeptides and the transport system for small peptides is intact in Hartnup disease.

Treatment

Treatment is directed at nicotinic acid or nicotinamide (50 to 300 mg daily) repletion and a high-protein diet.This result in favourable outcome in symptomatic patients, but because of intermittent nature of clinical presentation, the effectiveness of these treatment measures is difficult to evaluate.Tryptophan ethyl esters bypass the absorption defect and may be an option for treatment.

Substrate-Specific Defects in Amino Acid Transport

Rarely defective renal tubular reabsorption and/or impaired intestinal absorption of a single free amino acid have been reported in families. These disorders are inherited as an autosomal recessive trait.The substrate specific defects include transportation of cystine, lysine and histidine in kidney and selective malabsorption of methionine or tryptophan in intestine.Cystine defect can lead to renal calculi, lysine transport defect in kidney and intestine. This can cause seizures, mental and physical retardation.Similar defect in histidine metabolism can also cause mental retardation while tryptophan disorder can cause calcinosis and indoluria.

DISORDERS OF HEXOSE TRANSPORT

The cells use D-glucose for energy production and for many other anabolic purposes.There are two main classes of glucose transporters in humans: active Na^+-glucose cotransporters proteins (SGLT) and the facilitative glucose transporters (GLUT). Na^+-glucose cotransporters actively concentrate glucose inside intestinal and renal cells against concentration gradient, using the electrochemical potential of Na^+ as their energy source and it does not require insulin for its action. Defects in this class of transporters cause renal glycosuria (SGLT2) and intestinal glucose-galactose malabsorption (SGLT1).Facilitative glucose transporters allow glucose to enter cells along the concentration gradient.Defects in facilitative transporters cause the glucose-transporter protein syndrome (GLUT1), Fanconi-Bickel syndrome (GLUT2) and one subtype of glycogen storage disorder (GLUT 7).

Disorders of Concentrative Glucose Transporters

Renal Glycosuria is characterised by glycosuria at normal concentrations of blood glucose. The renal tubular malabsorption is specific for glucose. Unlike generalised defect of tubular disease, phosphate and amino acids are transported normally. The genetic basis is not understood. It is a benign condition, but occasionally may present with polyuria and polydipsia due to severe glycosuria.

In normal persons, glucose is reabsorbed throughout the proximal renal tubule by a sodium-dependent, phlorizin-inhibitable transport process. Reabsorptive capacity exceeds normal plasma glucose concentration.Maximal renal absorptive capacity is exceeded at a filtered load of around 18 mmol (325 mg)/minute/1.73 m^2 body surface area, which is tubular maximum for glucose (TmG). It is achieved at 10 mmol/L (200 mg/dL) of plasma glucose concentration.

Two patterns of glycosuria are recognised: type A, characterised by a reduced tubular maximum reabsorptive capacity, and type B, showing a reduced threshold for glycosuria, with normal TmG. Homozygotes with either of these recessively inherited mutations and heterozygotes with these allelic mutations present with renal glycosuria. Renal glycosuria may not be associated with impaired intestinal transport.

Glucose-Galactose malabsorption

It is characterised by profuse, watery diarrhoea in infants on milk or foods containing lactose, sucrose, glucose, or galactose. The primary defect is in sodium-hexose cotransporter in the intestinal and in renal brush border.A specific defect in intestinal absorption of glucose and galactose can be demonstrated by oral tolerance tests that produce absence of increase in plasma glucose or galactose. Active D-glucose and D-galactose transport is absent in affected children, and partial defect is present in their parents. Treatment with a glucose- and galactose-free diet leads to the resolution of symptoms in childhood. Fructose-containing or carbohydrate-free formulas are well tolerated. Although the basic transport defect is present throughout life, most patients show an improved tolerance for glucose and galactose with advancing age.

Few patients have renal glycosuria (type B renal glycosuria) at normal plasma glucose concentrations. Urinary glucose loss is not as severe as in isolated renal glycosuria.This finding suggests the presence of multiple glucose transport proteins in the kidney.In glucose-galactose malabsorption, transport of sugars in other tissues is normal, which suggests multiplicity and tissue specificity of hexose transporters.

DISORDERS OF FACILITATIVE GLUCOSE TRANSPORTERS

The influx and efflux of glucose in mammalian cells are mediated by five different facilitative glucose transporters (GLUT-1, 2, 3, 4, and 7). Mutations of gene for two of these transporters (GLUT1 and GLUT2) have been identified.Mutation in the gene encoding the ubiquitous GLUT1 transporter causes glucose-transporter protein syndrome. Patients with this disorder present with seizures, developmental delay, and microcephaly.They have normal blood glucose concentration but low glucose in their cerebrospinal fluid. GLUT1 is the predominant glucose transporter in the blood-brain barrier. This defect is expressed in other cells, such as erythrocytes and fibroblasts, but their energy requirements is less or they express additional glucose transporters.The treatment of this disorder is ketogenic diet to deliver alternative fuels to the brain.

Mutations in the GLUT2 transporter gene which is expressed mainly in liver, pancreatic β cells and in the basolateral membrane of gut and renal tubular cells have been identified in the autosomal recessive disorder Fanconi-Bickel syndrome.

Fanconi-Bickel Syndrome (due to defect in GLUT2) is characterised by proximal renal tubular dysfunction, impaired glucose and galactose utilisation which leads to accumulation of glycogen in liver and kidney.Patients present early in life with failure to thrive and polydipsia, with prominent glycosuria and aminoaciduria, rickets, fasting hypoglycemia with ketonuria, and prolonged postprandial hyperglycaemia and hyperlipidaemia. Patients typically have protuberant abdomen due to hepatomegaly and nephromegaly (because of accumulation of glycogen in hepatocytes and renal tubular cells). The prolonged post-prandial hyperglycaemia is due to decreased sugar uptake by the liver and defective insulin synthesis and

release by the pancreatic β cell. They may not develop diabetes because pancreatic β cells have alternative glucose transporters (GLUT1 and GLUT3) that can partially compensate for the absence of GLUT2 transporters.

Treatment

There is no specific treatment available for Fanconi-Bickel syndrome. Avoidance of galactose intake, replacement of the renal losses of water and electrolytes, vitamin D and diet rich in complex carbohydrates to prevent hypoglycaemia, as for patients with other glycogen storage diseases.

DEFECTIVE ANION TRANSPORT: CONGENITAL CHLORIDE DIARRHOEA (CHLORIDORRHOEA)

This is a rare, autosomal recessive disease caused by mutation in a chromosome 7 gene. The chloride/bicarbonate transport mechanism in the distal ileum and colon is defective causing severe watery diarrhoea, beginning at birth. Absence of chloride-bicarbonate ion exchange causes profound symptoms in fetus (polyhydramnios and absence of meconium). Watery diarrhoea is apparent on the first days of life. A hypokalaemic, hypochloraemic, hyponatraemic metabolic alkalosis develops with dehydration and secondary hyperaldosteronism. Faecal fluid contains an excess of chloride ion over the sum of the accompanying cations sodium and potassium(125 to 150 mEq/L). Faecal chloride concentration always exceeds 90 mmol/L when volume and serum electrolyte disturbances are corrected, and this chloridorrhoea is diagnostic. Renal chloride transport is normal. Decreased urine chloride results from the kidney's attempts to conserve salt and water. The defective gene in this condition, called *DRA* (for downregulated in adenoma), maps to chromosome 7q and encodes an anion transporter, which is expressed only in the gastrointestinal tract. A deletion of the Val 317 codon in the *DRA* gene is responsible for the Finnish form of congenital chloride diarrhoea.

Treatment consists of adequate, lifelong repletion of electrolyte and fluid. Correction of water, sodium chloride, and potassium chloride prevents growth and psychomotor retardation and the development of progressive renal damage. Treatment of hyperreninaemia and hypokalaemia with prostaglandin inhibitors reduces renal damage but does not alter intestinal symptoms or the need for chronic sodium chloride repletion. Omeprazole may decrease stool output and improve the social life of patients.

DEFECTIVE SODIUM TRANSPORT: CONGENITAL SODIUM DIARRHOEA

This is a rare syndrome caused by defect in sodium-hydrogen exchange in small intestine and colon. Similar to chloridorrhoea, patient presents with profuse watery, secretory diarrhoea from birth with history of polyhydramnios during pregnancy. But in contrast to alkalosis in chloride diarrhoea, acidosis is present here, and faecal chloride concentration is less than sodium concentration. Treatment with oral hydration fluid is effective in improving and maintaining growth.

PRIMARY HYPOMAGNESAEMIA

In this defective intestinal magnesium transport leads to severe hypomagnesaemia and even secondary hypocalcemic tetany in infancy. Other aspects of intestinal transport are normal. Treatment includes replacement of magnesium which need to continue indefinitely.

DEFECTIVE COPPER TRANSPORT: MENKES DISEASE (KINKY HAIR SYNDROME)

This is X-linked, multi-systemic disease disorder caused by defect in cellular copper transport affecting intestine as well other organs. Menkes gene is located on long arm of X-chromosome at Xq13.3. Orally ingested copper accumulates in intestine and there is defective absorption of copper. Patient presents with growth retardation, abnormal hair, cerebellar degeneration, severe vasculopathy, fractures and foetal outcome in early age. Serum level of copper and caeruloplasmin is low but copper content of cerebellum is increased. Available treatment options are few and include parental copper administration which can help few patients in avoiding neurological complications

A large number of membrane transport defects are genetically inherited. These cannot be described in this chapter but some of them are summarised in **Table 1**.

Table 1: Genetic Disorders of Membrane Transport

Class of Substance and Disorder	Substrates	Tissues Manifesting Defect	Molecular Basis	Clinical Features
Methionine malabsorption	Methionine	Jejunal mucosa	Methionine transport protein leading to Hydroxybutyricaciduria	White hair, mental retardation, convulsions, hyperpneic attacks, edema
Familial hypercholesterolaemia	Cholesterol	Fibroblasts, lymphoid lines, leukocytes	Membrane LDL-cholesterol receptor protein	Hypercholesterolaemia, tendon xanthomas, arcus corneae, coronary artery atherosclerosis
Defect in transport of long-chain fatty acids	Long-chain fatty acids	Liver	Fatty acid transporter	Nonketotic hypoglycaemia, acute liver failure
Hypouricaemia	Uric acid	Proximal renal tubule	Urate transport protein	Hypouricaemia, hyperuricosuria, hypercalciuria
Familial hypophosphatemic rickets	Inorganic phosphate	Proximal renal tubule, jejunal mucosa	Phosphate-regulator homologue to endopeptidases PHEX	Hypophosphataemia, phosphaturia, phosphatopaenic rickets/osteomalacia
Dent's syndrome, X-linked recessive hypophosphatemic rickets and nephrocalcinosis	Chloride, phosphate	Proximal renal tubule	Voltage-gated Cl^- channel CLCN5	Proteinuria, hypercalciuria, nephrocalcinosis, nephrolithiasis, rickets
Hypophosphatemic rickets with hypercalciuria	Phosphate	Renal tubule	Phosphate transporter	Hypophosphataemic rickets, hypercalciuria

Contd...

Contd...

Class of Substance and Disorder	Substrates	Tissues Manifesting Defect	Molecular Basis	Clinical Features
Bartter's syndrome	Sodium, chloride	Renal tubule	Na,K,2 ≥ Cl cotransporter, apical regulated K^+ channel, basolateral Cl^- channel	Hypochloraemic metabolic alkalosis, ATP-hypercalciuria, hyperaldosteronism
Gitelman's syndrome	Sodium, chloride	Distal convoluted tubule	Na^+/Cl^- cotransporter SLC12A3	Hypokalaemic metabolic alkalosis, hypomagnesaemia, hypocalciuria
Congenital myotonia	Chloride	Muscle	Cl^- channel CLCN1	Myotonia, muscle cramps
Pendred syndrome	Iodide, chloride	Thyroid, cochlea	Na^+-independent I^- and Cl^- transporter	Deafness, ± goiter
Cystic fibrosis	Chloride	Lung, pancreas, sweat gland	Ion channel protein	Pulmonary, pancreatic destruction
Distal renal tubular acidosis (type I gradient)	Chloride, bicarbonate	Distal renal tubule, erythrocytes	Anion exchanger SLC4A1	Hyperchloraemic acidosis, hypokalaemia, acquired nephrocalcinosis, hypercalciuria, elliptocytosis
Familial goiter	Inorganic iodide	Thyroid gland, salivary gland, gastric mucosa	Iodide transport protein	Congenital hypothyroidism (cretinism), goiter
Achondrogenesis type 1B, astelosteogenesis type 2, diatrophic dysplasia	Sulphate	Osteoblasts, chondrocytes	Sulphate transporter	Skeletal dysplasia, dwarfism, deformities
Proximal renal tubular acidosis (type II HCO_3^- wasting)	Hydrogen ion	Proximal renal tubule	Proximal tubule H^+ pump carrier protein	Hyperchloraemic acidosis, bicarbonate wasting
Distal renal tubular acidosis	Hydrogen ion	Distal nephron, cochlea	H^+ ATPase ATP6B1	Hyperchloraemic acidosis, growth retardation, sensineural deafness
Liddle's syndrome	Sodium	Collecting tubule	Epithelial Na^+ channel SCNN1 (activation)	Hypertension, hypokalaemia, metabolic alkalosis
Type I pseudohypoaldosteronism	Sodium	Collecting tubule	Epithelial Na^+ channel SCNN1 (inactivation)	Hyponatraemia, growth retardation, hyperkalaemia
Hyperkalaemic periodic paralysis, paramyotonia congenita	Sodium	Muscle	Muscle Na^+ channel a subunit SCN4A	Periodic paralysis, muscle wasting, variable myotonia
Darier disease	Calcium	Keratinocytes, muscle, brain	Sarcoplasmic Ca^{2+}-ATPase ATP2A2	Keratotic skin papules, bullous lesions, psychosis
Long QT syndrome	Potassium, sodium	Heart	Voltage-gated K^+ channels KCNQ1, KCNH2, KCNE2, Na^+ channel SCN5A	Syncope, arrhythmia, sudden death
Jervell and Lange-Nielsen syndrome	Potassium	Heart, inner ear	Voltage-gated K^+ channels KCNQ1, KCNE1	Syncope, arrhythmia, sudden death, deafness
Benign familial neonatal epilepsy	Potassium	Brain	Voltage-gated K^+ channels KCNQ2, KCNQ3	Neonatal convulsions normal development
Nephrogenic diabetes insipidus (AVP-resistant)	Water	Distal renal tubule	AVP receptor	Polyuria, polydipsia, hyposthenuria
Nephrogenic diabetes insipidus	Water	Collecting tubule	Aquaporin 2 (water channel)	Polyuria, dehydration, hyposthenuria
Juvenile pernicious anaemia	Cobalamin (vitamin B_{12})	Ileal mucosa	Receptor for intrinsic factor-cobalamin complex	Megaloblastic anaemia
Folate malabsorption	Folic acid	Small bowel	Folate transport protein	Megaloblastic anaemia
Rogers' syndrome	Thiamine	Ubiquitous	Thiamine transporter SLC19A2	Megaloblastic anaemia, diabetes, deafness
Glycogen storage disease type Ib	D-Glucose	Liver microsomes	Glucose-6-phosphate transporter	Hypoglycaemia, neutropaenia, glycogen storage disease

18.10 Amyloidosis

Manisha Sahay

INTRODUCTION

Amyloidosis refers to the extracellular tissue deposition of protein fibrils. Types of amyloidosis are shown in **Table 1**.

Most common are primary or AL Amyloid and Secondary or AA amyloid. The ratio of AA to AL amyloid is 2:1.

Table 1: Classification of Amyloidosis

Type	Protein	Organs	Clinical Setting
Localised			
ACal	Calcitonin	Thyroid	Medullary carcinoma of thyroid
AIAPP	Amylin	Pancreas	Type 2 diabetes mellitus, Insulinoma
ANF	Atrial natriuetic factor	Heart	Isolated atrial amyloid
Aβ	Aβ protein precursor	Brain	Alzheimer's disease, Down's syndrome
APro	Prolactin	Pituitary	Prolactinoma
APrP	Prion protein	Brain	Scrapie, Creutzfeldt-Jakob Disease (CJD)
Senile			
ATTR	Transthyretin (wild type)	Heart	Senile cardiac amyloid
Systemic			
AA	Serum amyloid A	Kidneys liver, spleen	Inflammatory disease, infection, malignancy
AL	Light chain	Kidneys, heart, nerves	Multiple myeloma
AH	Heavy chain		Other plasma cell conditions
$A\beta_2M$	β_2 Microglobulin	Periarticular, ligaments	Long-term dialysis
Inherited			
AA	Serum amyloid A	Kidneys	FMF, Muckle-Wells, TRAPS
ATTR	Transthyretin (prealbumin)	Nerves, heart	Familial amyloid polyneuropathy
A Cys	Cystatin C	Cerebral arteries	Hereditary cerebral haemorrhage with amyloid (Icelandic)
Aβ	Aβ precursor protein	Cerebral arteries	Hereditary cerebral haemorrhage with amyloid (Dutch)
AGel	Gelsolin	Eyes, cranial, and peripheral nerves	Finnish type familial amyloidosis
AFib	Fibrinogen Aα	Kidneys, liver	Hereditary non-neuropathic amyloidosis
AApoAI	Apolipoprotein AI	Kidneys, liver	Hereditary neuropathic/ neuropathic
AApoAII	Apolipoprotein AII	Kidneys	Hereditary non-neuropathic amyloidosis
ALys	Lysozyme	Kidneys, liver	Hereditary non-neuropathic amyloidosis

FMF = Familial Mediterranean fever; TRAPS = Tumour necrosis factor receptor antagonist periodic syndrome.

Primary/AL Amyloidosis

All forms of systemic amyloidosis in which the fibrils are derived from monoclonal light chains or their fragments, e.g. multiple myeloma, are considered primary amyloidosis.

AA/Secondary/Reactive Amyloidosis

This occurs secondary to various diseases (**Table 2**). In the developing world, AA amyloidosis is common due to prevalence of chronic infections. The commonest cause being tuberculosis. In 5% cases, underlying cause remains obscure. Fibrils are derived from serum amyloid associated protein (SAAP) which increases in inflammation.

Table 2: Conditions Associated with AA Amyloidosis

Chronic inflammatory diseases
- Rheumatoid arthritis and juvenile chronic arthritis
- Ankylosing spondylitis
- Psoriatic arthritis
- Reiter's syndrome
- Behçet's syndrome
- Adult Still's disease
- Crohn's disease

Chronic infections
- Tuberculosis
- Leprosy
- Osteomyelitis
- Bronchiectasis
- Decubitus ulcers

Malignancies
- Hodgkin's lymphoma
- Castleman's disease
- Renal cell carcinoma
- Hairy cell leukaemia

Inherited
- Familial Mediterranean fever
- Muckle-Wells syndrome

Dialysis-Related Amyloidosis (DRA)

DRA is a disorder caused by tissue deposition of β2 microglobulin which is a component of human leucocyte antigen.

Hereditary amyloidosis is dominant disorder (**Table 3**).

Table 3: Hereditary Amyloidosis

Protein	Clinical Picture
Transthyretin	Peripheral and autonomic neuropathy + varying degrees of visceral involvement
Gelsolin	Cranial neuropathy,renal Corneal lattice dystrophy Distal peripheral neuropathy
Apolipoprotein AI	Renal, Gastric ulcers, Polyneuropathy
Apolipoprotein AII	Renal
Lysozyme	Renal
Fibrinogen Aα	Renal and hepatomegaly

Organ-specific Amyloid

Amyloid deposition can be isolated to a single organ, e.g.cerebral amyloidosis (**Table 4**).

Table 4: Cerebral Amyloidosis

Syndrome	Precursor Protein
Alzheimer's disease	
Sporadic	Aβ peptide
Familial	Aβ peptide
Associated with Down's syndrome	Aβ peptide
Cerebral amyloid angiopathy	Aβ peptide
Hereditary cerebral haemorrhage with amyloidosis	
Dutch	Aβ peptide
Icelandic	Cystatin C
Cerebral amyloid with Prion's disease	
Gerstmann-Straussler-Scheinker disease	Prion peptide
Prion protein cerebral amyloid angiopathy	
Fatal familial insomnia	
Kuru	
Cruetzfeldt-Jakob's disease	

Age-related (Senile) Systemic Amyloidosis

Deposition of otherwise normal (wild-type) transthyretin in myocardium and other sites has been referred to as systemic senile amyloidosis (SSA).

Familial Mediterranean Fever (FMF)

FMF is common in Jews.The gene is recessive and is located on the short arm of chromosome 16 (**Table 5**).

Table 5: Comparison of Hereditary AA Amyloidosis

	FMF	Muckle-Wells	TRAPS
Race	Jews, Armenians, Turks	North European	North European
Inheritance	Autosomal recessive	Autosomal dominant	Autosomal dominant
Chromosome	16	1	12
Gene/protein	MEFV*/ marenostrin	Cryopyrin	TNF** receptor
Duration of fever	2-3 days		3 days to 3 weeks
Clinical	Abdominal pain,	Urticaria,	Rash, features
arthralgia,	arthralgia,	abdominal	
	pleurisy,	progressive	pain,
rash	deafness	arthralgia,	
			conjunctivitis
Amyloid	Very variable	30%	25%
Treatment	Colchicine	None known	Prednisolone, etanercept

**MEFV = Mediterranean fever; **TNF = Tumour necrosis factor.*

PATHOGENESIS OF AMYLOIDOSIS

All amyloids have a common conformation of anti-parallel β-sheet when studied by radiographic diffraction. This is responsible for the characteristic staining with Congo red.

1. *Proteolysis:* In AL amyloid light chains are proteolysed. In AA amyloid AA protein is a fragment of the circulating acute phase reactant SAA which is synthesised by hepatocytes, macrophages and regulated by cytokines. SAA is an apolipoprotein and is chemotactic.
2. *Increased availability* due to decreased clearance of β2 microglobulin in renal failure and dialysis leads to tissue deposition (DRA).
3. *Mutation:* In all the familial forms of amyloidosis, several mutations can occur that renders the protein amyloidogenic.

Other Constituents

Amyloid deposits contain several other components e.g., serum amyloid P (SAP), collagen IV, laminin, fibronectin, sulphated glycosaminoglycans (heparin sulphate glycoprotein) and apolipoprotein E. SAP is a normal serum glycoprotein produced in the liver.

CLINICAL MANIFESTATIONS

Skin and cardiac involvement, macroglossia, and peripheral neuropathy are rare in AA amyloidosis. **Figure 1** shows rare tongue involvement in primary amyloidosis.

Figure 1: Serratoglossia in a case of primary amyloidosis.
Courtesy: Dr Pangtey GS, LHMC, New Delhi.

Renal Disease

Renal involvement is the most common and serious problem seen in 80% in AA amyloid. The majority of patients have glomerular deposits with proteinuria, microscopic haematuria and casts. Vascular deposits result in chronic renal insufficiency. Tubular deposits cause syndromes of renal tubular acidosis or nephrogenic diabetes insipidus. The kidney size may be increased or normal. Chronic kidney disease is an important cause of death.

Non-Renal Findings

Hypofunction of endocrine glands and cardiac involvement

Hypofunction of endocrine glands can lead to endocrine deficiency syndrome and can result in cardiac involvement. Cardiac manifestations include restrictive cardiomyopathy,

systolic or diastolic dysfunction, heart failure, arrhythmia, heart block or infarction due to accumulation of amyloid in the coronary arteries.

Gastrointestinal disease

Hepatomegaly, splenomegaly, functional hyposplenism, gastroparesis, constipation, bacterial overgrowth, malabsorption and intestinal pseudo-obstruction may be seen.

Neurologic abnormalities

Mixed sensory and motor peripheral neuropathy and/or autonomic neuropathy is a prominent feature in heritable and AL amyloidoses. Central nervous system involvement is unusual with AL and AA but is common in hereditary amyloidoses.

Musculoskeletal disease

Amyloid infiltration of muscles causes pseudohypertrophy and macroglossia (AL amyloid). Arthropathy occurs due to amyloid deposition in joints e.g. "shoulder pad" sign in AL amyloid and DRA. Spondyloarthropathy, carpal tunnel syndrome, cauda equina compression and cystic bone lesions may be seen in DRA.

Haematologic abnormalities

Amyloidosis may be associated with a bleeding diathesis due to factor X deficiency , decreased synthesis of coagulation factors in patients with advanced liver disease, amyloid infiltration of blood vessels or acquired von Willebrand disease. Anaemia occurs due to renal failure or multiple myeloma and thrombo-cytopaenia due to splenomegaly. *Pulmonary infiltration* may be seen.

Skin: waxy thickening, easy bruising, subcutaneous nodules and periorbital purpura (raccoon eyes) are characteristic of AL amyloidosis (**Figure 2**).

Figure 2: Smooth and waxy papules over eyelid and raccoon eyes in case of primary amyloidosis.
Courtesy: Dr Pangtey GS, LHMC, New Delhi.

FMF: Presents with attacks of fever, abdominal pain, arthritis of large leg joints and serositis. The attacks last 48 to 72 hours.

DIAGNOSIS

Urine examination

In AL amyloid due to multiple myeloma, the dipstick which primarily detects albumin is negative while sulphosalicylic acid test for protein is positive (Bence Jones proteinuria).

Complete blood picture

It may show plasma cells. High ESR may be seen in myeloma and secondary amyloid.

Biochemistry

Serum calcium may be high and alkaline phosphate may be normal in myeloma.

Imaging

X-rays show lytic bone lesions in myeloma. In DRA radiolucent lesions, or bone cysts are seen and tend to enlarge and increase in number over time.

Ultrasonography is useful in estimating renal size.

ECHO may show speckled appearance of the myocardium.

CT and MRI are useful for detection of small lesions and for lesions of the nonaxial skeleton.

Biopsy

The diagnosis of amyloidosis should be confirmed by tissue biopsy. The abdominal subcutaneous fat is sensitive site for all systemic amyloidosis except DRA. Aspiration biopsy of subcutaneous fat with Congo red staining and examination using polarizing microscopy has a sensitivity of 57% to 85% and a specificity of 92% to 100% for AL or AA amyloidosis. If fat aspiration is negative then rectal biopsy (sensitivity – 84%), bone marrow biopsy (sensitivity – 50% to 55%), or skin biopsy (50%) or biopsy of the involved organ is done.

Light microscopy reveals diffuse extracellular deposition of amorphous pink, hyaline material (haematoxylin and eosin). These nodules stain weekly with periodic acid Schiff's (PAS) and methenamine silver stain and bind Congo red (leading to green birefringence under polarized light) and thioflavine T (producing an intense yellow-green fluorescence. Incubation with permanganate causes the fibrils to lose their affinity for Congo red in secondary, but not in primary amyloidosis.

Immunofluorescence is negative for immunoglobulins in AA amyloidosis, but is positive for monoclonal lambda or kappa light chains in AL amyloid. False negatives with immuno-fluorescence occur in 25% to 3%. Here immunoperoxidase can be helpful.

Electron microscopy fibrils are 8 to 10 nm in width, straight and unbranching and randomly orientated with pentagonal amyloid P component.

Amino acid sequencing or mass spectroscopy is the most straightforward approach to characterising the type of amyloid.

SAP scanning: Scintigraphy with technetium or radioiodine-labeled serum amyloid P component (SAP) can identify distribution of amyloid.

Paraproteins: Serum and urine protein electrophoresis followed by immunofixation is recommended. Quantitation of serum free light chains is suggested for AL patients who do not have monoclonal proteins by immunofixation.

Bone marrow biopsy demonstrates a monoclonal population of plasma cells.

Beta2-microglobulin levels: In DRA, plasma β2-micro-globulin concentration may be 30 to 50 mg/L(normal- 0.8 to 3.0 mg/L).

Chromosomal changes: Various chromosomal abnormalities may be found.

Natural History

The long-term prognosis of untreated amyloidosis is poor with median survival 4 and 31 months from the time of diagnosis with a 5-year survival of 43%.

TREATMENT

Specific Treatment

AL amyloidosis

Colchicine marginally improves survival.

Cytotoxic therapy: Regimes include prednisolone and melphalan or vincristine, carmustine, melphalan, cyclophos-phamide and prednisolone (VBMCP). Intensive chemotherapy with stem cell transplantation may be more effective. Interferon has been used in some.

Thalidomide: has been used with some success in myeloma. Its use is being explored in AL amyloid.

AA amyloidosis

Current treatment strategy in AA amyloidosis is to eliminate the supply of the precursor protein (SAA) by suppressing the acute phase response.

1. Surgical resection of the underlying cause of amyloidosis e.g. amputation of limbs affected by osteomyelitis is useful.
2. Medical:
   (a) Alkylating agents are effective for chronic rheumatological conditions, e.g. chlorambucil, cyclophosphamide with prednisolone
   (b) In RA podophylotoxin, a microtubule antagonist, along with azathioprine, chlorambucil, and cyclophosphamide may be useful.
   (c) Dimethlysulfoxide (DMSO) has been shown to be effective in some.
   (d) TNF-α antagonists offer a new approach to the management.

DRA

Increased clearance of β2-microglobulin by prolonged slow dialysis with noncuprophane high flux dialyzers should be utilised in DRA. The pathogenic effects of glycosylated beta2-microglobulin may be prevented by aminoguanidine that inhibits advanced glycation.

Hereditary amyloidoses

Liver transplantation is curative. Patients who present with advanced end-organ damage may benefit from combined hepatorenal or hepatocardiac transplantation

FMF

Colchicine has proved to be remarkably effective.

Drugs which reduce fibril formation

For example, Odo-deoxydoxorubicin (I-DOX) and Carboxy-pyrrolidin-hexanoyl-pyrrolidone-carboxylic acid (CPHPC).

Renal replacement therapy for amyloidosis

The survival on dialysis and after transplant is poorer as compared to other patients.

18.11 Disorders of Adipose Tissue and Obesity

Shashank R Joshi

INTRODUCTION

Obesity is a chronic and increasingly common disease globally characterised by excess body fat. It develops gradually and often persists throughout life. As a preventable cause of death, obesity is second only to smoking. Like any other chronic condition, such as diabetes or hypertension, obesity worsens when strategies applied for weight reduction are withdrawn. If it is not treated for the duration of the patient's life, obesity emerges as a potent co-morbid risk factor. Obesity has been described in *Charak Samhita*: *(Sutrasthana: Ch XXI v. 3-4)* in the context of body phenotypes with obese phenotype having the following 8 defects: shortening of lifespan, hampered movement, difficulty in sexual intercourse, debility, foul smell, over sweating, excessive much hunger, and excessive thirst. The rapid spread of urbanisation and industrialisation and dramatic lifestyle changes that accompany these trends has led to the pandemic of obesity, even in developing countries. Obesity has serious public health implications. Excess weight has been associated with mortality and morbidity.

PREVALENCE

Obesity is emerging as an important health problem in India. It is estimated that 22 million Indians are obese, especially abdominally obese. Obesity is the primary driver of non-communicable diseases like diabetes, cardiovascular diseases, disabilities like osteoarthritis and even cancer.

DEFINITION AND ASSESSMENT

In the past, visual inspection of a patient gave a subjective but fairly accurate estimate of the degree of obesity. Obesity is easily diagnosed using what has been called the eyeball test. 'If a person looks fat, the person is fat'. Presently, there are three commonly used objective methods of estimating obesity in clinical practice: (i) body mass index (BMI), (ii) waist-to-hip ratio (WHR), and waist circumference (WC) and (iii) fat distribution. The typical Asian Indian population has higher proportion of fat in their body composition which is now called the "thin, fat Indian" or the Y-Y paradox which illustrates that compared to white Caucasian and African Indians have more body fat for a given BMI. Due to this the BMI, WC, WHR norms for Asian Indian population have been re-worked out.

Body Mass Index

In 1998, the US National Heart, Lung and Blood Institute established guidelines to define 'overweight' and 'obesity' and now Indian guidelines have modified these values (**Tables 1 and 2**). The parameter used is BMI (also called Quetelet Index) and is calculated using the formula:

$$\text{BMI} = \frac{\text{Weight (kg)}}{[\text{Height (m)}]^2} = \text{kg/m}^2$$

Table 1: Classification of Overweight and Obesity by Body Mass Index (BMI) for Asian Indians

	Obesity Class	BMI (kg/m²)
Underweight		<18.5
Normal		18.5 to 22.9
Overweight		23.0 to 24.9
Obesity	I	25.0 to 29.9
	II	30.0 to 34.9
Extreme obesity (Moribund obesity)	III	≥35

Table 2: BMI cut-offs for Asian Indians. *According to WHO and IOTF guidelines

Body mass index
Overweight: 23 kg/m² (as opposed to 25*)
Obese: 25 kg/m² (as opposed to 30*)
Waist circumference
Measurement method to be clearly mentioned
Action level 1: 78 cm (M), 72 cm (F), to be further reached
Action level 2: 90 cm (M), 80 cm (F), accepted
Waist-to-hip ratio
0.88 (men), 0.80 (women)
This measure of abdominal obesity could be erroneous but some studies have shown it to closely correlate to coronary heart disease

** Reproduced with permission from: J Assoc Physicians India 2009; 57: 163-70.*

However, the drawback of the BMI method is that it does not account for weight distribution and lean body mass. Also, very muscular or very short individuals may be classified as obese when they are not.

Waist-to-Hip Ratio and Waist Circumference

The WHR provides information about the distribution of body fat. The desired WHR for men and women is less than 1.0 and 0.8, respectively. The waist circumference cut-offs for Indians are more than 80 cm for women and more than 90 cm for men.

Body Fat Distribution (Fat Phenotypes)

On the basis of distribution of body fat, obesity may be classified into android obesity and gynoid obesity. In android obesity, fat is deposited in the abdomen (above the waist i.e. apple-shaped bodies). Android obesity is also called as abdominal obesity or central obesity. In gynoid obesity, fat is collected on the hips and buttocks (below the waist or gluteo-femoral, i.e. pear-shaped bodies). Android obesity is associated with an increased risk of metabolic complications, such as coronary heart disease, diabetes mellitus, hypertension and dyslipidaemia while gynoid obesity makes the person more prone to mechanical disorders, such as varicose veins and disorders of the joints. Since men typically carry excess weight in the upper body and women in the lower body, men rather than women, should be targeted for weight reduction.

Waist circumference correlates well with abdominal fat content. In men, there is an increased risk if the waist circumference is 85 cm or more and substantial risk if it is 90 cm or more and for women, the figures are 80 cm or more, respectively.

Aetiology

Obesity is a multifactorial condition. The factors playing a role in eating and weight control include: genetic, cultural, socio-economic, behavioural, and situational. Metabolic, Physiological and now even Viral (adenovirus). Mostly obesity is primary, that is, no obvious cause exists other than an imbalance in energy intake and energy expenditure. When energy expenditure is less than energy intake, there will be weight gain. Other causes of obesity (though not common) include genetic alterations, endocrine diseases (including Cushing's syndrome, hypothyroidism and hypogonadism), drugs and neurological disorders. The endocrinopathies associated with obesity are Cushing's syndrome, hypothyroidism, insulinoma, craniopharyngioma, Turner's syndrome, male hypogonadism and polycystic ovarian syndrome. The genetic syndromes associated with obesity are Lawrence–Moon-Biedl (LMB), Prader-Willi, Alstrom, Carpenter, Cohen, Beckwith Wiedemann. The common medications which cause weight gain are given in **Table 3**.

Table 3: Common Medications Causing Weight Gain

Psychotropic medications
Tricyclic antidepressants
Monoamine oxidase inhibitors
Specific SSRIs
Atypical antipsychotics
Lithium
Specific anticonvulsants
β-adrenergic receptor blockers
Diabetic medications
Insulin
Sulphonylureas
Thiazolidinediones
Highly active antiretroviral therapy
Tamoxifen
Steroid Hormones
Glucocorticoids
Progestational steroids

Energy Equation in Obesity

To maintain a stable body weight, energy intake must be balanced by an equivalent amount of energy expenditure, as shown in the following equation:

$$\text{E-in} - \text{E-out} = \text{E-stored}$$

where, E-in represents energy intake, E-out represents energy expenditure, E-stored represents energy stored in the body.

Energy expenditure (E-out) involves several factors as shown in the following equation:

$$\text{E-out} = \text{RMR} + \text{EE-ACT} + \text{TEF}$$

where, RMR is the resting metabolic rate, EE-ACT is the energy expenditure associated with physical activity, TEF is the thermic effect of food.

The third component of energy expenditure is the thermic effect of food, which represents the energy expended in digesting, absorbing, interconverting, and storing ingested nutrients. Overall, the magnitude of the thermic effect of food is small (about 6% to 10% of total ingested energy). Both the amount and composition of food can affect the thermic effect of food. The energy regulation is controlled by the hypothalamic nuclei, viz. lateral hypothalamus controlling hunger and the ventromedial nuclei satiety (**Figure 1**).

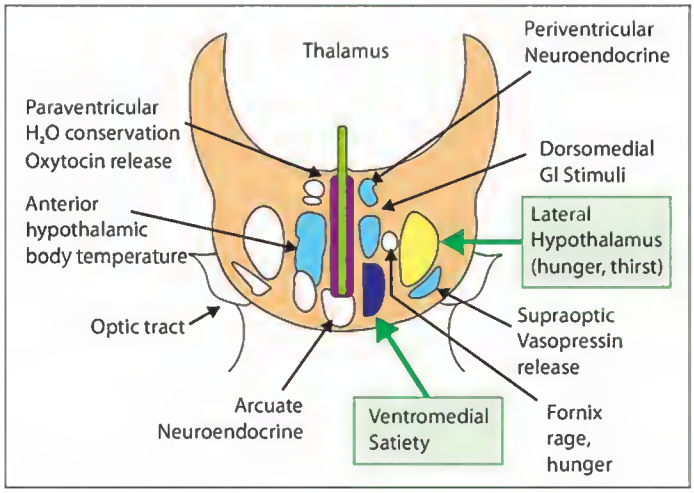

Figure 1: Role of hypothalamus in mediation of hunger and satiety.

GI = Gastrointestinal.

Goals of Weight Loss and Management

The overall goals of weight loss management are: to prevent further weight gain, to lose weight to achieve a realistic target BMI and to maintain a lower body weight over the long term (**Figure 2**). It is important that a realistic BMI rather than an ideal BMI should be aimed at in any weight loss programme. The initial goal of weight loss therapy is to reduce body weight by approximately 10% from baseline. If this goal is achieved, further weight loss can be attempted. A reasonable time period for a 10% reduction in body weight is 6 months of therapy. Not only are such reductions achievable, but importantly, modest losses of 5% to 10% of body weight has been shown to reduce health risks, such as hyperlipidaemia, hypertension and insulin resistance.

Modest reductions (5% to 10%) in weight and weight maintenance should be emphasised in any weight loss programme.

Strategies for Weight Loss and Weight Maintenance

Dietary therapy

The diet should be nutritionally adequate. It must be tailored to a person's tastes and habits. It should create a deficit of 500 to 1000 kcal per day. The fat content should be 30% or less of total calories. Emphasis should be on greater intake of fruits, vegetables and foods high in fiber. All crash diets for a few days or weeks are ineffective and are even harmful in long run. Satiety index is now used to frame modern weight loss diets. Sateity index is defined as a quantification of the duration of hunger suppression by a given amount of food (containing 1000 kJ), plus the amount voluntarily eaten when appetite returns. Protein is most satiating, followed by carbohydrates. Fat is poor at switching off appetite and very easy to store.

Exercise and physical activity

Sustained physical activity is most helpful in the prevention of weight regain. Most global guidelines recommend that adults

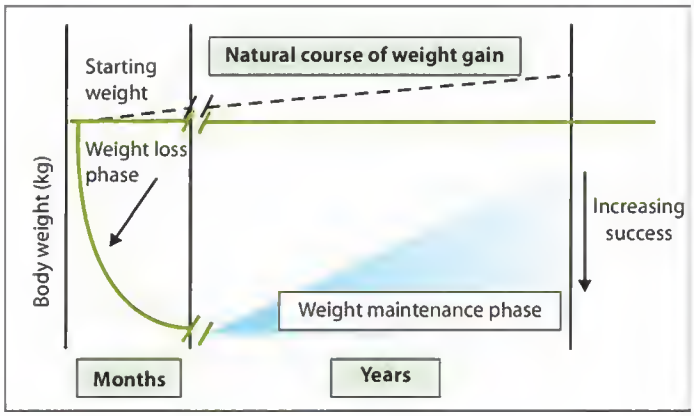

Figure 2: What is success in weight management?

participate in at least 30 minutes of moderate-intensity physical activity on most, and preferably all, days of the week. Exercise should be initiated slowly, and the intensity should be increased gradually. The patient can start by walking 30 minutes for 3 days a week and can build to 45 minutes of more intense walking for at least 5 days a week. Exercise can be done all at one time or intermittently over the day. However, as Asian Indians have sarcopaenia and excess fat, the Indian guidelines for physical activity have been modified recently.

The Indian guidelines for physical activity are as follows: 'Physical activity is defined as any activity leading to calorie consumption'. Physical activity reduces risk for cardiovascular diseases, diabetes and other disabilities associated with obesity. Current recommendations on physical activity are being made to change the mindset of Indians so as to make them think of movement as an opportunity and not as an inconvenience. Action is needed at the individual, community and societal level to help Indians become more physically active. Work related activity should be encouraged wherever possible. Brisk walking is the preferred initial mode of exercise and does not require any special training or equipment. Brisk walking is defined as walking at an intensity wherein an individual finds speaking difficult but not impossible. The physical activity can be accumulated throughout the day in blocks as short as 10 minutes. Physical activity should be increased gradually over period of time. Dynamic yoga should be encouraged. Children should undertake at least 60 minutes of outdoor physical activity daily. Screen time (TV Television or Computer) should be less than 2 hours a day.

There is a dose-response relationship between physical activity and health, greater benefit is derived by exceeding minimum recommendations. For additional and more extensive health benefits, adults can increase their aerobic physical activity to 300 minutes (5 hours) a week of moderate-intensity, or 150 minutes a week of vigorous-intensity aerobic physical activity. Aerobic activity is a kind of physical activity in which the body's large muscles move in a rhythmic manner for a sustained period of time. Muscle strengthening activity causes the body's muscles to work or hold against an applied force or weight. Moderate physical activity are activities which lead to caloric consumption three to six times higher than basal levels (3 to 6 METs). Vigorous physical activity are activities which lead to caloric consumption more than six times higher than basal levels (>6 METs).

Behavioural therapy

Behavioural therapy forms the cornerstone of any weight loss programme. This includes food intake diaries wherein the patient records not only what and how much was eaten, but also where, with whom, how, their feelings are involved and their degree of hunger. These diaries are analysed periodically, and new modes of eating can be suggested, including not eating between meals, eating only three times a day, watching the portions of food eaten, and eating slowly with concentration. The situations that trigger eating can be avoided or controlled. Behavioural therapy is usually done in groups, with dialogue between the trained group leader (psychologist, nutritionist, physician), the other group members and the patient.

Drug therapy

Pharmacotherapy must be used in conjunction with diet and physical activity to achieve and maintain a realistic degree of weight loss. This is merely an adjuvant and most drugs are now banned except orlistat. Drug therapy should be considered for patients with a BMI greater than 27 kg/m^2 and associated obesity-related complications (i.e. hypertension, coronary heart disease, hyperlipidaemia, diabetes and sleep apnoea) or for those with a BMI greater than 30 kg/m^2.

The only approved drug for obesity is now orlistat which is a gastrointestinal lipase inhibitor (**Figure 3**). **Table 4** discusses the dosage, precautions, contraindications and side effects of the orlistat.

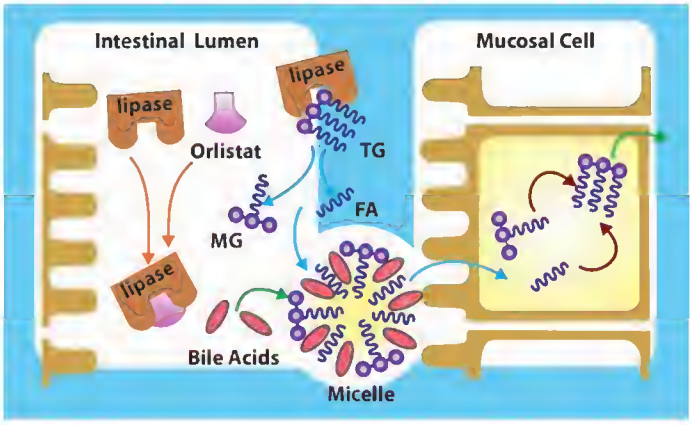

Figure 3: Orlistat prevents fat digestion and absorption by binding gastrointestinal lipases.

TG = Triglyceride; MG = Monoglyceride; FA = Fatty acid.

All other drugs which were available for obesity had or have been banned or have restricted use. Most recently sibutramine and rimonobant both have been withdrawn due to excess cardiovascular mortality and higher suicides, respectively. All the old appetite suppressants like adrenergic agents (e.g. amphetamine, methamphetamine, phenylpropanol amine, phentermine) as well as serotonergic agents (e.g. fenfluramine, dexfenfluramine, sibutramine) and thermogenic agents (e.g. ephedrine, caffeine) are all banned as they cause carcinoid related valvular heart defects and primary pulmonary hypertension. All forms of natural or alternative therapies are either hazardous, harmful or non-evident based with some questionable short-term data. The role of bariatric surgery is only restricted to morbid obesity with a BMI above 40 kg/m^2 and is currently experimental for all other indications. Surgery has no randomised controlled trials as well as long-term

evidence beyond two years and is only reserved for the severely obese morbid obese individuals. The Indian consensus on all therapies is given in **Table 5**.

Excess weight is definitely unattractive, but more importantly, it is a serious health hazard.

Table 4: Available Drug Options for Therapy: Precautions, Contraindications and Side effects

Drug	Class	Dose
Orlistat	Lipase inhibitor (Inhibits lipases, necessary for absorption of body fat)	60 mg or120 mg three times a day
Precautions		Should not be co-administered with cyclosporine
		Reduces absorption of fat-soluble vitamins. Hence, vitamin supplementation is recommended
		May increase levels of urinary oxalate. Hence it should be given with caution to patients with history of hyper-oxaluria or calcium oxalate nephrolithiasis
Contraindications		Hypersensitivity, chronic malabsorption syndrome or cholestasis
Side effects		Flatus with discharge, oily spotting, faecal urgency, fatty stools, faecal incontinence and increased defecation. These side effects increase when orlistat is taken along with a high fat meal.

Table 5: Obesity Treatment According to Body Mass Index

International (BMI)	25 to 26.9	27 to 29.9	30 to 34.9	35 to 39.9	>40
Asian Indians (BMI)	23+	25+	27+	32.5+	37.5+
Diet, Exercise, Behaviour	+	+	+	+	+
Pharmacotherapy*		With co-morbidities	+	+	+
Basic Surgery				With co-morbidities	+

*Can also be applied if waist circumference is 10 more than normal.
Reproduced with permission from: J Assoc Physicians India. 2009 Feb; 57: 163-70

CONCLUSION

Obesity is steeply increasing in India. Primary reasons are imbalanced foods and physical inactivity. Asian Indians have more body fat, more intra-abdominal and truncal subcutaneous fat and low muscle mass than white Caucasians; all conducive to the development of type 2 diabetes and cardiovascular disease. Morbidities occur at lower levels of BMI and WC in Asian Indians. Revised guidelines of BMI and WC mean that additional 15% additional population would be diagnosed as overweight/obese. More aggressive and early intervention according to revised guidelines will result in prevention of diabetes and reduction of epidemics of diabetes and CVD in Asian Indians.

18.12 Metabolic Syndrome

Anoop Misra

INTRODUCTION

Type 2 diabetes mellitus (T2DM) and coronary heart disease (CHD) are important non-communicable diseases (NCDs) in developed, as well as developing countries. Asian Indians have an unusually high predisposition to develop both these NCDs. During the previous three decades, the prevalence of T2DM has doubled in India. Insulin resistance and clustering of other proatherogenic factors, which are frequently seen in Asian Indians, may be principal contributory factors for high prevalence of T2DM.

DEMOGRAPHIC, NUTRITIONAL AND LIFESTYLE TRANSITION IN INDIA

Important demographic and economic changes are occurring in South Asia. The life expectancy and the percentage of the elderly population have increased. Increasing migration from villages to cities, urbanisation and mechanisation have increased. All these factors have brought forth adverse lifestyle changes, such as nutritional imbalance, physical inactivity, stress, and increased consumption of alcohol and tobacco, leading to obesity, insulin resistance and metabolic syndrome. A complex array of factors leads to the metabolic syndrome in Asian Indians (**Table 1**).

Insulin Resistance and the Metabolic Syndrome: Epidemiological Data

Inordinate high prevalence of cardiovascular risk factors, their clustering, and high mortality due to CHD in South Asians was initially reported from UK in 1980s. Particularly abdominal obesity, hyperinsulinaemia and dyslipidaemia in South Asians were significantly more than British Caucasians. In particular, low HDL-C levels and hypertriglyceridaemia were prevalent in both genders and abdominal obesity was particularly prevalent in women. Overall, prevalence of the metabolic syndrome in migrant South Asians varies from 20% to 32% (**Table 1**).

Table 1: Associations of Insulin Resistance and Other Cardiovascular Risk Factors in South Asians

Factors With Evidence of Positive Association	Factors With Weak/No Evidence of Association
Excess body fat	C-reactive protein
Abdominal obesity	Intramyocellular triglycerides
High truncal subcutaneous fat	Leptin
Low birth weight	
High levels of procoagulant factors	

Prevalence of the metabolic syndrome as defined by the National Cholesterol Education Programme, Adult Treatment Panel III (NCEP, ATP III) and other criteria indicates ranges from ~11% to ~41% in India. While these studies show high prevalence of the metabolic syndrome in Asian Indians living in India, truly representative data from all regions of India are not available.

Definitions of the Metabolic Syndrome

The NCEP, ATP III and International Diabetes Federation (IDF) definitions of the metabolic syndrome is based on simple clinical and biochemical parameters, which could be measured in any clinic or a simple laboratory. Other available definitions of the metabolic syndrome include measures which are expensive and difficult to analyse; fasting hyperinsulinaemia, microalbuminuria etc.

The metabolic syndrome is mostly defined by modified criteria; central obesity (defined as waist circumference (WC) ≥90 cm for males and ≥80 cm for females, raised triglyceride (TG) levels: ≥150 mg/dL or on specific treatment for this lipid abnormality; reduced high density lipoprotein (HDL): less than 40 mg/dL in males and less than 50 mg/dL in females or on specific treatment for this lipid abnormality; raised blood pressure (BP): systolic BP ≥130 mm Hg or diastolic BP ≥85 mm Hg or on treatment of previously diagnosed hypertension; and raised fasting plasma glucose (FPG) ≥100 mg/dL or previously diagnosed diabetes. Three out of five criteria have to be present to define the metabolic syndrome.

Body Fat Distribution of South Asians: Relationship with Insulin Resistance and Other Cardiovascular Risk Factors

Excess body fat

Several distinctive features of body composition of South Asians have been recorded. Most investigators agree that South Asians have high percentage of body fat. For example; despite lower average body mass index (BMI) value, the migrant Asian Indians have higher percentage of body fat as compared to white Caucasians and Blacks.

Abdominal obesity

High prevalence of abdominal obesity is particularly the characteristic of the South Asians and uniformly recorded by several investigators. Abdominal adiposity has also been reported in those with a BMI less than 25 kg/m^2. Further, although the average WC in South Asians appears to be lower, abdominal adiposity is significantly more than the white Caucasians.

Truncal subcutaneous fat

A particularly distinctive body composition feature seen in South Asians is thick subcutaneous adipose tissue as highlighted by the investigators who used skinfold measurements in their investigations.

Other Insulin Resistance-associated Factors in South Asians (**Figure 1**)

High procoagulant tendency (high levels of plasminogen activator inhibitor-1, fibrinogen etc) has been demonstrated in South Asians with insulin resistance and other cardiovascular diseases. Low adiponectin levels have been reported in children, as well as in adults with insulin resistance and metabolic syndrome. Other associations include high levels of high-sensitivity C-reactive protein and pro-inflammatory cytokines (tumour necrosis factor-α and interleukin-6), impaired flow-mediated, endothelium-dependent dilatation, polycystic ovarian syndrome, high levels of non-esterified fatty acids and high oxidative stress.

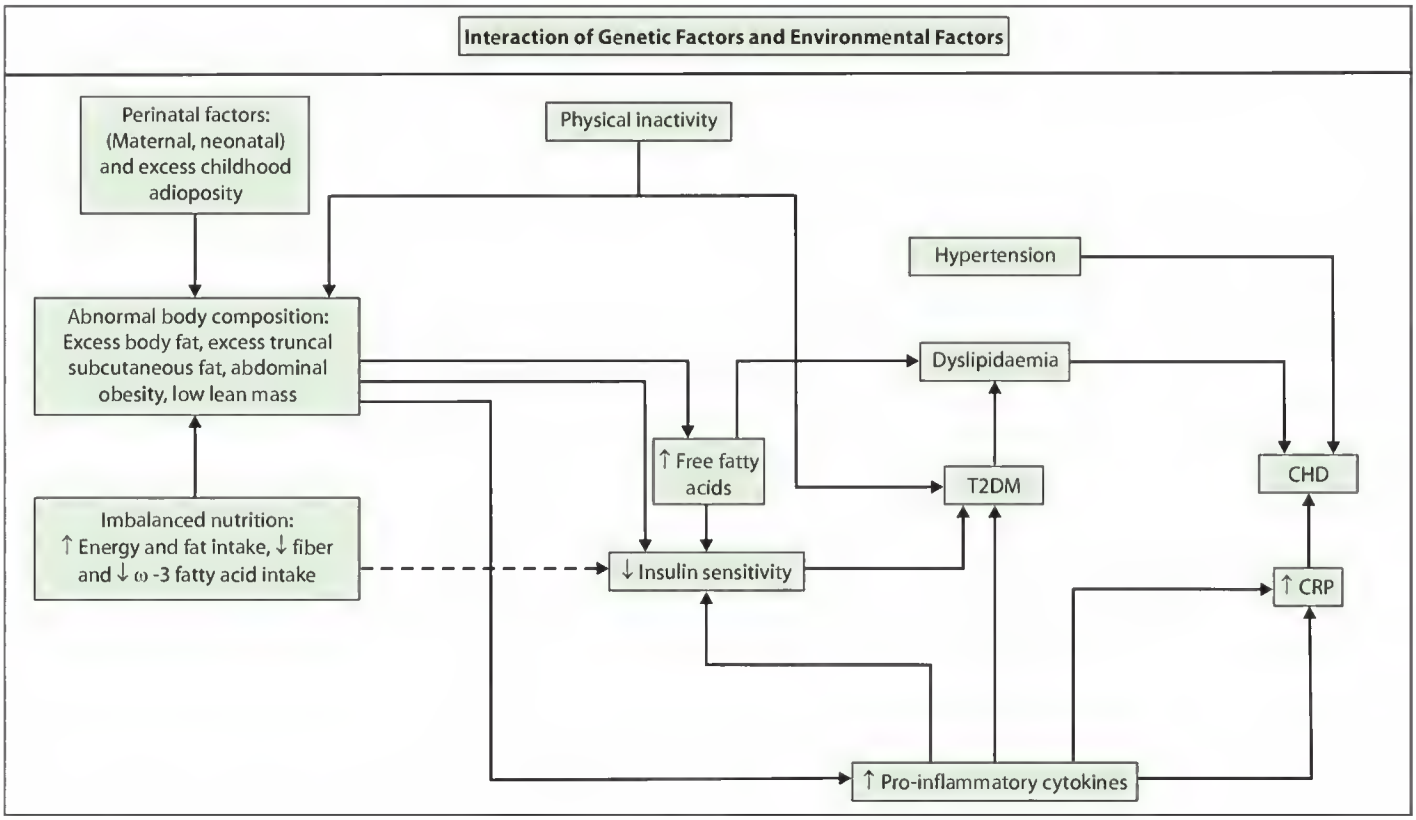

Figure 1: Complex interactions of genetic, perinatal, nutritional and other acquired factors in the development of insulin resistance, T2DM and CHD in Asian Indians.

T2DM = Type 2 diabetes mellitus; CRP = C-reactive protein; CHD = Coronary heart disease.

Prevention and Control of the Metabolic Syndrome in Asian Indians

1. Intensive efforts should be made to make South Asians aware that they are at more risk for the development of T2DM and CHD.
2. The preventive measures should be particularly vigorous for those with the family history of T2DM or premature CHD.
3. The therapeutic lifestyle changes should be encouraged from the childhood. Regular physical activity should be advised and television and internet usage should be restricted.
4. Body weight and anthropometric indices should be maintained within normal limits. The physicians should be made aware that these provisional limits for defining normal BMI and WC might be revised in the future.
   (a) Based on the recent data, and provisional recommendations of World Health Organization, BMI should be maintained between 19 to 23 kg/m^2.
   (b) The WC should be maintained below 90 cm for men and 80 cm for women.
5. Overweight individuals and those with abdominal obesity should be actively managed to lose weight by lifestyle measures.
6. Detection of one component of the metabolic syndrome should lead to search for the other components and its management.
7. Currently, no drug (e.g., metformin) is recommended for the management of insulin resistance and the metabolic syndrome. However, these guidelines may change in future, particularly for those who have prediabetes.
8. Adequate nutrition during the intrauterine period should be given to prevent early-life adverse events, which may promote insulin resistance in adulthood.
9. Research on insulin resistance and the metabolic syndrome in South Asians should be targeted on the following:
   (a) Prevalence of metabolic syndrome in various South Asian countries,
   (b) Aetiological factors of insulin resistance, particularly genetic studies,
   (c) Associations of specific macro- and micro-nutrients in South Asian diet with insulin resistance (e.g., omega-3 polyunsaturated fatty acids and dietary fibre),
   (d) Relationship with novel cardiovascular risk factors (e.g., C-reactive protein),
   (e) Intervention with insulin-sensitizers and other drugs,
   (f) Prevalence of the metabolic syndrome and morbidity correlation in children,
   (g) Best methods of imparting lifestyle and diet-related health messages in children, and
   (h) Increasing awareness of ill effects of the metabolic syndrome in populations.
10. Finally, the National Control Programmes for diabetes and cardiovascular diseases should be adequately strengthened and modified in view of the recent knowledge and guidelines.

19.1 Kidney—Structure and Functions

Sanjay K Agarwal

Kidneys are paired intra-abdominal organs lying opposite the upper lumbar vertebrae, and weigh 150 g each. Each kidney has an outer layer, the *cortex*, and an inner layer, the *medulla*. Both abut on to the renal pelvis; the cortex sends down columns of cortical tissue (columns of Bertin) separating the medullary pyramids (**Figure 1**). There are about 8 to 18 medullary pyramids in each kidney. They terminate in the papillary tips, which project into the calyces. The hilum of the kidney takes the vasculature to and from the kidney along with its draining system, the pelvis and ureter. The vein is the most anterior and the ureter is most posterior of the three structures. The renal arteries are frequently multiple with up to 25% persons having more than one renal artery on each side.

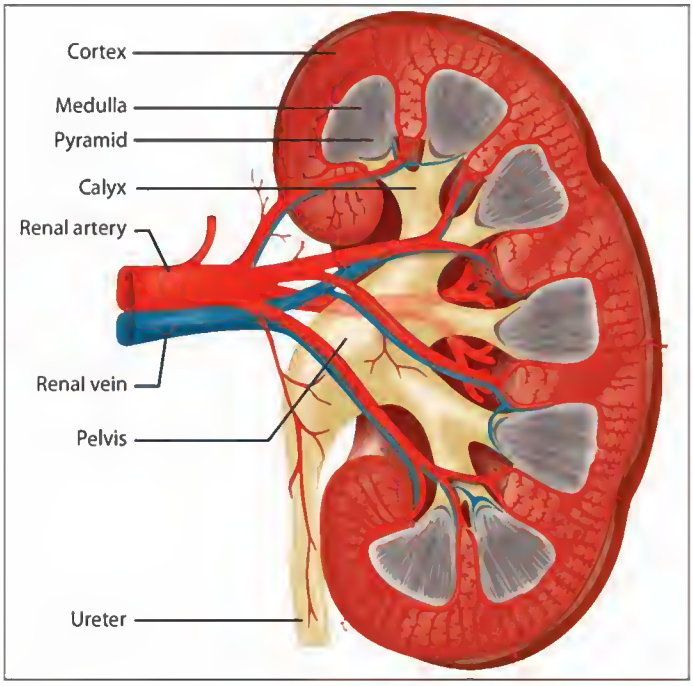

Figure 1: Cross section of kidney depicting major structures.

The renal arteries break up into arching branches known as *arcuate arteries,* which run at the cortico-medullary junction and are end-arteries, anastomosing solely through capillary channels. The *interlobular arteries* branch off the arcuate arteries and run at right angles towards the renal capsule, and branching again at right angles into afferent arterioles supplying the glomeruli; some branches go down into the medulla, first passing through the juxta-medullary glomeruli and then becoming large straight vascular channels known as '*vasa recta*' which pass down into the depths of renal pyramids (**Figure 2**). Then they bend back up to reach the arcuate veins at the cortico-medullary junction. The tips of the papillae have a special arterial supply of their own from the 'spiral arteries', branches of the interlobular arteries in the pelvis of the kidney. The afferent arterioles break up into 20 to 40 capillary loops in

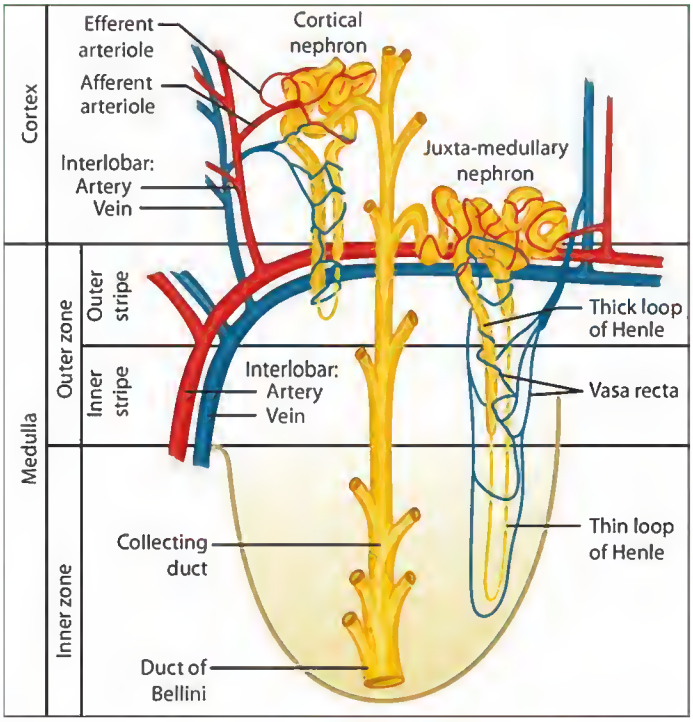

Figure 2: Distribution of renal circulation.

each glomerulus, which rejoin to form the efferent arterioles. This then splits up again to form a second capillary network, which surrounds the tubules, both proximal and distal; this network itself empties into interlobar veins.

The anatomical and functional unit of the kidney is the nephron. This consists of a glomerulus with proximal convoluted tubules (PCT), loop of Henle (LOH), distal convoluted tubules (DCT) and collecting ducts (CDs) (**Figure 3**). There are approximately 1 million nephrons in each kidney. The majority of glomeruli are in the cortex. The PCT, DCT and blood vessels constitute the bulk of the non-glomerular cortical tissue. The medulla is composed of some LOH, vasa recta and a mass of CDs. This is an important structure responsible for the water conservation.

Bowman's capsule is a specialised invagination of the PCT and is lined by parietal epithelial cells (PEC) which are flatter and less noticeable than the larger, pale staining visceral epithelial cells (VEC) which line the outer side of the capillary tuft. Electron microscopy of the glomerulus reveals that the VEC do not lie in close opposition to the glomerular basement membrane (GBM); extension of the cytoplasm of the cells, called 'foot process', come into contact with the GBM at intervals leaving many areas of the GBM surface free of the epithelial cell contact. These areas have a mean width of 240 A° and are known as 'slit pores'. The main filtration barrier is the GBM, consisting of a ramification of fibres with a mean diameter of lumen between the fibres of 52 A°.

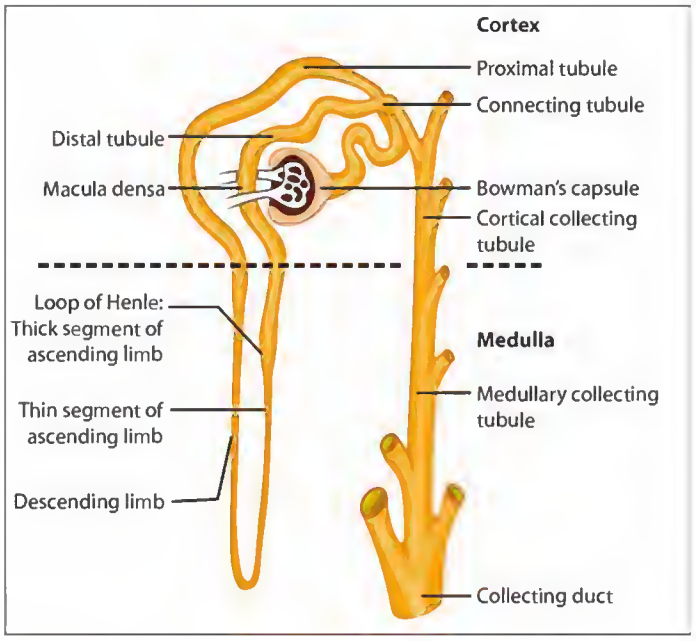

Figure 3: Various parts of the nephron.

The GBM (**Figure 4**) runs through all the capillary walls, sandwiched between the foot processes of the VEC on the one side and the endothelial cells of vessels on the other side. It is continuous with the basement membrane of the tubules. Its thickness is 3000 A° in humans. Capillary walls are lined by endothelial cells, which lie on the basement membrane from the inner side. There are fenestrations in between the endothelial cells. They are closed by a diaphragm. The endothelial cells of the glomeruli are continuous with the endothelial lining of the afferent and efferent arterioles. Studies of hereditary proteinuric syndromes have highlighted the presence of various transmembrane proteins (nephrin, fatty acid transporter tumour suppressor homolog-1 (FAT1), and FAT2, podocin and CD2-associated protein (CD2AP) that participate in the formation of the slit diaphragm (SD), which is important in preventing protein leakage. Slit diaphragms are firmly attached to the actin cytoskeleton through linker proteins, including the catenins, zona occludens 1 (ZO-1), CD2AP, and Nck,

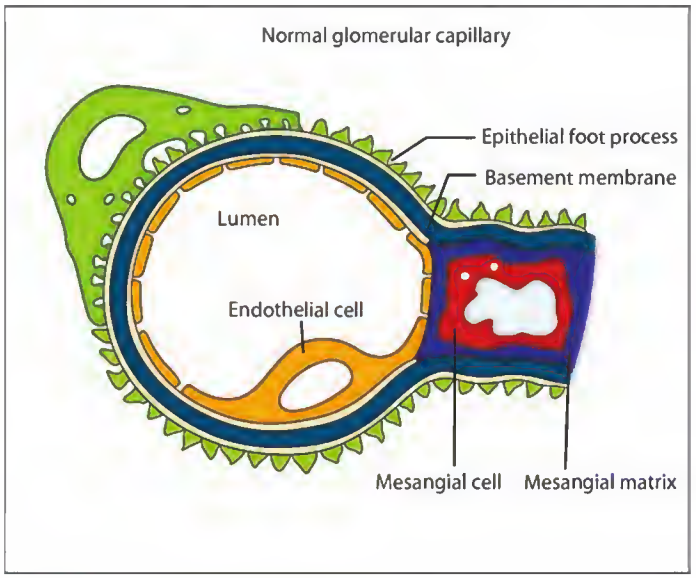

Figure 4: Glomerular basement membrane and its components.

which likely explains why genetic defects altering SD structure and function are usually associated with actin cytoskeleton re-organisation and foot process effacement.

At the point where the DCT are in contact with the afferent arteriole, the latter contains the juxta-glomerulus apparatus (JGA), a series of granular cells believed to be the source of the enzyme 'renin'. The efferent arteriolar wall is composed of smooth muscle with an endothelial lining. The structure of peritubular capillaries is such as to promote ready exchange of materials between the tubular cells and capillaries. The PCT are confined to the cortex of the kidney; these connect the glomerulus proximally with the descending limb of LOH. LOH is shaped like a 'U' tube connecting PCT and DCT, dipping down a variable distance into the medulla.

There is no clear-cut place where thick ascending limb of LOH becomes DCT. The epithelium of DCT is columnar and the surface being covered with numerous microvilli. As the CDs are approached the cell height becomes smaller, giving way to the cuboidal cells of the CDs. At the site where DCT approaches the vascular pole of the glomerulus, the nuclei of the epithelial cells become crowded, come closer and appear darker staining than in other part of DCT. This hypernuclear area is known as *'macula densa'*. The cortical collecting ducts (CCDs) are a continuation of the DCT. These run into medullary collecting ducts. Medullary collecting duct cells have a cuboidal shape; have light cytoplasm and relatively few mitochondria. They in fact resemble 'light cells' of CCDs. The collecting ducts run into the 'papillary ducts of Bellini'. In the papillary ducts, the cells are columnar in shape, have a basal nuclei and few mitochondria. The ducts of Bellini join the renal pelvis, which is covered with transitional epithelium.

FUNCTIONS OF KIDNEY

The kidneys maintain the internal environment within narrow limits in spite of great variation in intake and metabolic activity. The main functions of the kidney are regulation of body water, electrolytes, acid base balance, excretion of nitrogenous waste products, drugs and poisons, regulation of blood pressure, erythropoietin production and control of vitamin D metabolism.

Glomerular Filtration

The glomeruli filter about 180 litres of fluid each day although only approximately one and a half litres is passed as urine. Glomerular filtration rate (GFR) is defined as the amount of plasma being filtered by the glomeruli per minute. The normal GFR in Indians is approximately 75 to 79 mL/min/1.73m^2. In women, the figure is slightly lower. GFR is determined by: (1) sum of hydrostatic and colloid osmotic forces across the glomerular capillary membrane which gives the net filtration pressure; and (2) glomerular capillary ultrafiltration coefficient Kf.

Tubular Handling

The permeability of solutes across the tubules is determined by their lipid solubility and membrane pores. Pores which handle the transfer of water are called aquaporins. There are many types of aquaporins though the two important types are, aquaporin-1 (AQP1), which is found in the PCT, descending limb of the LOH, and vasa recta and aquaporin-2 (AQP2), localised to the apical membrane of the CCT and connecting tubule. Not

only does AQP2 provide the necessary pathway for water permeation that is regulated by ADH-dependent trafficking to the apical membrane, but it also has an immeasurably low permeability to urea and ions even as small as H_3O^+ or H^+.

Tubular Reabsorption and Secretion

Reabsorption can be an active process, transport against the electrochemical gradient or a passive process with transport along the electrochemical gradient. Active transport energy is provided by the action of appropriate enzymes inside the tubular cells. Being an active process, there is a limit to the maximum amount transported, which is called tubular maximum (TM). Glucose is competitively reabsorbed in the proximal tubules along with xylose, fructose and galactose. Similar to glucose, amino acids are also absorbed in the proximal tubules. Glycine, arginine and lysine have TM but many others like histidine, methionine, tryptophan, leucine and phenylalanine have very efficient reabsorption mechanism without a measurable TM. There are enzymes involved in tubular secretion with a TM of some of the substances. In addition to para-aminohippuric acid, renal tubules secrete radio-contrast media, phenol red, penicillins, probenecid and many other drugs. Many of the substances being secreted from the tubules share common mechanisms and compete with each other.

REGULATION OF BODY WATER

Water filtered from the glomerulus is 180 litres per day of which about 99% is reabsorbed. Most of it is absorbed passively in proximal tubule with sodium (**Figure 5**). Tubular fluid remains isotonic in the PCT. What happens in LOH and beyond depends upon the presence and concentration of anti-diuretic hormone (ADH). If ADH is low/shut-off, water passes through the thin part of LOH but not through the thick part of LOH. The urine in DCT is hypotonic and in the absence of ADH, urine remains dilute as it passes down in the CD. The water channel responsible for the high water permeability of the luminal membrane in response to vasopressin in aquaporin-2(AQP2). The AQP3 and AQP4 are located on the basolateral membranes and are probably involved in water exit from the cell.

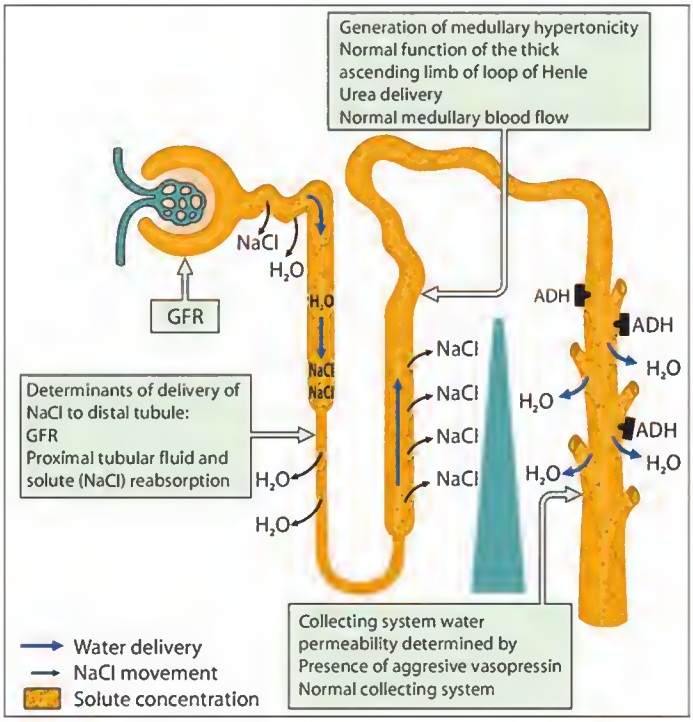

Figure 5: Salt and water handling by the tubules.

During water deprivation, the solute content of medulla is much higher than that of the cortex. Solute content increases progressively as we approach the inner medulla. Osmolarity of tissue at inner medulla is same as that of urine passed while the osmolarity of cortex is same as that of plasma. Urine in CD is also hyperosmolar. The mechanism which accounts best for the phenomenon of urine concentration, is that of *'counter-current multiplier system'*. The capillary loops of the medulla have comparatively low blood flow, and the exchange of gases and solutes occurs between the arterial and venous limbs working as a *'counter-current exchanger'*. Conserving a high content of solute and carbon dioxide (CO_2) in the deeper zones of medulla. The LOH is the site of the counter-current multiplier system.

Another important issue is the concept of 'free-water'. Free water clearance (C_{H_2O}) is the volume of blood plasma that is cleared of solute-free water per unit time. Values less than zero imply that the kidney is conserving water resulting in the production of concentrated urine. Since urine flow is determined by the rate at which plasma is cleared of solutes and water (as discussed above), urine flow (V) is given as the sum of osmolar (C_{osm}) and free water clearance (C_{H_2O}) :

$$V = C_{osm} + C_{H_2O}$$

Since osmolar clearance is given as the product of urine flow rate and the ratio of urine to plasma osmolality, this is commonly represented as

$$C_{H_2O} = V - \frac{U_{osm}}{P_{osm}} V$$

HANDLING OF SMALL IONS

In the initial part of the proximal tubule, 60% of filtered sodium is actively reabsorbed. This is an *isosmotic reabsorption*. About 25% sodium reabsorption occurs in the thick ascending limb of LOH through the apically expressed sodium-potassium-chloride co-transporter (NKCC2), which uses the sodium gradient across the membrane to transport chloride and potassium into the cell. Sodium leaves the cell actively through the basolateral sodium–potassium ATPase (Na-K-ATPase). In contrast, chloride diffuses passively through two basolateral chloride channels, ClC-Ka and ClC-Kb. Distal tubular reabsorption of sodium occurs both in the DCT and in the CD. Sodium reabsorption is dependent on aldosterone, and corticosteroid, which cause an increase in sodium reabsorption and various natriuretic factors. The mechanism of absorption of sodium in the ascending LOH is by means of a sodium pump located in the tubular cells. The 'sodium pump' is thought to receive energy by the conversion of ATP to ADP. Na-K ATPase carries out this conversion.

Potassium is reabsorbed and secreted by the renal tubule. More than half of filtered potassium is passively reabsorbed by the end of the PCT. Potassium is then added to tubular fluid in the descending limb of LOH. The major site of active potassium reabsorption is the thick ascending limb of the LOH, so that, by the end of the DCT, only 10% to 15% of filtered potassium remains in the tubule lumen. Potassium is secreted mainly by the principal cells of the CCD and outer MCD. Potassium reabsorption occurs via the intercalated cells of the MCD.

ACIDIFICATION OF URINE

Acidification of the urine is closely related to bicarbonate reabsorption. Large amounts of hydrogen ion are being secreted into the proximal tubule. Secretion of hydrogen removes most bicarbonate from the proximal tubular fluid. The hydrogen ion coming from the tubular cells is exchanged for sodium ions. The source of the hydrogen ion is carbonic acid. The bicarbonate ions inside the cells, together with sodium ions, enter the interstitial fluid and then the peritubular capillaries. Carbonic anhydrase (CA) inside the cells causes a very rapid combination of water and CO_2 to form carbonic acid. In the tubular lumen, CO_2 produced by the action of hydrogen ion on bicarbonate can diffuse rapidly into the tubular cells. Hydrogen ion also combines with buffers, and with ammonia to form ammonium ion. A little hydrogen ion remains free in solution. The combination of hydrogen ion with buffer is measured as 'titratable acidity.' This is defined as the amount of alkali in mEq required to titrate the urine to a pH of 7.4. In the distal tubule, phosphate and creatinine are the two most important buffers. Ammonia, which is produced by mechanisms in the tubular cells, diffuses into the tubular urine where it reacts with free hydrogen ion to form ammonium ion (NH_4^+). This NH_4^+ cannot diffuse freely back through the tubular cell wall and so urinary ammonium ion is a measure of part of hydrogen ion secretion.

EXCRETION OF WASTE PRODUCTS

Urea Handling

The kidneys excrete urea entirely by means of glomerular filtration. Half the filtered urea is reabsorbed by the tubules. Urea contributes to the high medullary osmolality during the formation of concentrated urine. About 40% to 50% of the filtered urea diffuses out of the proximal tubule by a passive process. In the descending LOH, urea enters the tubular fluid from the medullary interstitium and CD, so that by the time the DCT is entered the tubular fluid once again contains an amount of urea equal to that present in the glomerular filtrate. As the tubular fluid passes down the CD, a large amount of urea is lost into the medullary interstitium. In the presence of vasopressin, the DCT and CD have an increased permeability to urea so that when concentrated urine is being formed an increased amount of urea diffuses into the medullary interstitium so increasing its osmolality, and thus extracts water from the LOH.

Creatinine Handling

Creatinine, a breakdown product of muscle metabolism is excreted primarily by glomerular filtration. It is related mainly to an individual's muscle mass. As it is not significantly handled by tubules, creatinine is useful for making an estimation of GFR, though in many situations it is not critically reliable. However, it is definitely much better than urea.

EXCRETION OF DRUGS AND POISONS

The kidneys share with the liver the important job of disposing of drugs and poisons. Water-soluble drugs are primarily excreted in the urine. Kidneys are peculiarly vulnerable to toxic damage for two main reasons. First, they have a very rich blood supply in proportion to their weight, and secondly, excretion involves concentration of drugs in the renal tubules. This is why the renal tubules tend to take the brunt of the damage. In patients with kidney damage drugs excreted by the kidneys must be given with extreme caution because inadequate excretion can cause toxic blood levels; and the high blood levels in turn may be toxic to the kidneys.

REGULATION OF BLOOD PRESSURE

Hypertension is more common in glomerular than in tubulo-interstitial diseases. A well-known cause of renovascular hypertension is renal artery stenosis. A hormone called renin is manufactured in the kidneys by juxta-glomerular cells. Renin acts on angiotensinogen to ultimately produce angiotensin II, which has a vasoconstrictor effect on blood vessels. The kidneys of patients with essential hypertension excrete normal amounts of salt and water at higher-than-normal renal perfusion pressures.

CONTROL OF ERYTHROPOIESIS

The cells producing erythropoietin in the kidney are peritubular fibroblasts in the renal cortex. Erythropoietin concentrations are decreased or increased under a variety of conditions largely reflecting alterations of oxygen delivery to tissues. In addition to changes in oxygen delivery, some metabolic factors also influence erythropoietin production. In a somewhat simplified way, it is those conditions of reduced oxygen supply and increased oxygen demand that lead to increased circulating erythropoietin concentrations, whereas decreased concentrations are typical of conditions with increased oxygen supply or reduced oxygen demand.

CONTROL OF VITAMIN D, CALCIUM AND PHOSPHATE METABOLISM

Vitamin D is converted into its active 1,25 dihydroxyvitamin D in the proximal tubule by the enzyme-1α hydroxylase. Other than calcium, serum PO_4 excretion stimulates the activity of this enzyme. In addition, kidneys also control calcium and PO_4 excretion. After filtering at glomerulus, 60% to 70% of Ca is absorbed from PCT; 80% passive and 20% active. Ca is further reabsorbed in small amounts within the medullary segment of the TALOH. Active transcellular Ca transport can be stimulated by both parathyroid hormone (PTH) and active vitamin-D in the cTAL. In the early DCT, thiazide-activated Ca transport occurs. At DCT also Ca reabsorption is regulated by PTH and $1,25(OH)_2D_3$. About 10% of the filtered Ca is reabsorbed in the DCT, with another 3% to 10% in the connecting tubule (CNT) by way of mechanisms similar to those in the DCT.

Most of the inorganic PO_4 is filtered at glomerulus and 80% to 90% is reabsorbed in the PCT by way of a sodium gradient-dependent process (Na-Pi cotransport) and the rest is excreted in the urine. Most of the dietary, hormonal and metabolic factors that regulate renal tubular PO_4 reabsorption modulate the PCT expression of the type II Na-Pi cotransport protein. Some amount of filtered PO_4 is also reabsorbed in distal segments of the nephron.

CONCLUSION

Kidney is a complex, but vital human organ. The structural and functional unit of the kidney is the nephron. In addition to its excretory function, role of kidney in endocrine functions and in maintenance of blood pressure is equally important.

19.2 Kidney Disease—A Clinical Approach

Vijay Kher

INTRODUCTION

Patients with kidney disease may have a variety of clinical presentations. Some have symptoms directly related to the kidney (gross haematuria, flank pain) while others may have extra-renal symptoms (oedema, hypertension, signs of uraemia). However, many patients are asymptomatic and are noted on routine examination to have an elevated plasma creatinine concentration or an abnormal urinalysis. Each of these groups requires a step-wise approach so as to arrive at a definitive diagnosis.

Over the last few years, there have been certain changes in the terminology of kidney disease. Acute renal failure (ARF) is now termed as acute kidney injury (AKI) to reflect the entire spectrum of severity of ARF. Similarly chronic renal failure (CRF) is now termed as chronic kidney disease (CKD). The term renal has been replaced by kidney to make it more patient friendly. The term failure has been replaced by disease as failure seemed to connote a helplessness on part of the nephrologists in managing patients with kidney disease. The term end stage renal disease (ESRD) has also been changed to chronic kidney disease stage V [glomerular filtration rate (GFR) less than 15 mL/min], as most of these patients can be given many years of good quality life with kidney transplantation or maintenance dialysis and cannot be considered as end stage.

The diagnosis of kidney disease is based on the evaluation of signs, symptoms and a series of investigations. The diagnosis is complicated by the fact that most of the signs and symptoms are non-specific and also appear fairly late in the course of the disease. A simple approach to a patient with kidney disease is to match the patient's clinical features into one of the following syndromes:

1. Asymptomatic urinary abnormality
2. Urinary tract infection (UTI)
3. Hypertension
4. Acute kidney injury
5. Rapidly progressive renal failure (RPRF)
6. Acute nephritic syndrome
7. Nephrotic syndrome (NS)
8. Chronic kidney disease
9. Urinary tract obstruction
10. Tubule function defects
11. Congenital/genetic syndromes

SIGNS AND SYMPTOMS OF KIDNEY DISEASE

The first step in evaluating a patient for kidney disease is to look for clinical features suggestive of kidney disease. These could be a change in urine output like polyuria or nocturia, which relates to loss of the concentrating ability of the kidney or oliguria (<400 mL urine in 24 hours) or anuria (<50 mL urine in 24 hours) which may be symptoms of AKI; whereas dysuria, frequency, urgency could suggest urinary tract infection (UTI), or a pathology in bladder, prostate or urethra. Oedema around eyes, haematuria, proteinuria and hypertension are suggestive of glomerular disease. Flank pain, haematuria and graveluria may suggest stone disease.

The window to kidney disease is the examination of the urine, for specific gravity, glycosuria, proteinuria and microscopic examination for red blood cells (RBCs), white blood cells (WBCs) and casts or any other cells. The urinary specific gravity and osmolality may be relatively fixed around 1010 and 290 mOsmol/L respectively, signifying the inability of the kidneys to concentrate or dilute the urine. Presence of RBCs casts with proteinuria suggests glomerulonephritis; WBCs casts in a patient with fever, chills and flank pain suggest acute pyelonephritis; eosinophiluria and eosinophilia in a patient with AKI suggests drug-induced interstitial nephritis; broad casts suggest CKD. An ultrasound is mandatory for evaluation of any patient with kidney disease as it provides information on the size and echogenicity of the kidneys as well as the morphology of the ureters, urinary bladder, urethra, prostate.

ASYMPTOMATIC URINARY ABNORMALITY

Asymptomatic patients are most commonly detected to have kidney disease following routine investigations, such as urine analysis, blood pressure measurement, biochemical analyses or as part of a health screening programme. In some patients, kidney disease is detected during clinical examination for health insurance, occupational purposes, or during pregnancy. Asymptomatic patients may be detected as a result of investigation of family members following the diagnosis of a familial renal disease. Asymptomatic patients may have either abnormal urinary excretion of protein, microscopic haematuria, abnormal imaging of kidney or urinary tract or a combination of these.

Technetium 99mm mercaptoacetyltriglycine diethylene-triamine-penta-acetic acid (DTPA) or MAG3 scan provides an excellent evaluation of function and GFR assessment of each kidney and can be used for the diagnosis and follow-up of patients with obstructive uropathy and renovascular hypertension. ^{99}Tc DMSA is useful in detecting scars in the renal parenchyma.

Routine ultrasound screening during pregnancy has resulted in prenatal detection of urological disorders. Neonatal ultrasound scanning has led to a predictable increase in the detection of urinary tract abnormalities, the most common of which is hydronephrosis.

Mild, asymptomatic proteinuria can be divided into three categories: transient, orthostatic, and persistent. Transient proteinuria is by far the most common, occurring in 4% of men and 7% of women on a single examination, with resolution on subsequent examinations. A transient increase in protein excretion may be seen with fever and exercise, as well as with

symptomatic UTI. Orthostatic proteinuria primarily occurs in adolescents; it is characterised by increased protein excretion in the upright position, but normal protein excretion when the patient is supine. Both transient and orthostatic proteinuria are benign conditions requiring no further evaluation or specific therapy. Persistent proteinuria, in comparison, is more likely to reflect some underlying renal or systemic disorder. There are three types of persistent proteinuria: glomerular, tubular, and overflow.

1. Glomerular proteinuria implies proteinuria as a result of increased glomerular permeability and usually consists of excretion of albumin.
2. Tubular proteinuria implies increased excretion of proteins due to non absorption of low molecular weight proteins which are filtered through a normal glomerular filter as in tubulo intersitital disease.
3. Overflow proteinuria is excretion of proteins which are increased in the plasma as in multiple myeloma and light chain proteinuria.

The evaluation of the patient with mild proteinuria should begin by testing the urine on at least two occasions. The urine sediment should also be examined. If the proteinuria persists, a renal ultrasonogram should be performed looking for a structural lesion, such as chronic pyelonephritis or polycystic kidney disease. A renal biopsy is generally performed if there is some sign of progressive disease, such as increasing protein excretion or a rise in the plasma creatinine concentration.

Haematuria may be grossly visible or microscopic. Gross haematuria is suspected because of the presence of red or brown urine. The color change does not necessarily reflect the degree of blood loss, since as little as 1 mL of blood per litre of urine can induce a visible colour change. In addition, the intermittent excretion of red to brown urine can be seen in a variety of clinical conditions (myoglobinuria or porphyria) other than bleeding into the urinary tract. Thus, the initial step in the evaluation of such patients is centrifugation of the specimen to see if the red colour is in the urine sediment (RBCs) or the supernatant (pigments like myoglobin as in myoglobinuria, haemoglobin in urine as in intravascular haemolysis). Although haematuria is commonly defined as the presence of more than 2 RBCs per high power field in spun urine sediment, there is no 'safe' lower limit below which significant disease can be excluded. The causes vary with age with the most common being inflammation or infection of the prostate or bladder, stones, and in older patients, malignancy. The investigations should be done as per the flow chart (**Figure 1**). If no diagnosis is apparent from the history, urinalysis, radiologic tests, or cystoscopy, then the most likely causes of persistent isolated haematuria are a mild glomerulopathy or a predisposition to stone disease, particularly in young and middle-aged patients. If haematuria is associated with nephrotic range proteinuria, it almost always suggests glomerular disease. Microscopic haematuria in itself cannot cause heavy proteinuria.

URINARY TRACT INFECTION

Infections of the urinary tract are common, distressing, and can occasionally be life-threatening. The clinical features, diagnosis, treatment, complications, and long-term significance of infection vary, depending on the site of infection and the presence or absence of structural or functional abnormality within the urinary tract. Diagnosis requires demonstration of bacteriuria and/or pyuria. In children, UTI may cause significant long-term morbidity, particularly, renal scarring, hypertension and renal impairment, which may not be evident clinically until adult life. Hence, in children even the first episode of UTI mandates a detailed work-up and evaluation.

HYPERTENSION

Hypertension is defined as an elevation of blood pressure $\geq$140/90 mmHg. This may be the first sign of an underlying kidney disease, especially in patients <35 years of age. In referral centres, 2% to 5% of hypertensive patients have renovascular hypertension. Renal ultrasound may reveal a unilateral contracted kidney suggesting an underlying renovascular aetiology and/or renal parenchymal aetiology. Another important cause of renal hypertension is reflux nephropathy, which leads to scarring of the kidneys.

ACUTE KIDNEY INJURY

AKI is a sudden and reversible loss of kidney function usually preceded by loss of blood or fluid, kidney ischaemia, hypotension or caused by drugs. It mostly recovers in 4 to 12 weeks time. The incidence of AKI is very high in hospitalised patients. An incidence of 15% has been reported among patients admitted to intensive care units, whereas among all hospitalised patients, rates of 2% to 5% have been reported. The two major causes of AKI are acute tubular necrosis (ATN, due to ischaemia or the administration of a nephrotoxin) and prerenal disease (due to heart failure, true volume depletion, or sepsis).

RAPIDLY PROGRESSIVE RENAL FAILURE

RPRF is described as insidious onset (*versus* abrupt onset in AKI) deterioration (over days to weeks) in renal function. The most important cause of RPRF is rapidly progressive glomerulonephritis (RPGN). This is characterised morphologically by extensive crescent formation and clinically by progression to end-stage renal disease in most untreated patients within a period of weeks to months. The severity of the disease is in part related to the degree of crescent formation: patients with circumferential crescents in more than 80% of the glomeruli tend to present with advanced renal failure that may not respond well to therapy. Patients should undergo early renal biopsy, which should include immunofluorescence and light microscopy and appropriate serologic assays. These include anti-neutrophil cytoplasmic antibodies (ANCA), anti-GBM antibodies, antinuclear antibodies and complement levels. The other important causes of RPRF are acute interstitial nephritis (which could be drug-induced or due to acute pyelonephritis), malignant hypertension, haemolytic uraemic syndrome and obstructive uropathy.

ACUTE NEPHRITIC SYNDROME

Acute nephritic syndrome is characterised by haematuria, proteinuria, oedema and hypertension. The prototype of this disease is acute post streptococcal glomerulonephritis. However, it can occur as a result of many bacterial or viral infections. This occurs 10 to 20 days following infection. Some of these patients may present with severe hypertension, oedema and renal failure.

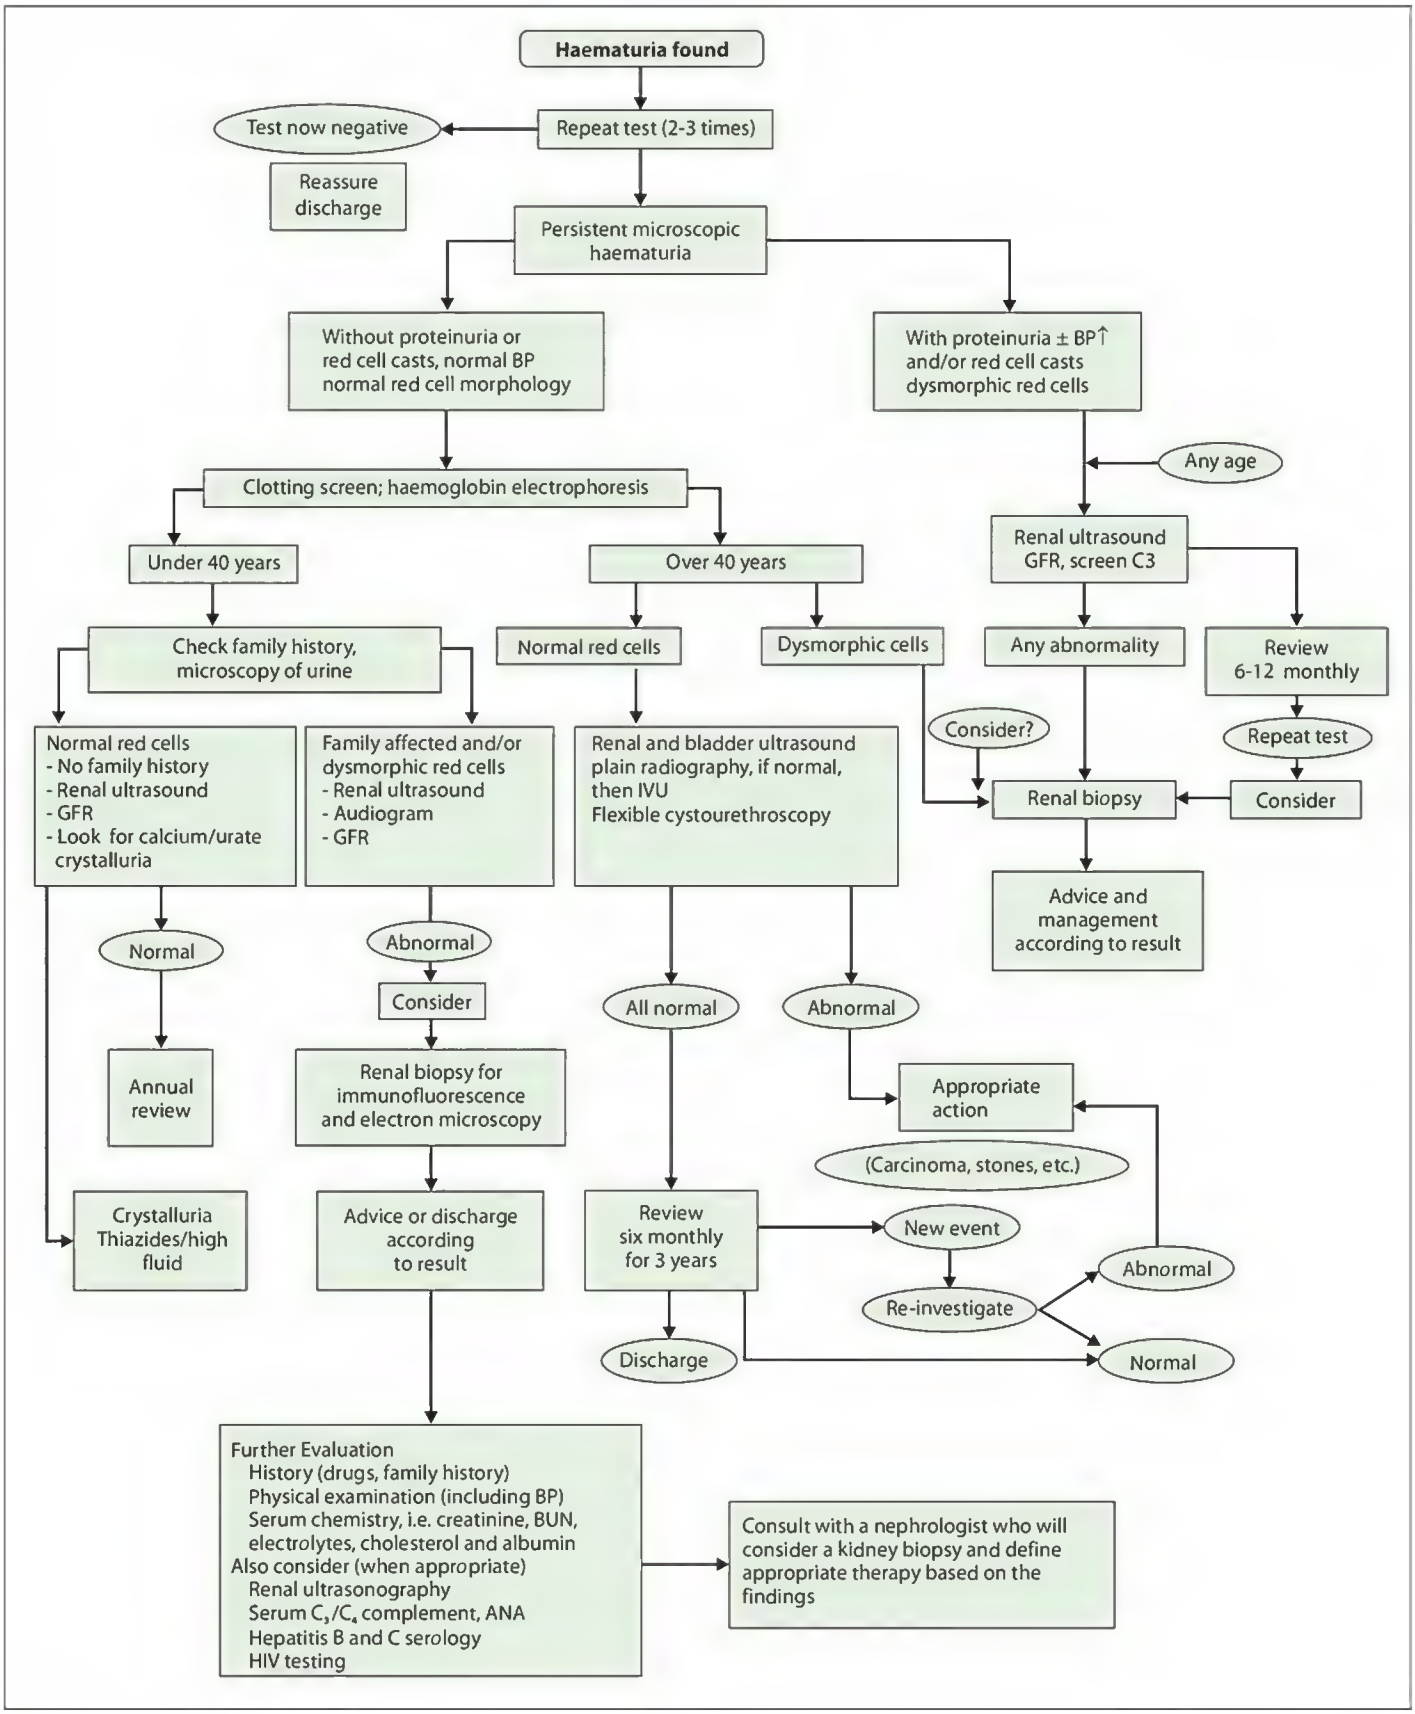

Figure 1: Evaluation of a patient with haematuria.

BP = Blood pressure; GFR = Glomerular filtration rate; IVU = Intravenous urogram; BUN = Blood urea nitrogen; ANA = Antinuclear antibody; HIV = Human immunodeficiency virus.

Most of these patients resolve completely with time. The other important renal diseases mimicking this syndrome are immunoglobulin (Ig)A nephropathy and mesangiocapillary glomerulonephritis.

NEPHROTIC SYNDROME

The nephrotic syndrome is caused by renal diseases that increase the permeability across the glomerular filtration barrier. It is classically characterised by four clinical features, but

the last two may not be seen in all patients: (i) nephrotic range proteinuria—urinary protein excretion greater than 50 mg/kg per day or urine protein-to-creatinine ratio >2, (ii) hypoalbuminaemia—serum albumin concentration <3 g/dL (30 g/L), (iii) oedema, and (iv) hyperlipidaemia. Although, oedema is generally the presenting sign of nephrotic syndrome, the diagnosis is confirmed by the presence of nephrotic range proteinuria and hypoalbuminaemia.

Primary nephrotic syndrome refers to nephrotic syndrome in the absence of an identifiable systemic disease. Within this category are patients who have a bland sediment and no glomerular inflammation on renal biopsy, i.e. minimal change disease (MCD), focal glomerulosclerosis and membranous nephropathy. Patients with primary glomerulonephritis, who have an active sediment and glomerular inflammation on renal biopsy have mesangiocapillary glomerulonephritis or mesangioproliferative glomerulonephritis. Secondary nephrotic syndrome refers to nephrotic syndrome in the presence of an identifiable systemic disease, e.g. lupus nephritis.

In children corticosteroid therapy can be initiated in patients with a high probability of having MCD without confirmation of the diagnosis by renal biopsy. In adults, a kidney biopsy is considered mandatory prior to starting any kind of immunosuppressive therapy. Children with idiopathic nephrotic syndrome treated with empirical steroid therapy can be further classified based upon their response to corticosteroid therapy: (a) steroid-responsive nephrotic syndrome—majority of the children with idiopathic nephrotic syndrome are steroid responsive. In these patients, the most likely histologic lesion is MCD, although some patients with focal segmental glomeruloscerosis (FSGS) will also respond to corticosteroid therapy. Patients who are steroid responsive have a favourable long-term outcome; and (b) steroid-resistant nephrotic syndrome—approximately 25% of all children with nephrotic syndrome will not respond to corticosteroids. The response rate is better in younger children, who are much more likely to have MCD. Some children with steroid-resistant nephrotic syndrome have genetic mutations of podocyte proteins.

CHRONIC KIDNEY DISEASE

CKD is a syndrome that results from progressive and irreversible destruction of nephrons resulting from a number of causes. It is defined as kidney damage for ≥3 months, as defined by structural or functional abnormalities of the kidney, with or without decreased GFR, manifest by either: (i) pathological abnormalities or the presence of markers of kidney damage, including abnormalities in the composition of the blood or urine, or abnormalities in imaging studies or (ii) GFR <60 mL/min/1.73m^2 for 3 months, with or without kidney damage. This is usually progressive in nature. In most of the cases, demonstration of bilateral contracted kidneys, alongwith the clinical features of uraemia serve as the distinguishing features of chronicity. However, in CKD due to diabetes, amyloidosis and polycystic kidney disease, the kidney size may be normal or even bigger. Recently, a classification system which utilises GFR rather than serum creatinine for staging of CKD has been proposed by the National Kidney Foundation (**Table 1**).

Once a patient has been diagnosed to have kidney disease, the next step is to assess his level of renal function. Routinely a physician diagnoses kidney disease when serum creatinine and blood urea are elevated. However, the patient is said to have renal dysfunction once the GFR declines below normal. Normal GFR in an adult varies from 100 to 130 mL/min. There is an age-related decline in GFR of 1mL/min/year after the age of 30 years. The relationship of serum creatinine and urea to GFR is curvilinear and not linear, where serum creatinine and urea does not rise till the GFR declines to about 50%. Most of the patients are usually asymptomatic or mildly symptomatic at that stage. This is because of functional and structural adaptations that take place in the surviving nephrons, which compensate by increasing their functional capability. GFR can be assessed by either 24 hrs urinary creatinine clearance or estimating GFR from serum creatinine by either modification of diet in renal disease (MDRD) formula or Cockroft-Gault formula (**Table 2**).

Table 1: Definition and Staging of Chronic Kidney Disease (CKD)

Stage and Definition	Glomerular Filtration Rate (GFR) (mL/min/1.73m^2)	Clinical Plan of Action
At increased risk	>90 (with risk factors for CKD)	Screen for CKD; reduce risk of CKD
Kidney damage with normal or increased GFR	>90	Diagnose and treat; treat coexisting conditions; slow progression; reduce risk of cardiovascular disease
Kidney damage with mildly decreased GFR	60 to 89	Estimate rate of progression
Moderately decreased GFR	30 to 59	Evaluate and treat complications
Severely decreased GFR	15 to 29	Prepare for dialysis and kidney transplantation
Kidney failure	<15 (or dialysis)	Dialysis and kidney transplantation (if uraemia is present)

Table 2: Formula for Estimation of Glomerular Filtration Rate (GFR)

Cockroft-Gault Formula

CCr in Men : $\frac{(140 - \text{age}) \times \text{weight}}{72 \times \text{P. Creatinine}}$

CCr in Women : 0.85 × value from above

[Where age in years, weight in kilograms and P. Creatinine in mg/dL]

Abbreviated MDRD Study Equation

Estimated GFR (mL/min/1.73m^2)

186 × (Scr) – 1.54 × (Age) – 0.203 × (0.742 if female) × (1.210 if African – American)

exp (5.228 – 1.154 × ln (Scr) – 0.203 × in (Age) – 0.299 if female) + (0.192 if African – American)

Once the diagnosis of CKD is established, it is important to make an attempt to find out the specific disease that caused the kidney failure. According to the recent United States Renal Data System (USRDS) data, diabetes mellitus is regarded as the leading cause of kidney failure. In India, most of the data has been generated from single centre experiences (**Table 3**). Chronic glomerulonephritis and diabetic nephropathy are

Table 3: Aetiology of Chronic Kidney Diseases in India

Disease	SGPGI, Lucknow (%)	PGI, Chandigarh (%)	Apollo Hospital, Chennai (%)
Chronic glomerulonephritis	28.6	36.6	18.2
Diabetic nephropathy	23.3	23.8	26.7
Chronic interstitial nephritis	16.5	14.3	27.0
Hypertensive nephrosclerosis	4.1	13.5	10.0
Obstructive nephropathy	6.4	—	1.2
Autosomal dominant polycystic kidney disease	2.0	3.5	2.0
Unknown	16.2	3.7	—
Miscellaneous	3.0	4.3	—

leading causes of CKD. In order to establish the underlying cause, one must look for appropriate clinical features and use suitable laboratory tests. If the kidney size is preserved then one should attempt a kidney biopsy to find out the cause but if kidneys are shrunken then the cause of kidney disease may be difficult to detect. There is increasing evidence that patients with any degree of CKD have a substantial increase in cardiovascular risk that can, in part, be explained by an increase in traditional risk factors such as hypertension, diabetes, and the metabolic syndrome. Among patients with CKD, the risk of death, particularly due to cardiovascular disease, is much higher than the risk of eventually requiring dialysis. It is important for every physician taking care of patients of CKD to identify factors which may have aggravated the degree of kidney failure, as once these factors are corrected, kidney function may improve at least partially (**Table 4**).

CONGENITAL/GENETIC SYNDROMES

This includes a varied spectrum of diseases like autosomal dominant and recessive polycystic kidney disease, congenital nephrotic syndrome (Finnish type), Alport's syndrome, Fabry's disease and juvenile nephronopthisis. The diagnosis of these entities is suspected on a positive family history, characteristic clinical features and requires a high index of suspicion. Genetic counselling is an integral part of the management of these diseases.

Table 4: Common Reversible Factors in Chronic Kidney Disease

Volume depletion
- Vomiting, diarrhoea, excessive diuresis, congestive heart failure

Urinary tract obstruction
- Nephrolithiasis, papillary necrosis, bladder outlet obstruction

Infection
- Renal or extra-renal

Vascular disease
- Uncontrolled or accelerated hypertension

Nephrotoxic drugs
- Aminoglycosides, cephalosporins, tetracycline, amphotericin, radio-contrast agents, NSAIDs, diuretics

Electrolyte and metabolic disorders
- Hyperphosphataemia, hyperuricaemia, acidosis

Catabolic states
- Surgery, burns, gastrointestinal bleed, steroids, chemotherapy

Vasculitis
- Systemic lupus erythematosus, Wegener's granulomatosis, microscopic polyarteritis

Pregnancy
- Pre-eclampsia, eclampsia

19.3 Acute Kidney Injury

Alan F Almeida, Jatin P Kothari

INTRODUCTION AND DEFINITION

The term 'acute kidney injury (AKI)' has now replaced the previously used 'acute renal failure (ARF)' that described an illness with a sudden and rapid decline in renal function, causing retention of nitrogenous waste products such as blood urea nitrogen and creatinine. The older term failed to describe the dynamic process extending across the 3 phases of initiation (or insult), maintenance and recovery and focused on the presence or absence of overt kidney failure. The new terminology considers the disease as a spectrum of injury that extends from less severe forms to more advanced injury where renal replacement therapy (RRT) may be needed.

Clinically, AKI results in a failure to maintain fluid, electrolyte and acid-base homoeostasis and may be either non-oliguric (urine output >400 mL/day), oliguric (<400 mL/day) or anuric (<100 mL/day). Lower urine volumes are associated with more severe initial injury and have implications for volume status, electrolyte imbalance and prognosis. However, conversion from an oliguric to a non-oliguric state may not necessarily ameliorate the condition.

AKI can occur in a patient with previously normal renal function or may complicate the clinical course of pre-existing kidney disease. Further, AKI may occur as an isolated process or as a part of multiorgan failure.

The Acute Kidney Injury Network definition includes the following elements as diagnostic criteria: an abrupt (within 48 hours) absolute increase in the serum creatinine concentration of $\geq$0.3 mg/dL from baseline, a percentage increase in the serum creatinine concentration of $\geq$50%, or oliguria of less than 0.5 mL/kg per hour for more than 6 hours. The diagnostic criteria are applied only after volume status has been optimised. The staging of AKI is shown in **Table 1**.

Table 1: Staging of Acute Kidney Injury

Stage	S. Creatinine Criteria	Urine Output Criteria
1	Increased 1.5 to 2 fold*	<0.5 mL/kg/hour for >6 hours
2	Increased 2 to 3 fold*	<0.5 mL/kg/hour for >12 hours
3	Increased >3 fold* or absolute value >4 mg/dL	<0.3 mL/kg/hour for 24 hours or anuria for 12 hours

** Above baseline level.*

CLASSIFICATION

AKI can be divided into pre-renal, intrinsic and post-renal categories based on the underlying causative mechanisms.

Pre-Renal Acute Kidney Injury

The appropriate physiologic response to renal hypoperfusion is pre-renal AKI. If hypoperfusion is corrected in time, the integrity of the renal parenchymal tissue is maintained and glomerular filtration rate (GFR) rapidly improves. If uncorrected, intrinsic damage ensues. Any condition characterised by hypovolemia, low cardiac output, systemic vasodilatation or intrarenal vasoconstriction can cause hypoperfusion. True or 'effective' hypovolaemia manifests with a fall in systemic arterial pressure, setting in motion corrective neural and humoral responses (activation of baroreceptors, sympathetic nervous system activation, renin-angiotensin-aldosterone system activation and ADH release). However, these compensatory mechanisms fail if the mean arterial blood pressure is less than 70 to 80 mmHg. The major causes of pre-renal AKI are shown in **Table 2**.

Table 2: Causes of Pre-Renal Acute Kidney Injury

Mechanism	Cause	Conditions
Intravascular volume depletion	Haemorrhage	Trauma, surgical, GI, post-partum,
	GI losses	Vomiting, NG suction, diarrhoea
	Renal losses	Drug-induced or osmotic diuresis, adrenal insufficiency
	Skin and mucous membrane losses 'Third-space' losses	Burns, hyperthermia, pancreatitis, crush syndrome, hypoalbuminaemia
Decreased cardiac output		Myocardial, valvular, pericardial diseases, pulmonary hypertension, pulmonary embolism, mechanical ventilation, systemic vasodilatation, antihypertensive drugs
Renal vasoconstriction		Norepinephrine, liver disease, sepsis, hypercalcaemia
Impaired autoregulation		ACEi in renal artery stenosis NSAIDs inhibition of prostaglandin synthesis in states of renal hypoperfusion

GI = Gastrointestinal; NG = Nasogastric; ACEi = Angiotensin converting enzyme inhibitors; NSAIDs = Nonsteroidal anti-inflammatory drugs.

Intrinsic Renal Failure

Acute tubular necrosis (ATN) is the commonest renal lesion in patients with intrinsic renal failure and may result from severe renal hypoperfusion (untreated pre-renal AKI) or nephrotoxic injury. Ischaemic ATN is more likely to occur in patients with trauma, major surgery, severe burns, severe hypovolaemia and overwhelming sepsis. On the other hand, nephrotoxic injury results from several drugs and toxins. **Table 3** shows the major causes of intrinsic AKI.

Post-Renal Acute Kidney Injury

Obstruction to urine flow may occur at the urethral meatus or bladder neck, both ureters or from obstruction to a single

functioning kidney. Less than 5% of AKI is consequent to obstructive causes. **Table 4** shows the causes of post-renal AKI.

Table 3: Major Causes of Intrinsic Acute Kidney Injury

Large Vessel Disease (Bilateral)
- Artery: Thrombosis, embolism/atheroembolism, aortic dissection involving renal arteries, Takayasu's aortoarteritis
- Vein: Thrombosis

Glomerular Disease
- Inflammatory: Acute or rapidly progressive glomerulonephritis, vasculitis, radiation
- Vasospastic: Malignant hypertension, scleroderma
- Haematologic: Haemolytic-uraemic-syndrome or thrombotic thrombocytopaenic purpura, DIC, hyperviscosity syndromes

Injury to Renal Tubule Acute Tubular Necrosis (ATN)
- Ischaemia
- Toxins
  - Exogenous: Antibiotics, anticancer agents, radiocontrast media
  - Endogenous: Myoglobin, haemoglobin, light chains, uric acid, tumour lysis

Acute Tubulointerstitial Disease
- Allergic interstitial nephritis (antibiotics, NSAIDs)
- Infections (bacterial, leptospirosis, fungal)
- Acute renal allograft rejection
- Infiltration (lymphoma, leukaemia)

DIC = Disseminated intra-vascular coagulation; NSAIDs = Nonsteroidal anti-inflammatory drugs.

Table 4: Causes of Post-Renal Acute Kidney Injury

Obstruction	Site	Cause
Ureteric	Intra-luminal	Stones, blood clot, sloughed renal papilla, uric acid/sulfa crystals, fungus balls, tumour
	Intra-mural	Oedema after ureteric surgery, ureteric fibrosis
	Extra-ureteric	Accidental ligation during pelvic surgery
Bladder neck	Intra-luminal	Stones, blood clot, sloughed renal papilla
	Intra-mural	Bladder cancer, infection with mural oedema, neurogenic bladder
	Extra-mural	Prostatic hypertrophy, prostate cancer
Urethral		Phimosis, congenital valves, stricture

AETIOLOGY

AKI is becoming increasingly prevalent, both in the developing and the developed countries. The incidence of AKI varies considerably depending on the selected definition of AKI and the population reported on. Differences do exist between AKI in the developed as compared to developing countries with predominantly 'hospital-acquired AKI' being reported by the former while 'community-acquired AKI' is commoner in the developing countries. In the developed world, trauma and surgery precede the onset of AKI in 60% of cases. In contrast, drugs and toxins (18% to 33%), medical disorders (30% to 35%) and gynaeco-obstetric complications (5% to 10%) account for AKI in the developing countries. In tropical countries, medical causes predominate (60% to 67%) with specific infections such as *falciparum malaria* being particularly common. Severe malaria, leptospirosis, dengue haemorrhagic fever, hantavirus nephropathy, complications of human immunodeficiency virus/acquired immunodeficiency syndrome, shigellosis and snake envenomation are frequent causes of AKI. In tropical regions, AKI related to toxicity of herbal and non-herbal products is also encountered.

PATHOGENESIS AND PATHOLOGY

A multi-phase process (hypoperfusion, injury initiation, maintenance and repair) characterises the development of ischaemic ATN. Histologic changes include effacement and loss of proximal tubule brush border, patchy loss of tubule cells, focal areas of proximal tubule dilatation, distal tubule casts, and areas of cellular regeneration that appear during the phase of recovery of renal function. The functional loss, however, is usually more prominent than the severity of the histologic changes. Necrosis is restricted to the outer medullary regions.

Increased sodium chloride delivery to the macula densa of individual nephrons (glomerular filtration with impaired proximal and loop reabsorptive function) activates the tubuloglomerular feedback mechanism causing afferent arteriolar constriction, which lowers the GFR in an attempt to reduce tubule flow rate. Backleak of filtered tubular fluid may occur across the damaged tubule epithelium.

Intra-tubular obstruction by cells and casts is also an important component of ATN. The intra-luminal casts are composed, in part, of Tamm-Horsfall protein, which is converted into a gel-like polymer in the setting of high local luminal sodium concentrations which is the characteristic of ATN.

CLINICAL AND LABORATORY EVALUATION

In patients with AKI, an in-depth history, detailed physical examination and urinalysis, careful review of all medical records and drug history, selective use of laboratory tests and renal imaging, evaluation of the response to fluid repletion and, at times, a renal biopsy, may help to uncover the cause of the renal dysfunction (**Table 5**). CKD also needs to be distinguished from AKI by features listed in **Table 6**. The use of certain indices helps in differentiation between pre-renal and intrinsic AKI (**Table 7**).

Table 5: Clinical and Laboratory Evaluation of Acute Kidney Injury

Detailed history (including drug/intervention history; review of medical records, physical examination [weight and fundoscopy])
Urinalysis: Routine and microscopic
Routine blood chemistry (BUN, creatinine, electrolytes, HCO_3, Ca, PO_4)
Complete haemogram
Special tests: Urine for eosinophila, Bence-Jones protein
Serology: ANA, ANCA, anti-GBM, complement, cryoglobulins, protein electrophoresis, ASO
Imaging: Renal ultrasound, plain radiograph of abdomen, computed tomographic urography
Renal biopsy

BUN = Blood ureo nitrogen; HCO_3 = Bicorbonote; Co = Colcium; PO_4 = Phosphote; ANA = Anti-nucleor ontibody; ANCA = Anti-neutrophil cytoplosmic ontibody; GBM = Glomerular bosement membrone; ASO = Anti-streptolysin O.

Table 6: Differentiating Acute Kidney Injury (AKI) from Chronic Kidney Disease (CKD)

Feature	AKI	CKD
Antecedent history of renal disease	Absent	Present
Prior sustained elevation of creatinine for >3 months	Absent	Present
Anaemia	Usually absent at onset	Present
Elevated serum phosphorus, decreased serum calcium, elevated serum PTH	Absent (in early phase)	Present
Neuropathy	Absent	Present
Band keratopathy	Absent	Present
Renal bone disease	Absent	Present
Small kidneys on sonography	Absent	Present (in some kidney diseases normal/ large sizes)
Tolerance to azotemia, acidosis	Absent	Present
Stability of azotemia	Absent (daily rise)	Present

Table 7: Differentiating Between Pre-renal and Intrinsic Acute Kidney Injury (AKI)

Diagnostic Index	Pre-renal (AKI)	Intrinsic (AKI)
Urinary Na^+ concentration (mEq/L)	<20	>40
Fractional excretion of Na^+ (%) (UNa × PCr/PNa × UCr) × 100	<1	>1
Urinary urea nitrogen/Plasma Urea nitrogen ratio	>8	<3
Urinary creatinine/ratio	>40	<20
Urine osmolality (mOsm/kg H_2O)	>500	<250
Blood urea nitrogen/creatinine ratio	>20	<10 to 15
Renal failure index (UNa/UCr/PCr)	<1	>1
Urine sediment	Normal	Granular casts and tubule epithelial cells

Newer Biomarkers in Acute Kidney Injury

Serum creatinine represents a poor biomarker (acute decline in kidney function may not be reflected by a rise in serum creatinine for several hours). Analytical interference (variation in reported creatinine concentrations using differing methods reflect calibration differences) and imprecision point to a need for better, alternative biomarkers (serum and/or urinary). Neutrophil gelatinase-associated lipocalin (NGAL), kidney injury molecule-1 (KIM-1), interleukin-18 (IL-18), and cystatin C are being evaluated in a number of studies for their utility in detecting AKI in different patient cohorts. However, it would still be premature to use them in clinical settings.

TREATMENT

Pharmacological therapies to shorten the course of AKI hitherto have been unsuccessful. The rationale for the use of loop diuretics lies in their capability to reduce energy requirements of the cells of the ascending limb of loop of Henle, ameliorating ischaemic damage. Conversion of oliguric to non-oliguric AKI facilitates the management of fluid and electrolyte disturbances and reduces the requirement for renal replacement therapy.

Significant metabolic/immunologic disturbances, induction of a pro-inflammatory state exacerbated by malnutrition mandates provision of appropriate nutritional support in an attempt to improve outcomes. Nutritional recommendations should consider the cause of AKI and prefer the enteral route. A provision of a nutritional prescription of 25 to 35 kcal/kg/day and up to a maximum of 1.7 g amino acids/kg/day, especially in hypercatabolic patients is essential. Trace elements and water-soluble vitamins should be supplemented as required. Fluid and potassium intake need to be restricted in oliguric patients.

Treatment of Complications

AKI is associated with an inability of the body to maintain homeostasis, derangements in electrolyte and water metabolism, divalent homeostasis and acid-base balance. The commonly encountered complications are shown in **Table 8**. Indications for initiation of RRT are shown in **Table 9**.

Table 8: Complications of Acute Kidney Injury

Complications	Manifestations
Metabolic	Hyperkalaemia Hypocalcaemia Hyperphosphataemia Hypermagnesaemia Hyperuricaemia Metabolic acidosis (increased anion gap)
Cardiovascular	Cardiac arrhythmias Pulmonary oedema Pericarditis/pericardial effusion
Gastrointestinal	Gastrointestinal haemorrhage
Neurologic	Altered sensorium Seizures
Haematologic	Anaemia Bleeding
Miscellaneous	Infections (pneumonia, urinary tract infection, septicaemia)

Table 9: Indications for Renal Replacement Therapy in Patients with Acute Kidney Injury

Biochemical Indications	Clinical Indications
Refractory hyperkalaemia (>6.5 mEq/L)	Urine output <0.3 mL/kg for 24 hours or
Metabolic acidosis (pH ≤7.10)	Absolute anuria for 12 hours
Electrolyte disturbances (hypercalcaemia)	Multiple organ failure
Tumour lysis syndrome (hyperuricaemia/ hyperphosphataemia)	Volume overload Pericarditis, encephalopathy, uraemic bleeding

The choice of the RRT modality should be guided by the individual patient's clinical status, medical and nursing expertise and availability of modality. Intermittent haemodialysis (IHD) is the standard form of therapy. Slow low efficiency haemodialysis is superior to IHD in haemodynamically unstable patients. Peritoneal dialysis may be used in the setting of a non-hypercatabolic AKI and in children.

PREVENTION OF ACUTE KIDNEY INJURY

AKI may develop if risk factors exist, viz. age >75 years, pre-existing CKD (eGFR <60 mL/min/1.73 m^2), cardiac failure, atherosclerotic peripheral vascular disease, liver disease, diabetes mellitus, nephrotoxic medications, hypovolaemia and sepsis.

Appropriate and adequate fluid replacement, optimisation of haemodynamic status, if necessary with inotrope/vasopressor administration, management/prevention of sepsis are essential components of prevention. Nephrotoxic medications should be stopped in patients at risk of developing AKI. Drug doses need to be adjusted depending on severity of kidney dysfunction to reduce toxicity.

Patients who are identified as being at risk of contrast induced-AKI should receive pre-procedure volume expansion with 0.9% sodium chloride or isotonic sodium bicarbonate. Low osmolar agents are associated with a decreased risk of nephrotoxicity as compared to the high osmolar agents. The dose of contrast media should be minimised. N-acetylcysteine should also be given prior to the procedure.

19.4 Chronic Kidney Disease

Ashok L Kirpalani, Hardik Shah

DEFINITION AND CLASSIFICATION OF CHRONIC KIDNEY DISEASE

The world is currently facing a global epidemic of chronic kidney disease (CKD). As morbidity and mortality from infectious diseases has declined, life-expectancy has increased and chronic degenerative diseases have become more prevalent. CKD is unique amongst the chronic non-infectious illnesses in that, there is a very real window of opportunity to continue living comfortably in spite of being terminally ill. The duration of artificial prolongation of life is largely proportional to the financial resources of the patient and/or his provider. The beneficiary patient, however, is a very severe drain on the economy of his provider. In developing countries like India, it is usually the family that shoulders an immense financial burden. An insignificant percentage of the patients of CKD are supported by the government, employers or insurance companies. Whosoever is picking up the 'tab', the financial burden of the end-stage renal disease (ESRD) population is fast becoming unmanageable for the provider—be it government, family, employers, charitable organisations or insurers. It is, therefore, the need of the hour to tackle this problem not at the therapeutic end of this disease but at the 'preventable' beginning of it. The nephrology community realises this urgent need because of the severe resource crunch, not only of funds, but also of qualified nephrologists and dialysis infrastructure.

The National Kidney Foundation (NKF) of USA and the European Renal Association (ERA) have enunciated a new name for chronic renal failure; defined the stages of CKD and published the guidelines for appropriate interventions for 'preventing' CKD and its progression at each stage.

WHY RENAME CHRONIC RENAL FAILURE?

The word 'renal' is not easily understood by the lay public whereas the name 'kidney' is generally well understood. The concept of 'failure' is no longer apt for a disease which has seen much medical success by way of intervention in slowing its progression from its first stage to the final 'end-stage'.

DEFINITION OF CHRONIC KIDNEY DISEASE

The National Kidney Foundation-Kidney Disease Outcomes Quality Initiative (NKF-KDOQI) working group has defined CKD as given below, which has been accepted and adopted internationally:

1. The presence of markers of kidney damage for more than 3 months, as defined by structural or functional abnormalities of the kidney with or without decreased glomerular filtration rate (GFR), manifest by either pathological abnormalities or other markers of kidney damage, including abnormalities in the composition of blood or urine, or abnormalities in imaging tests; or
2. The presence of GFR less than 60 mL/min/1.73 m^2 for more than 3 months with or without other signs of kidney damage as described above.

Furthermore, 5 stages of chronic kidney disease have been defined as shown in **Table 1**.

Table 1: Stages of Chronic Kidney Disease*

Stage	Description	GFR
1	Kidney damage with normal or ↑ GFR	≥90 mL/min
2	Kidney damage with mild ↓ in GFR	60 to 89 mL/min
3	Moderate ↓ in GFR	30 to 59 mL/min
4	Severe ↓ in GFR	15 to 29 mL/min
5	Kidney failure	<15 mL/min, or patient on dialysis

**Adapted from NKF-KDOQI guidelines on chronic kidney disease. GFR = Glomerular filtration rate.*

Recently, CKD stage 5 has been further subclassified into stage 5D if a patient is on dialysis or 5T, if the patient has undergone kidney transplantation. If kidney function deteriorates post kidney transplant, the patient can be grouped into stage 5T-1 to stage 5T-4 as per the GFR criteria above.

Moreover, stage 3 CKD has been further divided into stage 3A (GFR 45 to 59 mL/min) and stage 3B (GFR 30-44 mL/min), since those in stage 3B are far more likely to progress to stage 5 than those in stage 3A.

In India, the Indian Society of Nephrology (ISN) has developed a CKD registry wherein epidemiological data of CKD patients is collected and analysed. A recent report of this registry shows that patients first presented to a nephrologist at stage 5 in 47.5%, stage 4 in 25.5%, stage 3 in 19.6%, stage 2 in 4.9% and stage 1 in 2.5%. It is very unfortunate that 50% of patients present for the first time to a nephrologist in CKD stage 5, when they cannot be offered anything more than dialysis or transplantation. It should be the endeavour of all treating physicians, particularly the internists, to pick up most of the CKD population much earlier in stages 1 and 2, when much more can be offered to slow down its progression. In fact, the target of prevention should be stage 0, i.e. the population at risk. The population 'at risk' for development of CKD is listed in **Table 2**.

Before proceeding further an important query must be answered: do these Western criteria accurately apply to the Indian population? The NKF (USA) data, upon which this classification has been made, is based on a heterogeneous population but would still have a bias towards white and black population. The people of the Indian subcontinent are ethnically different, particularly in body weight, muscle mass and dietary habits. Physicians who have evaluated the

normal Indian population for GFR, particularly of normal living donors for fitness for organ donation, have reported unexpectedly low creatinine clearance values in otherwise disease-free people. This appears to be related to low protein intake. The average per capita protein intake in the developed world is 50% higher than in the developing world (105 g vs 57.3 g).

Table 2: Population at Risk for Developing Chronic Kidney Disease

Age >65 years
Diabetes type 1 and 2
Family history of renal disease
Autoimmune disease
Systemic infections
Urinary tract infections/stones
Urinary tract obstructions
Recovery of acute kidney injury
Hypertensives
Drug abusers: Nonsteroidal anti-inflammatory drugs, analgesics/ heroin
Neoplasia
Low birth weight
Reduced kidney mass

In vegetarians, who consume neither milk nor eggs, the protein intake can be 20% to 40% less than in lacto-ovo-vegetarians. Studies have demonstrated an acute and delayed increase of GFR following oral protein loading which can also be duplicated by intravenous aminoacid loading. These studies confirm that vegetarianism results in a low GFR which can be stimulated by ingestion of a large protein meal. An infusion of amino acids mimics a large protein meal and the resultant increase in GFR has been called the 'renal reserve', which may be as high as 80% to 100% of the baseline value.

Chronically decreased GFR in the absence of kidney damage is a phenomenon much more likely to be found in our Indian population, where a large percentage of the population are vegetarian and even among those who are non-vegetarian, since meals are predominantly 'non-meat' in content and frequency.

There are other causes of chronically decreased GFR, such as unilateral nephrectomy, extra-cellular fluid volume depletion and systemic illness such as heart failure and liver cirrhosis. The patient with GFR between 60 and 90 mL/min, therefore, presents in the grey zone. When presented with this situation, the clinician can only diagnose CKD if the other markers of kidney damage, such as urinary abnormalities, pathological appearance or hypertension are also present.

AETIOPATHOLOGY OF CHRONIC KIDNEY DISEASE

Table 3 classifies CKD by aetiopathology. The relative incidence of the common causes, i.e. diabetes, hypertension, glomerulonephritis, interstitial nephritis, cystic or hereditary diseases are shown among the various races. In all races, diabetic glomerulosclerosis appears to be the commonest (**Table 4**).

Table 3: Classification of Chronic Kidney Disease by Pathology and Aetiology

Pathology	Aetiology
Diabetic glomerulosclerosis	Diabetes mellitus (type 1 & 2)
Glomerular diseases (primary or secondary)	Largely unknown
Proliferative glomerulonephritis	Systemic lupus erythematous, vasculitis, hepatitis B or C, human immunodeficiency virus (HIV) bacterial endocarditis
Minimal change disease	Hodgkin's disease
Focal glomerular sclerosis	HIV, heroin toxicity
Membranous nephropathy	Drug toxicity, solid tumours
Fibrillary glomerular diseases	Amyloidosis, light chain disease
Hereditary nephritis	Alport's syndrome
Vascular diseases	
Diseases of large size vessels	Renal artery stenosis, aortoarteritis
Diseases of medium size vessels (nephrosclerosis)	Hypertension
Diseases of small vessels (microangiopathy)	Haemolytic uraemic syndrome, vasculitis, sickle cell disease
Tubulointerstitial diseases	
Tubulointerstitial nephritis	Infections, drugs, sarcoidosis
Reflux nephropathy	Vesico-ureteric reflux
Obstructive nephropathy	Stones, prostatism, malignancy
Myeloma kidney	Multiple myeloma
Cystic diseases	
Polycystic kidney disease	Autosomal dominant or recessive
Tuberous sclerosis	
Von-Hippel-Lindau disease	
Medullary cystic disease	

Table 4: Incidence and Prevalence of Various Types of Chronic Kidney Disease*

Aetiology	Whites*	Blacks*	Asian-Americans*	Indians**
Diabetes mellitus	43.5%	42.1%	42.6%	31.2%
Hypertension	24.0%	32.9%	23.5%	14.1%

INTERVENTIONS IN CHRONIC KIDNEY DISEASE

The goals of proposed interventions are listed in **Table 5**. Of all these interventions, early detection and the successful delaying of progression, fall in the purview of the entire medical community. It is this one intervention which can result in reducing the incidence of CKD.

The patient may present at stages 0-1 to any doctor, except the nephrologist. If the doctor is ignorant of this disease, the moment of opportunity that presents at this stage is missed,

which can be in the form of antenatal foetal sonography; maternal antenatal care in the antenatal clinic; pre- school and yearly school health check-ups; pre-employment and pre-military health check-ups; pre-insurance health check-ups; pre-operative check-ups; periodical medical examination popularly known as 'executive health check-up' quite popular nowadays in the big metros. Diabetic clinics are one example of screening patients 'at risk'. Similarly 'hypertension' clinics are now available.

Waiting for these 'moments' of opportunity has the inherent limitation that many 'silent' cases would be undetected until the late irreversible stages are reached. It is, therefore, necessary to take the initiative to pick up those silent cases actively at the community level and the individual level.

Table 5: Proposed Interventions (Primary Prevention and Strategies for Delaying Progression to Next Stage)

Strategies for Delaying Progression to Next Stage	Goals
ACE inhibitor or ARB or both	Proteinuria <0.5 g/day and GFR decline <2 mL/min/year
Additional antihypertensive as needed	BP <130/80 if proteinuria <1 g/day and BP <125/75 if proteinuria >1 g/day
Dietary protein restriction	0.6 to 0.8 g/kg/day (caution in vegetarians)
Glycaemic control	HbA1c <7%
Cholesterol lowering therapy	LDL <100 mg/dL
Anaemia correction	Target Hb 10 to 12 g/dL
Dietary salt restriction	3 to 5 g/day (except in salt wasting states)
Smoking cessation	
Weight control	Ideal body weight
Reduce elevated Ca x PO_4	Keep Ca and PO_4 at normal levels
Avoid nephrotoxic drugs	product

Delay/treat co-existing cardiovascular abnormalities.

Prepare for impending ESRD physically, emotionally and socioeconomically by:

- *Early placement of vascular access (AV fistula) or peritoneal dialysis (CAPD) catheter.*
- *Educate patient and family about renal replacement therapy (RRT) options.*
- *Explain financial implications.*

Initiate timely RRT, i.e. renal transplant, maintenance haemodialysis or peritoneal dialysis.

Community Initiatives

The entire population of the village is screened by house-to-house visits of health care workers over a period of time. During the visit, the health care worker takes history, checks blood pressure (BP) and conducts a urine examination of every family member. Suspected cases are then sent to the referral hospitals.

The Kidney Disease Early Evaluation and Prevention (KEEP) projects of the NKF (USA) and Screening and Early Evaluation of Kidney disease (SEEK) of India are both very similar in design. These projects function by setting up kidney detection camps periodically all over the nation and inviting normal persons to come and get investigated for detection of stage 0 or 1 CKD.

An exhaustive screening of the individual should consist of history including all symptoms with relation to urine characteristics, particularly for haematuria and frothing of urine, urine flow, fluid retention, oedema, BP, diabetes, past and family history of all predisposing conditions included in stage 0.

Physical examination focussing particularly on BP, oedema, signs of congestive heart failure (CHF), per abdomen examination including genitalia should be done.

Laboratory tests should include urine for protein, sugar and microscopic examination particularly for haematuria and pyuria; serum creatinine estimation and GFR.

The level of GFR is a strong predictor of the 'time-to-onset' of ESRD as well as the risk of CKD. However, GFR cannot be measured directly, the amount of a physiological, freely filterable and non-secreted or metabolised solute, such as inulin, in the urine is an indirect marker of the amount filtered at the glomerulus. The most widely used measures of GFR are based on the 24 hours creatinine clearance or serum creatinine concentration.

Serum creatinine and creatinine clearance

Creatinine is mainly derived from metabolism of creatinine in muscle and its generation is proportional to the total muscle mass. Creatinine generation is higher in men, younger individuals and in blacks than in whites. A difference in serum creatinine according to age, gender, race, and protein intake exists. Moreover, the traditional method of serum creatinine estimation (alkaline picrate method) also detects non-creatinine chromogens compared to modern autoanalysers leading to lab variations in serum creatinine and over estimation of GFR when compared by the latter method. Substances like ketones and bilirubin may lead to spuriously elevated and decreased creatinine, respectively.

The amount of creatinine excreted in the urine is a composite of both the filtered and the secreted creatinine. Creatinine clearance over-estimates GFR by 10% to 40% in normal individuals, and is greater and more unpredictable in patients with CKD. As much as two-third of the total daily creatinine excretion can occur by extra-renal elimination in patients with severely reduced kidney function.

The normal level of GFR varies according to age, gender and body size. After the age of 20 to 30 years, the GFR declines at the rate of 1 mL/min/1.73m^2. Thus, by the age of 70, it is approximately 70 mL/min/1.73m^2. In the Indian population, a comparatively lower creatinine excretion can be expected due to relatively lower muscle mass.

The usual method of estimating GFR in clinical practice by collection of the 24-hour urinary sample with estimation of its creatinine content and using the formula given below:

Creatinine clearance = uv/p, with correction for body surface area of 1.73.

Some other major drawbacks of this method are inaccurate collection (samples thrown away, timing is wrong, urine passed with faeces is lost, most patients do not understand the collection process as also many of the laboratory or ward staff designated to do this); it is laborious, obnoxious due to smell, messy and time consuming; and it has been shown that the prediction equations described hereafter are equally accurate and much easier to use in clinical practice (**Table 6**).

Table 6: Estimating the Creatinine Clearance from Prediction Equations (The eGFR)

Cockroft-Gault equation

Cr. Cl (mL/min) = (140 – age) x weight/72 x S. Cr (x 0.85, if female)

MDRD, Serum variables

GFR (mL/min/1.73 m^2) = 170 x (S. Cr)-.999 x (Age)-0.176 x (SUN)-0.170 x (Alb)-0.318

x 0.762, if female

x 1.180, if black

Schwartz formula (in children)

Cr. Cl (mL/min) = 0.55 x length / S. Cr

The value of eGFR is illustrated in the example below:

A 62-year-old lady, height 155 cm, weight 50 kg, has a S. Cr of 1.1 mg/dL. Her eGFR by Cockroft-Gault formula is 42 mL/min.

A 24 year old man, height 170 cm, weight 65 kg, has S. Cr of 1.1 mg/dL. His eGFR is 95 mL/min.

If the eGFR had been overlooked, the lady would be considered normal, but by the CKD criteria, she is already in CKD stage 3, irrespective of her urinalysis findings

Cr. Cl = Creatinine clearance; MDRD = Modification of diet in renal disease; SUN = Serum urea nitrogen; Alb = Albumin; CKD = Chronic kidney disease; S. Cr = Serum creatinine.

Cystatin C

Cystatin C, a protein encoded by CST3 gene, has low molecular weight of 13.3 kilodaltons and is removed from the bloodstream by glomerular filtration as a single pass. Subsequently, it is metabolised in the tubules and does not appear in urine. Serum cystatin C levels are now accepted as an alternate method for estimating glomerular function. The need for an alternate method to serum creatinine arises because of the limitations of serum creatinine estimation particularly in children, small sized adults with poor muscle mass, pregnant women and renal transplant recipients. In such patients, creatinine value increases within the accepted range of 0.6 to 1.2 mg/dL are not indicative of the magnitude of fluxes in GFR and the treating physician is likely to fail to pick up an alarming reduction in GFR before it is too late to take remedial measures. The serum cystatin C levels have best been validated in these situations as an alternate method of evaluating renal function. The cost, however, is prohibitive presently as very few laboratories in India offer this test. As the substance does not come in the urine, there is no way of doing a cystatin clearance similar to creatinine clearance. Formulas for estimating GFR from serum cystatin levels are available, but beyond the purview of this text.

Guidelines for GFR Estimation

Blood urea is a poor estimate of GFR. Serum creatinine should not be used alone as an estimation of renal function. Creatinine clearance by timed urine collections or prediction equations provides additional information in defining and staging CKD. Every laboratory should supply estimated GFR by prediction equations using one of the two available adult/child formulae derived from serum creatinine, adjusting for age, sex and body mass index. Timed urinary collections of creatinine clearance may be reserved for the specific circumstances outlined in the text. Isotopic methods of GFR estimation may be used as confirmatory tests in confusing circumstances.

CLINICAL PRESENTATION OF CHRONIC KIDNEY DISEASE

The signs, symptoms and metabolic derangements of CKD may be either due to alteration of the normal homoeostatic functions of the kidney, or accumulation of the nitrogenous end-products of protein catabolism, i.e. the uraemic toxins which produce the clinical syndrome of 'uraemia' (**Table 7**).

Table 7: Clinical Presentations of Chronic Kidney Disease

Clinical Presentation	GFR (mL/min/ 1.73 m^2)	Proteinuria	Urine Sediment	Imaging Studies	Other Features
Decreased GFR	15 to 89	NA	NA	NA	Complications due to reduced GFR
Kidney failure (ESRF)	<15 or treated by dialysis	NA	NA	NA	Uraemia
Hypertension due to kidney disease	NA	±	±	Depending on aetiology	HBP

ESRF = End-stage renal failure; NA = Not available.

Clinical effects of abnormal physiology not attributable to accumulation of nitrogenous wastes are given in **Table 8**.

Table 8: Clinical Effects of Abnormal Physiology not Attributable to Accumulation of Nitrogenous Wastes

- Deranged renin angiotensin aldosterone axis
  - Hypertension
- Water and salt homoeostasis derangement
- Oedema
- Dehydration
- Congestive heart failure
- Hypertension
- Hypo- and hyper natraemia
- Potassium homoeostasis
  - Hypokalaemia
  - Hyperkalaemia
- Acid-base disturbances
  - Metabolic acidosis
- Bone, calcium and phosphorus metabolism
  - Renal bone disease
  - Extra-osseous and vascular calcification
- Erythropoietin deficiency
  - Anaemia
- Insulin metabolism
  - Hypoglycaemia
  - Hyperglycaemia
- Other endocrinopathies
  - Amenorrhoea
  - Sterility
- Growth failure

EFFECTS OF ALTERED HOMEOSTATIC RENAL FUNCTIONS

Hypertension in Chronic Kidney Disease

Secondary hypertension is a result of CKD and may result from renal vascular or parenchymal pathology. **Table 9** shows the relationship of hypertension to stages of CKD.

Table 9: Stages of CKD and Relationship with Hypertension

GFR (mL/min/1.73 m²)	With Kidney Damage		Without Kidney Damage	
	With HBP	Without HBP	With HBP	Without HBP
>90	1	1	High blood pressure	Normal
60 to 89	2	2	High blood pressure With decreased GFR	Decreased GFR
30 to 59	3	3	3	3
15 to 29	4	4	4	4
<15 (or dialysis)	5	5	5	5

HBP = High blood pressure.

Note: The 'grey' shaded areas in this table represent high blood pressure (BP) alone, high BP with low GFR (60-90 mL/min) and low GFR (60-90 mL/min) without high BP.

These categories include patients with essential hypertension with target organ renal damage (nephrosclerosis) or just low GFR associated with old age. The presence of other target organ damage, such as retinal changes, diastolic dysfunction, left ventricular hypertrophy or a history of cardiovascular events or cerebrovascular accidents, would help to differentiate one from the other. Although not strictly CKD, such patients would best deserve intervention just like CKD stages 1 and 2.

The kidneys regulate BP by renal salt and water excretion as well as by autoregulation involving the renin-angiotensin aldosterone axis. With deranged renal function, hypertension results either from renin-angiotensin and aldosterone excess or volume expansion due to failure to excrete salt and water. In addition, there may be contributions by pre-existing essential hypertension, increased sympathetic activity, altered prostaglandin/bradykinin/nitric oxide/endothelin homeostasis; parathyroid hormone/hypercalcaemia/intracellular calcium disturbance and calcification of the vasculature; drugs producing hypertension like erythropoeitin, cyclosporine, tacrolimus and steroids may also contribute. The hypertension of CKD can vary from mild to malignant and is sometimes difficult to treat. Many patients require two or more drugs having different pharmacological actions.

Water Balance

As kidneys deteriorate the ability to concentrate and dilute the urine in states of dehydration and overhydration, respectively, is lost. As a result, the patient may present with polyuria and nocturia or with oliguria and oedema. This defect results in a fixed urine specific gravity also known as isosthenuria (specific gravity = 1.010) both in dehydrated and in overhydrated states. The nocturia also causes overnight volume depletion and worsening uraemic symptoms, particularly nausea, and vomiting, known as 'morning sickness of uraemia'. A 200 mL glass of water at bed-time will help overcome this symptom.

As renal function deteriorates further and GFR approaches levels seen in stage 5, some patients become oliguric and develop oedema and CHF. Once the patient is initiated on dialysis, the urine output gradually tends to decrease with time.

Sodium

The sodium balance behaves similar to water. Most patients will have a mild-to-moderate overload of total body salt and water, until they reach CKD stage 5 when they will manifest gross sodium overload. Total body sodium overload will manifest as oedema and hypertension causing the intravascular compartment to be expanded. The patient with nephrotic syndrome will have extravascular volume overload due to total body sodium overload, but their intravascular volume is contracted when there is severe hypoproteinaemia. The fluid in this situation will accumulate in the subcutaneous tissues and the body cavities causing ascites and hydrothorax.

A few patients have true sodium deficit which is due to salt wasting states like interstitial nephritis. More often, however, this is due to non-renal factors such as fever, vomiting, diarrhoea and excessive diuretic use. Such patients present with thirst, dry mucus membranes, sunken eyeballs and fontanelles, orthostatic syncope, hypotension and tachycardia. Recognising this state is vital because correction by salt and water repletion can result in reversal of acute on chronic renal failure, a most satisfying result for both the patient and the treating physician.

Potassium

Hyperkalaemia is a life-threatening emergency but occurs only when there is oliguria. The non-oliguric patients will manifest hyperkalaemia when there is a concomitant metabolic acidosis, e.g. diabetic acidosis, biguanide misuse, renal tubular acidosis type 4 (hyporeninaemic hypoaldosteronism commonly seen in early diabetic nephropathy), large dietary overload of potassium and drugs like angiotensin converting enzyme inhibitors and angiotensin receptor blockers, potassium sparing diuretics like spironolactone, eplerenone, amiloride, calcineurin inhibitors like cyclosporine, tacrolimus, or beta-blockers and nonsteroidal anti-inflammatory drugs.

Hypokalaemia is usually iatrogenic due to diuretic use or from gastrointestinal losses. It may also be due to secondary hyperaldosteronism due to hyper-reninaemia of kidney disease.

Acid-Base Disorders

The kidneys excrete H^+ ions by the process of glomerular filtration and by tubular secretion of titrable acid and ammonia. The patient with early CKD has a normal anion gap acidosis with hyperchloraemia. Later, the chloride levels become normal and the accumulation of anions like phosphate, urate, hippurate and sulphate cause an increased anion gap and plasma bicarbonate levels between 14 and 20 mEq/L. Chronic acidosis also stimulates cytokine production and enhances malnutrition and protein catabolism. The bones in chronic renal acidosis will buffer hydrogen ion at the cost of calcium and phosphorus and this weaken the bones. In children, acidosis reduces growth hormone secretion and reduces stature. Appropriate alkali repletion is very useful in combating the effects of acidosis.

ENDOCRINE DYSFUNCTION OF CHRONIC KIDNEY DISEASE

Anaemia

Anaemia in CKD is due to deficient erythropoietin synthesis and is usually seen in CKD stage 3 and later. It is normochromic and normocytic. Anaemia seen in stages 1 and 2 is usually due to some other cause such as iron, B12, folate deficiency. It may also be a concomitant manifestation of the original multisystem disorder involving kidneys such as systemic lupus erythematous,

myeloma or haemolysis of haemolytic uraemic syndrome or paroxysmal nocturnal haemoglobinuria. Patients with adult polycystic kidney disease may not manifest anaemia as early as other CKD due to relatively high erythropoietin levels.

Deranged Carbohydrate Metabolism

Insulin, which is synthesised in the pancreas, is degraded by the proximal tubular cells of the kidneys. Prolonged insulin half-life due to impaired degradation has an effect of enhancing insulin levels, and therefore, relatively lowering blood glucose levels. The diabetic with incipient nephropathy often first presents to the nephrologist with recent onset of hypoglycaemic attacks or reduction in requirements of insulin or oral hypoglycaemic agents. Non-diabetic CKD patients often have mildly elevated blood glucose levels and impaired glucose tolerance which usually does not require therapeutic reduction of blood glucose.

Calcium, Phosphorus and Bone Metabolism

There is failure to excrete phosphorus, defective conversion of 25 $(OH)D_3$ to $1,25(OH)_2D_3$ which are the two most important physiological impairments that lead to renal bone disease.

At the cellular level there is defective bone which could be high due to increased PTH (i.e. hyperparathyroidism) or low due to decreased PTH (adynamic bone disease); or impaired matrix mineralisation as seen in osteomalacia or rickets (in children).

The commonest symptoms of bone disease, whatever their pathogenesis and histology are bone pains. The intensity of pain may be crippling enough to leave the patient bedridden and immobile, or trivial, requiring occasional pain medications. Pathological fractures may occur with trivial injury or spontaneously.

The altered calcium and phosphorus metabolism has extra-osseous manifestations. The accelerated coronary calcification due to an elevated calcium-phosphorus product has been dealt with later in this chapter. The elevated parathormone level is attributed the role of being a uraemic toxin. The manifestations of altered calcium, phosphorus and bone metabolism are first seen in CKD stage 3.

Uric Acid Accumulation and Gout

Renal dysfunction produces hyperuricaemia but this seldom causes secondary gout. The use of diuretics exacerbates hyperuricaemia. It is debatable whether there is a need to treat hyperuricaemia in the absence of clinical gout since this may also contribute to progression of CKD.

Dyslipidaemia

Dyslipidaemia is triggered by proteinuria and hypo-proteinaemia. It is mostly severe in the nephrotic syndrome but also seen in CKD manifesting otherwise.

CHRONIC KIDNEY DISEASE AND THE HEART

Recent focus on early CKD has shown that even patients of CKD stages 1 to 4 have a much higher cardiovascular morbidity and mortality. The CKD Registry of India showed that 28.7% patients in CKD stage 4 and as many as 48.5% patients in CKD stage 5 had prevalent cardiovascular disease.

The contributing factors to pathogenesis are hypertension, anaemia, uraemic cardiomyopathy, accelerated atherosclerosis associated with microalbuminuria, hyperlipidaemia (total cholesterol and high LDL+VLDL), cardiac calcification due to hyperparathyroidism, high phosphorus and high calcium - phosphorus product, high homocysteine levels and high C-reactive protein, hypoalbuminaemia and malnutrition producing a state of microinflammation.

Only a fraction of CKD patients reach stage 5 because of cardiovascular mortality and other natural causes of death. Prevention in CKD must therefore, encompass efforts to reduce cardiovascular morbidity and mortality in CKD stages 1 to 4, modifying the risk factors which lead to it.

Manifestations attributable to uraemic toxins are enumerated in **Table 10**.

Table 10: Manifestations Attributable to Uraemic Toxins

Cardiovascular system	
	Atheroma
	Arteriosclerosis
	Cardiomyopathy
	Decreased diastolic compliance
	Pericarditis
Nervous system	
	Concentration disturbances
	Cramps
	Dementia
	Depression
	Fatigue
	Headache
	Seizures
	Asterixis (flaps)
	Neuropathy
	Restless legs
	Sleep disorders
	Stupor, coma
Haematological system	
	Bleeding
	Hypercoagulability
Immunological system	
	Inadequate antibody formation
	Stimulation of inflammation
	Susceptibility to cancer
	Susceptibility to infection
Endocrinology	
	Dyslipidaemia
	Glucose tolerance
	Growth retardation
	Hyperparathyroidism
	Impotence, diminished libido
Bone disease	
	Adynamic bone disease
	Amyloidosis (β_2 microglobulin)
	Osteitis fibrosa
	Osteomalacia
	Osteoporosis
Skin	
	Melanosis
	Pruritus
	Uraemic frost
Gastrointestinal system	
	Anorexia
	Dyspepsia
	Hiccups
	Nausea, vomiting
Pulmonary system	
	Pleuritis
	Sleep apnoea syndrome
Miscellaneous	
	Hypothermia
	Thirst
	Uraemic foetor
	Weight loss

CONCLUSION

Screening for undiagnosed CKD and its early detection is aimed at reducing the incidence and delaying the progression to end-stage renal failure, postponing the need for dialysis or renal transplant. The average life expectancy of a 40-year-old patient with CKD after starting maintenance haemodialysis is 7 to 11 years. With appropriate intervention, if we are able to delay the onset of ESRD and protect him from cardiovascular morbidity between 40 and 60 years of age, the patient will have had 20 years of independent life. He can fulfil his social obligations, bring up his family, earn his own income and save enough so that he can himself afford to take care of his dialysis requirement for 3 to 5 years at the age of 60 years and above!

All this can only be possible if the whole medical community, and not nephrologists alone, get involved in the early diagnosis and screening for CKD.

19.5 Primary Glomerular Diseases

Vinay Sakhuja, Sanjay D' Cruz

INTRODUCTION

Glomerular diseases are classified as *primary* when the pathology is confined to the kidney and the aetiology is idiopathic or unknown. They are classified as *secondary* when part of a multi-system disorder.

The major clinical syndromes of glomerular disease are classified according to combinations of features like proteinuria, haematuria, oliguria, reduction in glomerular filtration rate, salt and water retention and hypertension (**Table 1**). Specific glomerular diseases tend to produce characteristic syndromes, but different glomerular diseases can produce the same syndrome. The diagnosis of a glomerular disease requires recognition of one of these syndromes followed by laboratory evaluation. Evaluation of pathologic features on a kidney biopsy specimen is often required for a definitive diagnosis.

Table 1: Major Glomerular Clinical Syndromes

Acute glomerulonephritis
Rapidly progressive glomerulonephritis
Asymptomatic urinary abnormalities: asymptomatic proteinuria, asymptomatic microscopic haematuria, recurrent gross haematuria
Nephrotic syndrome
Chronic glomerulonephritis

Glomerular diseases can be caused by a variety of mechanisms. Most glomerular diseases are immune mediated. Immune mediated glomerular injury is mainly of two types viz. *immune complex*-mediated injury and *antibody*-mediated injury. Immune complexes may cause injury through two mechanisms viz. (i) *in situ* formation of immune complexes through interaction of circulating antibodies with extrinsic antigens that have been planted within the glomerulus, as in post-streptococcal glomerulonephritis (PSGN), and (ii) intra-glomerular trapping and deposition in the subendothelial space or mesangium of *circulating* immune complexes formed in the systemic circulation as in mesangiocapillary glomerulonephritis. Glomerular lesions caused by anti-glomerular basement membrane antibody and anti-neutrophilic cytoplasmic antibodies (ANCA) are examples of antibody-mediated injury.

However, non-immune mechanisms also contribute to glomerular injury and these include *metabolic* injury as in diabetes mellitus, *haemodynamic* injury caused by hypertension or reduced renal mass, *deposition* injury as occurs in amyloidosis, *infection* related damage due to human immunodeficiency virus, *toxin* induced injury due to verotoxin and nonsteroidal anti-inflammatory drugs and finally *inherited* disorders as in Alport's syndrome.

ACUTE GLOMERULONEPHRITIS

The acute nephritic syndrome (ANS) is characterised by abrupt onset of haematuria, mild proteinuria, reduced glomerular filtration rate (GFR), oliguria and salt and water retention leading to hypertension. It can follow many bacterial and viral infections. The prototype is PSGN which is described in detail below. Many other systemic diseases may also present with an ANS. Evaluation of the serum complement level is a useful tool in differentiating these conditions (**Table 2**).

Table 2: Diseases Causing Acute Nephritic Syndrome, Classified according to Serum Complement Levels

Low Complement Level	Normal Complement Level
Post-infectious glomerulonephritis	IgA nephropathy
Mesangiocapillary glomerulonephritis	Idiopathic crescentic glomerulonephritis
Infective endocarditis	Anti-GBM disease
Essential mixed cryoglobulinaemia	Vasculitides
	Henoch Schönlein purpura
	Wegener's granulomatosis
	Microscopic polyangiitis
Systemic lupus erythematosus	

IgA = Immunoglobulin A; GBM= Glomerular basement membrane.

POST-STREPTOCOCCAL GLOMERULONEPHRITIS

PSGN follows infection with only certain strains of group A (β-haemolytic) streptococci, designated as nephritogenic. These include skin infection with *Streptococci M* types 2, 49, 55, 57, and 60 and throat infection with *Streptococci M* types 1, 3, 4, 12, 25, 18 and 49. Subclinical episodes occur about four times more commonly than clinical disease. PSGN can occur sporadically or as part of an epidemic. During epidemics, the clinical attack rate is nearly 10%.

PSGN is primarily a disease of children with peak incidence between ages of 2 and 12 years. The latent period following streptococcal infection is shorter for pharyngeal infection (7 to 14 days) than for cutaneous infection (3 to 4 weeks). The classical presentation of PSGN is with ANS presenting with haematuria (100%), oedema (80% to 90%), and hypertension(60% to 80%) with or without oliguria (10% to 20%).

Haematuria may be gross resulting in smoky urine or microscopic. Features of circulatory congestion and pulmonary oedema may at times dominate the clinical picture. Atypical manifestations include encephalopathy due to hypertension.

Laboratory Features

Haematuria is a universal finding. Red blood cell (RBC) casts and dysmorphic RBC are often seen in the urinary sediment. Subnephrotic proteinuria is present in more than 75% patients. GFR is usually decreased. Skin or throat cultures may reveal growth of streptococci. Antibodies to extra-cellular products of streptococci are markers of recent infection. These include anti-streptolysin, anti-nicotinamide adenine dinucleotidase, anti-hyaluronidase (AHase), and anti-DNAse B after pharyngitis,

and anti-DNAse B and AHase titers following skin infections. Generally, the antibody titers are elevated at 1 week, peak at 1 month, and fall toward pre-infection levels after several months. Serum levels of C3 are low at presentation and return to baseline within 8 to 12 weeks. Alternate complement pathway is activated. Prolonged hypocomplementemia suggests an alternative diagnosis. Fractional excretion of sodium is low. Circulating immune complexes and cryoglobulins are found in 60% of cases. Anaemia and hypoalbuminaemia may be seen due to haemodilution. Nephrotic syndrome is unusual.

Pathology

Light microscopy reveals a diffuse exudative endocapillary proliferative glomerulonephritis (**Figure 1**). All glomeruli are affected and usually to an equal degree. The glomerular tufts are larger than normal and hypercellular. The cell types typically present include endothelial and mesangial cells and polymorphonuclear leucocytes. Sometimes there is extracapillary proliferation leading to crescent formation. Immunofluorescence microscopy reveals granular deposition of IgG and C3 in the mesangium and along capillary walls. Electron microscopy characteristically reveals discrete subepithelial electron dense deposits. Renal biopsy is indicated only in atypical cases with rapidly deteriorating renal function or nephrotic range proteinuria.

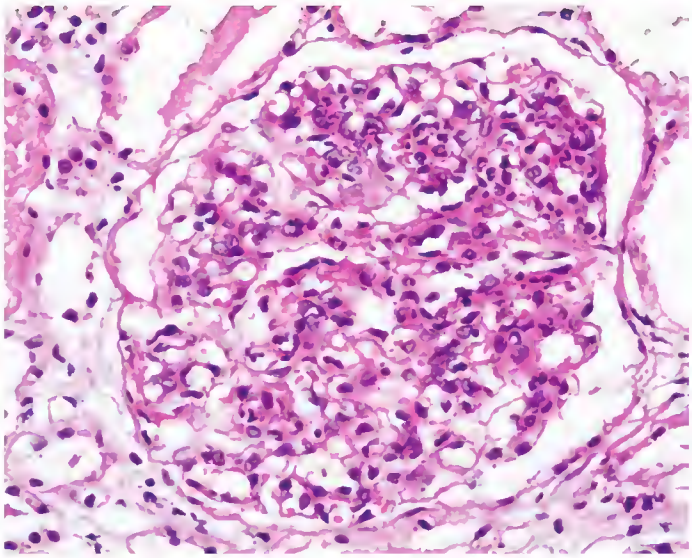

Figure 1: Glomerulus is enlarged and hypercellular due to inflammatory cell infiltration along with proliferation of endothelial cells (PSGN).

Therapy and Course

Anti-streptococcal drugs given to patients, family members and immediate contacts may limit the spread of infection. However, early anti-microbial therapy does not have any impact on the subsequent development of PSGN. Oedema responds to diuretics and salt restriction while antihypertensive agents are used to control hypertension. Most cases are expected to undergo spontaneous recovery within 1 to 2 weeks. In children the prognosis is excellent. Complete recovery occurs in 95% of cases. Bad prognostic markers include late age of onset, sporadic disease, massive proteinuria, sustained hypertension and presence of crescents on light microscopy.

RAPIDLY PROGRESSIVE GLOMERULONEPHRITIS (RPGN)

RPGN is characterised by a rapid and progressive decline in renal function over days to weeks because of underlying glomerular disease. If left untreated it leads to end stage renal failure over weeks to months. RPGN has to be differentiated from other causes of rapidly progressive renal failure (RPRF). There are many causes of RPRF including malignant hypertension and scleroderma renal crisis. In RPGN, there is an underlying glomerulonephritis which leads to RPRF.

RPGN is also known as crescentic glomerulonephritis because of the frequent presence of extensive pathognomonic crescents (**Figure 2**). Crescents are defined as the presence of 2 or more layers of cells in Bowman's space. The cells in the crescent are derived predominantly from monocytes (macrophages) that have gained entry into Bowman's space through damaged capillaries and from parietal epithelial cells lining the space.

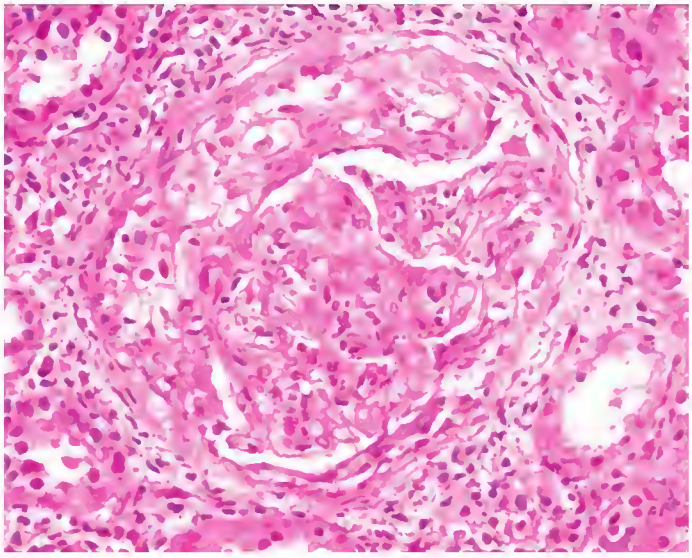

Figure 2: RPGN—Glomerular tuft is collapsed with the "epithelial crescent" on top left side.

The pattern of antibody deposition on immunofluorescence and presence or absence of ANCA is useful in classifying RPGN into three types viz., Type I (anti GBM disease), Type II (immune complex mediated), Type III (pauci-immune with ANCA positivity) (**Table 3**).

Table 3: Diseases Associated with Crescentic Glomerulonephritis

Primary glomerular diseases
Idiopathic crescentic glomerulonephritis (GN) (Types I-III)
Superimposed on other primary glomerular disease
Mesangiocapillary GN, IgA nephropathy
Associated with infectious diseases
PSGN, infective endocarditis, visceral abscess
Associated with drugs
Penicillamine, rifampicin
Associated with multisystem diseases
Systemic lupus erythematosus
Goodpasture's disease
Cryoglobulinaemia
Vasculitides
Wegener's granulomatosis
Churg-Strauss syndrome
Microscopic polyangiitis
Henoch-Schönlein purpura

PRIMARY CRESCENTIC GLOMERULONEPHRITIS TYPE I (ANTI-GBM ANTIBODY MEDIATED)

This type constitutes 5% to 10% of RPGN. It has a bimodal age distribution occurring between 20 and 30 years or 50 and 70 years with male preponderance. It is characterised by presence of either circulating or basement membrane bound anti-GBM antibodies. It may be precipitated by an influenza like illness or exposure to hydrocarbons and smoking.

Clinical Features

Mostly the onset is insidious but at times it may be abrupt. Oliguria and azotemia are early manifestations. Hypertension, if present, is usually mild. Absence of pulmonary haemorrhage differentiates this condition from Goodpasture's disease.

Laboratory Features

Urine microscopy usually reveals active urinary sediment with RBC casts and dysmorphic RBCs. Serum complement is normal. Circulating anti-GBM antibodies are detectable in plasma. Chest radiograph reveals bilateral infiltrates due to alveolar haemorrhage in those with Goodpasture's disease. Anaemia may be out of proportion to renal dysfunction due to pulmonary haemorrhage.

Pathology

Light microscopy shows extensive crescent formation in various stages of development involving more than 50% of the glomeruli. The glomerular tuft is compressed by proliferation of epithelial cells that occupy most of the Bowman's space. Crescents are cellular to begin with and later become fibrous. IF reveals smooth linear deposition of IgG on the basement membrane often accompanied by C3 deposition.

Treatment and Course

The two principles of therapy are: (1) rapid removal of circulating antibody, primarily by plasmapheresis; and (2) stopping further production of antibodies using immunosuppression. Aggressive therapy must be initiated early to prevent permanent renal dysfunction. Therapy hinges on intensive 2 to 4 litre plasma exchanges on alternate days for two weeks in conjunction with oral steroids and cyclophosphamide. Immunosuppressive therapy is required to inhibit antibody production and rebound hypersynthesis, which may occur following discontinuation of plasma exchange. Cyclophosphamide 2 mg/kg orally is instituted and continued for 6 months. Prednisolone at (1 mg/kg) is also initiated and gradually tapered over 6 months following clinical remission. With this therapy circulating antibody usually falls to undetectable levels within a few weeks. Before the availability of current therapy, the mortality rate was more than 90%, with a mean survival time of less than 4 months. Currently, with the combination of plasmapheresis, corticosteroids, and cyclophosphamide, the mortality rate has been reduced to less than 20%. Bad prognostic markers are circumferential and fibrous crescents, tubulointerstitial fibrosis and serum creatinine more than 6 mg/dL at presentation.

TYPE II (IMMUNE COMPLEX MEDIATED) CRESCENTIC GLOMERULONEPHRITIS

Clinical Features

It accounts for approximately 30% to 50% of all cases of idiopathic crescentic glomerulonephritis and most frequently affects children and young adults. Both sexes are affected equally. Patients are usually normotensive; hypertension if present is mild. Renal function may be deranged at presentation and rapidly deteriorates if left untreated.

Laboratory Features

There is active urinary sediment along with subnephrotic proteinuria. Complement levels are low. Anti-GBM antibodies and ANCA are notable by their absence.

Pathology

Crescents are present in more than 50% of glomeruli along with endocapillary proliferation. Immunofluorescence typically shows scattered deposits of IgG and IgM in the mesangium and peripheral capillary loops usually in association with C3. Electron microscopy reveals electron dense deposits in the mesangium and subepithelial region.

Course and Therapy

Spontaneous remission may often occur in children. Others should be treated with pulse methylprednisolone infusion 1000 mg intravenously for 3 days followed by oral steroids in tapering doses for 3 months. In dialysis dependent patients there may be a role for cytotoxic agents.

TYPE III (PAUCI-IMMUNE) CRESCENTIC GLOMERULONEPHRITIS

Clinical Features

Many of these patients have some form of small vessel vasculitis in which the kidneys are predominantly involved. It constitutes about 50% of all cases of crescentic glomerulonephritis.

This disorder tends to involve middle aged persons, with a slight male preponderance. Constitutional symptoms like fever, malaise, weight loss and symptoms suggestive of vasculitis like skin rash (palpable purpura), joint pain and abdominal pain may be present.

Laboratory Features

Urine analysis is similar to other types of crescentic glomerulonephritis. Anti-GBM antibodies, circulating immune complexes, rheumatoid factor and cryoglobulins are absent. Complement levels are normal. The hallmark of this condition is the presence of p-ANCA with specificity for anti-myeloperoxidase autoantibodies in the majority (70%) of patients; a small fraction (20%) may have c-ANCA with specificity for proteinase-3.

Pathology

Apart from the ubiquitous crescents, segmental or diffuse necrotising lesions are frequently seen in the glomeruli indicative of underlying vasculitis. Immunofluorescence typically reveals paucity or absence of immune deposits. Fibrin related antigens may be seen in the crescents.

Course and Therapy

Most patients are treated with pulse steroids to begin with followed by a combination of steroids along with daily oral or intermittent pulse cyclophosphamide. The dose of methyl-prednisolone is 7 mg/kg per day intravenously (not to exceed 1 g) for 3 days, followed by oral prednisone at 1 mg/kg per day (not to exceed 80 mg) for 4 weeks, and then tapered off gradually over 6 months. Relapses may occur later in the course of the

disease. The only predictor of renal survival is the serum creatinine value at the time of diagnosis. Intravenous and oral cyclophosphamide are equally efficacious. Intravenous therapy is initially administered at a dose of 0.5 g/m^2, and the oral dose is 2 mg/kg per day. Plasmapheresis should be done in dialysis dependent patients only. After induction of remission which takes 3 to 6 months, patients may be put on maintenance therapy with azathioprine. The prognosis of this condition is intermediate between type I and type II crescentic glomerulonephritis.

IMMUNOGLOBULIN A NEPHROPATHY (IgAN)

This entity was first described by Berger and Hinglais in 1968. While Henoch-Schönlein purpura (HSP) is diagnosed when purpura is associated with arthralgia, abdominal pain and concomitant glomerulonephritis, IgAN is the monosymptomatic form of HSP in which there are no extra-renal manifestations. It is the most common form of primary glomerular disease in some parts of south east Asia but accounts for only 5% of glomerular disease in India. The male to female ratio is 2:1. Familial cases have also been described. It is most commonly seen in the second and third decades of life. It is sometimes associated with other conditions like cirrhosis of liver, gluten enteropathy, dermatitis herpetiformis, Crohn's disease and seronegative arthropathy.

Clinical Features

Presentation of IgAN is highly variable, both clinically and pathologically. Clinical features range from asymptomatic gross haematuria which is often recurrent (40% to 50%) to asymptomatic urinary abnormalities (30%), nephritic syndrome, nephrotic syndrome (10%) and rarely RPGN. There may be associated loin pain during episodes of gross haematuria. Spontaneously resolving acute renal failure (ARF) can occur. ARF may be due to crescentic glomerulonephritis or due to tubular occlusion by RBCs. Episodic, gross haematuria is more common in younger people, whereas an abnormal urine sediment is more frequent in older individuals. At times episodes of haematuria immediately follow an upper respiratory catarrh, the so called 'synpharyngitic' nephritis. Patients are usually normotensive, but hypertension may occur later in a minority.

Pathophysiology

The pathogenesis of IgAN remains incompletely understood. Immunofluorscence findings of granular deposits of IgA and C_3 in the mesangium suggest that this disease is the result of the deposition of circulating immune complexes. Deposited IgA is predominantly polymeric IgA1, which is mainly derived from the mucosal immune system.

Laboratory Features

Urine analysis invariably reveals microscopic haematuria and proteinuria in the subnephrotic range. GFR is usually normal at presentation but can decline during bouts of gross haematuria. Serum IgA levels are increased in upto 50% of patients. C_3 and C_4 are usually normal. Skin biopsies may reveal dermal capillary deposits of IgA in up to 50% patients.

Pathology

Almost any glomerular lesion with the possible exception of membranous nephropathy may be seen in patients of IgAN. The most common light microscopy findings are focal, or more often, diffuse increase in mesangial cellularity and mesangial matrix with intracapillary or extracapillary proliferative lesions. Interstitial fibrosis, tubular atrophy and vascular sclerosis may be seen in advanced disease. Immunofluorescence findings are diagnostic of this disease. Immunofluorscence shows predominant IgA deposition in a diffuse granular pattern in the mesangium and occasionally in the capillary wall. Some IgG and C3 deposits may accompany IgA. Electron microscopy shows electron dense deposits in the mesangium.

Course and Therapy

Although this disease usually follows a relatively benign course, end-stage renal disease (ESRD) occurs in 15% to 20% of patients within 10 years. Currently no cure exists for IgAN. Majority of patients require management of proteinuria and hypertension with angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs). Steroids should be used only in those with nephrotic range proteinuria. Patients with crescentic glomerulonephritis can be treated similarly to patients with idiopathic RPGN by using intravenous pulse methylprednisone followed by oral prednisone and cyclophosphamide. Poor prognostic factors are male gender, older age, hypertension, renal insufficiency at presentation, nephrotic range proteinuria, diffuse proliferative lesions associated with crescents, tubular atrophy and interstitial fibrosis.

NEPHROTIC SYNDROME

The nephrotic syndrome is characterised by heavy proteinuria (>3.5 g/24 hours/1.73m^2 in adults and >40 mg/m^2 per hour in children) leading to hypoalbuminaemia and oedema. The spot urinary protein to creatinine ratio is in excess of 3.5. Oedema is the commonest manifestation of the nephrotic syndrome. Pathogenesis of oedema may be explained by the 'underfill theory' according to which, hypoalbuminaemia lowers the plasma colloid osmotic pressure, causing greater transcapillary filtration of water throughout the body and thus the development of oedema. Oedema may also be explained by the 'overfill theory', according to which primary renal sodium retention causing an increased blood volume provokes oedema. Oedema initially develops around the eyes and ankles. With time, it becomes generalised and may be associated with an increase in weight, the development of ascites and pleural effusions. Hypertension, haematuria, and azotemia may also occur. Hyperlipidaemia (elevated total cholesterol, triglycerides, low and very low density lipoproteins) and lipiduria is also common. This results from hypoproteinaemia stimulating protein, including lipoprotein synthesis by the liver, and diminution of lipid catabolism caused by reduced levels of lipoprotein lipase.

Concomittant losses of other plasma proteins may lead to various complications. The loss of antithrombin III and plasminogen in urine, along with the increase in clotting factors, especially factors V, VII, VIII, and X, and fibrinogen increases the risk for venous and arterial thrombosis and pulmonary embolism. In children, arterial thromboses are more common whereas in adults, thromboses are more common in the venous territory. The risk of thrombosis is inversely related to serum albumin concentration. Vitamin D-binding protein may be lost in the urine, leading to hypovitaminosis D, with malabsorption of calcium. Urinary losses of Ig and a complement factor

(properdin factor B) that opsonises certain bacteria may increase the risk of sepsis due to capsulated organisms. The most common infectious complications are cellulitis, pneumonia, and peritonitis. Iron resistant anaemia may result from urinary losses of transferrin. Hypovolemia, raised intra-renal interstitial pressure and intra-tubular obstruction due to casts may lead to acute renal failure.

Examination of urine is mandatory in all cases of suspected nephrotic syndrome. Nephrotic range proteinuria will be apparent by 3+ or 4+ readings on the dipstick. The urine sediment may show red cells and/or casts. By use of a polarising microscope, one can see oval fat bodies and fatty casts.

In addition to specific therapy, supportive measures like adequate protein intake, salt restriction and use of diuretics, control of hypertension and hyperlipidaemia and minimisation of proteinuria with ACE inhibitors or ARBs should be instituted. Routine immunisations in children should be delayed until the patient is off immunosuppression for 3 months. Pneumococcal and influenza vaccination are recommended in all adults.

Although a renal biopsy is necessary for confirmation of the histologic diagnosis, the age of onset, selectivity of proteinuria, activity of urine sediment, presence or absence of hypertension, serum complement levels and presence of renal insufficiency can help to distinguish between the four primary glomerular diseases (**Table 4**).

Table 4: Differential Diagnosis of Primary Glomerular Diseases with a Nephrotic Syndrome

Histology	Age	Proteinuria	Microscopic Haematuria	Hyper-tension	↓GFR	C3
MCD	Children	Selective	–	–	–	N
FSGS	Children and Adults	Nonselective	±	+	±	N
MGN	Older adults	Nonselective	±	±	–	N
MPGN	Children and adults	Nonselective	++	++	++	–

MCD = Minimal change disease; FSGS = Focal segmental glomerulosclerosis; MGN = Membranous glomerulonephritis; MPGN = Membranoproliferative glomerulonephritis.

PRIMARY GLOMERULAR DISEASES CAUSING NEPHROTIC SYNDROME

Minimal Change Disease

Minimal change disease (MCD) is the most common cause (85%) of nephrotic syndrome in children. The incidence peaks in children aged 2 years, with approximately 80% being younger than 6 years at the time of diagnosis. It also occurs in adults in whom it accounts for 15% to 20% of all nephrotics. Almost all cases are idiopathic, but a very small minority may have an identifiable cause such as non steroidal anti-inflammatory drugs or Hodgkin's lymphoma.

Clinical Features

In children, there is a male preponderance (2:1), whereas both sexes are equally affected in adults. Onset is usually abrupt following an upper respiratory catarrh. History of atopy may be forthcoming in children. Oedema is a prominent feature. Heavy proteinuria over an extended period of time may lead to a state of protein malnutrition. Hypertension is unusual.

Laboratory Features

Nephrotic range proteinuria is almost invariably seen. Proteinuria is typically highly selective (IgG/Transferrin clearance <0.1). Microscopic haematuria is unusual. Renal function is usually normal. In children, the diagnosis can be confirmed by a complete remission induced by steroids and a renal biopsy is not required. In adults, however, since MCD is not as common, a biopsy is required before therapy.

Pathology

On light microscopy the glomeruli appear normal (**Figure 3**). Protein and lipid droplets may be seen in tubular epithelial cells. There is no significant glomerular deposition of immunoglobulins or complement on immunofluorscence. Electron microscopy reveals retraction of the epithelial foot processes along with obliteration of slit pores.

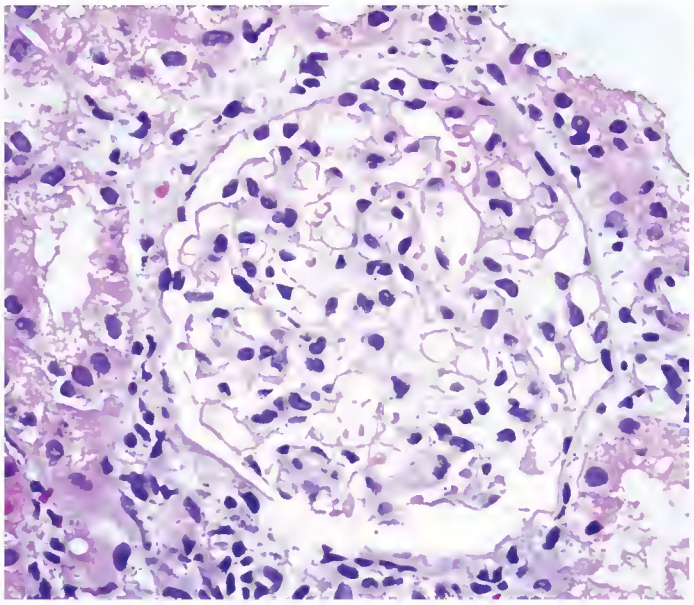

Figure 3: MCD—Glomerulus showing normal morphology on light microscopy.

Course and Therapy

Corticosteroids are the mainstay of therapy. Prednisolone is given in a dose of 60 mg/m^2 per day for 6 weeks followed by 40 mg/m^2 on alternate days for 6 weeks in children. In adults prednisolone is given at 1mg/kg per day usually not exceeding 80 mg/day and the duration of therapy may have to be prolonged to achieve remission. Approximately 90% of children respond within 2 weeks to steroids whereas the time to remission is up to 16 weeks in adults.

Depending on the response to steroids, patients may be classified as *primary responders* with no relapse, *infrequent relapsers, frequent relapsers*—initial steroid response with >2 relapses in first 6 months or >3 in a year, *steroid dependent*—relapse when steroids are being tapered or within 2 weeks of cessation of steroids and *steroid resistant*—if no reduction in proteinuria occurs by 12 to 16 weeks.

In patients who need steroids repeatedly for relapses or are steroid dependent, cyclophosphamide (2 mg/kg/day) for 12 weeks may be given to induce a prolonged remission. Cyclosporine (3 to 4 mg/kg/day) can also be used in patients with frequent relapses or steroid dependency. The prognosis is excellent for steroid responsive patients with 25 years survival in excess of 90%.

FOCAL SEGMENTAL GLOMERULOSCLEROSIS (FSGS)

FSGS was first described in 1957 by Arnold Rich. FSGS may be idiopathic or secondary (**Table 5**). The primary pathophysiologic process in FSGS is an injury inherent within or directed to podocytes.

Table 5: Diseases Associated with Focal Segmental Glomerulosclerosis (FSGS)

Primary (idiopathic) FSGS
Secondary
Genetic: Mutations in podocin, a- actinin 4
Reduced nephron mass: Solitary kidney, vesicoureteric reflux, renal allograft
Drugs: Heroin, Lithium, Pamidronate
Haemodynamic causes: Sickle cell disease, morbid obesity
Infections: Human immunodeficiency virus, parvovirus
Miscellaneous: Alport's syndrome, sarcoidosis, lymphoma

Clinical Features

The incidence of FSGS has been increasing in the last decade and it now accounts for 25% to 30% of idiopathic nephrotic syndrome in adults and 10% to 20% in children. The lesion is 3 times more common in males. Nephrotic syndrome is the most common clinical presentation. Less than a third of patients with FSGS present with subnephrotic proteinuria. Hypertension is seen in 50% of patients. Onset is typically insidious. Frequently, the onset of oedema follows a recent upper respiratory catarrh.

Laboratory Features

Proteinuria is typically nonselective. Microscopic haematuria is common. Serum creatinine concentration is usually normal in early stages. Serum complement levels are normal. Patients may have proximal tubular defects manifesting as renal glycosuria and aminoaciduria.

Pathology

The characteristic lesion in FSGS is focal and segmental solidification of the glomerular tuft, usually in the perihilar region (**Figure 4**). The capillaries are segmentally obliterated by accumulation of acellular matrix and hyaline deposits, along with adhesion to the Bowman's capsule (synechiae formation). Initially lesions appear in the juxtamedullary cortex. Globally sclerosed glomeruli may be seen with disease progression. Many morphologic subsets, such as a cellular variant (endocapillary hypercellularity), a collapsing variant (FSGS with mesangial hypercellularity), and FSGS with tip lesions, have been described. On immunofluroescence, granular deposits of IgM and C3 are often found in the sclerotic areas. On electron microscopy, most of the glomeruli show segmental foot process effacement.

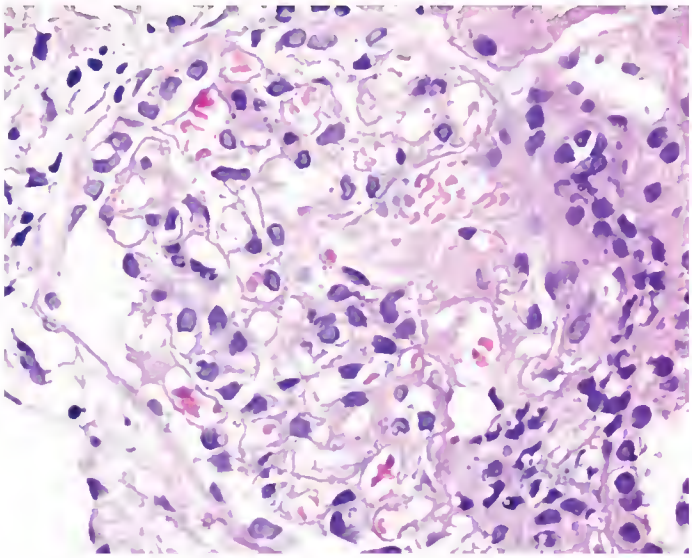

Figure 4: FSGS—Glomerulus showing a focus of sclerosis at the hilar end at 3 o'clock position.

Course and Therapy

The typical course is characterised by oedema that is difficult to manage, proteinuria that is refractory to corticosteroids and immunosuppressive agents, worsening hypertension and a progressive loss of renal function. Ten-year renal survival is in the range of 40% when nephrotic syndrome is present and up to 85% when proteinuria is subnephrotic. Corticosteroid therapy (1 mg/kg/day) may be given and may have to be extended to six months to induce remission. Lasting remission occurs in 20% to 30%, a relapsing course in 15% and a steroid unresponsive course with progressive renal insufficiency in about 60%. In steroid dependent cases cyclophosphamide or cyclosporine may be tried. Prolonged use of cyclophosphamide may lead to gonadal toxicity; therefore, persisting with cyclophosphamide beyond 3 months in patients who do not respond is unwise. Cyclosporine may be beneficial in patients unresponsive to prednisone and cyclophosphamide. Those with an older age of onset, male sex, massive proteinuria, persistent hypertension, initial abnormal GFR, hilar glomerulosclerosis, collapsing variant and severe mesangial proliferation on kidney biopsy have worse outcomes. Recurrence rate after kidney transplantation is up to 30%.

MEMBRANOUS GLOMERULONEPHRITIS (MGN)

MGN is the commonest cause of nephrotic syndrome in adults accounting for about 25% of all cases. The male-to-female ratio is 2:1 with a peak incidence in fourth and fifth decades. It can be primary (80%) or secondary (20%) (**Table 6**). Primary disease has recently been shown to be caused by antibodies to the phospholipase A_2 receptor. Onset before 20 years or after 60 years of age is more likely to be associated with secondary causes. In adults, systemic lupus erythematosus is the commonest cause, while in children hepatitis B is the commonest cause of secondary MGN.

Table 6: Diseases Associated with Membranous Nephropathy

Primary
Secondary
Auto-immune disease: Ankylosing spondylitis, dermatomyositis, mixed connective-tissue disease, rheumatoid arthritis, Sjögren's syndrome, systemic lupus erythematosus, systemic sclerosis
Infections: Filariasis, hepatitis B, hepatitis C, leprosy, Quartan malaria
Malignancies: Carcinoma (lung, colon, breast, stomach), lymphoma
Drugs: Captopril, gold, mercurials, penicillamine
Miscellaneous: *De novo* in renal allografts, sarcoidosis, sickle cell disease

Clinical Features

The onset is insidious. Most of the patients present with a nephrotic syndrome while 20% present with subnephrotic

proteinuria. Hypertension may be present but is not characteristic of the disease in its early stages. Azotaemia occurs late in the course of the disease. There is an increased propensity for renal vein and deep vein thrombosis and embolic complications.

Laboratory Features

Nephrotic range proteinuria which is non-selective is seen in over 80% of patients. Microscopic haematuria may be seen in a minority. Serum complement levels are usually normal. Screening for secondary forms may be done where appropriate. An exhaustive work-up for malignancy is not recommended. An age-appropriate health screening (mammography, sigmoidoscopy) should be performed. Other tests include antinuclear antibodies, hepatitis B serology, anti-hepatitis C antibodies and cryoglobulins.

Pathology

All glomeruli are involved. The characteristic feature on light microscopy is diffuse and uniform thickening of capillary basement membrane with patent lumina and without any proliferation of endothelial or epithelial cells. The mesangium is normocellular (**Figure 5**). On silver stain, spikes may be seen on the outer aspect of the basement membrane. Immunofluroescence reveals uniform granular deposits of IgG and C3 outlining all the capillaries but sparing the mesangium. On electron microscopy, 4 stages of MGN have been described, viz. *stage 1*: basement membrane appears normal using light microscopy, but, with electron microscopy, subepithelial electron-dense deposits are seen along the capillary walls; *stage 2:* numerous and larger deposits with spikes in between adjacent deposits are seen; *stage 3:* the spikes extend and completely surround the deposits; and *stage 4:* electron-dense deposits become more lucent giving the basement membrane a 'swiss cheese appearance'.

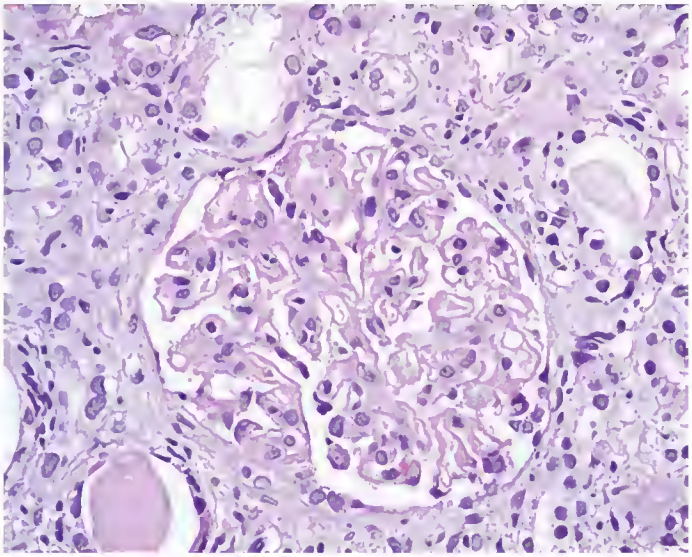

Figure 5: MGN—Glomerulus showing diffusely thickened capillary walls.

Course and Therapy

According to the course of the disease, patients may be divided into 3 groups of approximately equal size, viz. (i) one-third have a spontaneous complete remission which occurs within the first 2 years of onset, (ii) one third have persistent proteinuria with stable renal function, and (iii) one-third progress to ESRD over a decade. The incidence rate of ESRD is 14% at 5 years, 35% at 10 years, and 41% at 15 years. Poor prognostic markers are male sex, older age at onset, uncontrolled hypertension, reduced GFR at presentation, persistent heavy proteinuria and renal histology showing focal glomerulosclerosis and interstitial fibrosis.

Due to the indolent nature of the disease and tendency for spontaneous remission, not all patients need treatment; however, they must be followed up closely. Patients with persistent massive proteinuria, thromboembolism, and or renal insufficiency at presentation merit treatment. Oral glucocorticoids are not effective. The modified "Ponticelli regimen" comprising of sequential therapy in alternate months with high dose pulse methyl prednisolone for 3 days followed by oral prednisolone 0.5 mg/kg per day for 27 days in months 1, 3 and 5 and oral cyclophosphamide 2 mg/kg per day in months 2, 4 and 6 increases the likelihood of complete or partial remission. Cyclosporine may be tried in those patients in whom the above regimen cannot be used or is ineffective. Recently, mycophenolate mofetil has been used with some success. Promising results have also recently been obtained with rituximab, a monoclonal antibody against the CD20 antigen of B lymphocytes.

Anti-coagulation is indicated in those who have a thromboembolic complication and should continue until hypoalbuminaemia has been corrected.

MEMBRANOPROLIFERATIVE GLOMERULONEPHRITIS (MPGN)

Also called mesangiocapillary glomerulonephritis, MPGN accounts for approximately 10% of adults with a nephrotic syndrome. On the basis of immunopathology and ultrastructure analysis, 3 subtypes are recognised. MPGN types I and III are variants of immune complex-mediated disease while MPGN II has no known association with immune complexes. MPGN may be either primary or secondary (**Table 7**).

Table 7: Diseases Associated with MPGN

Primary (idiopathic)
Type I, Type II (dense deposit disease) and Type III
Secondary
Auto-immune disease: Systemic lupus erythematosus, Sjögren's syndrome, cryoglobulinaemia
Infections: Hepatitis B, hepatitis C, infective endocarditis, visceral abscess, infected shunts, leprosy
Malignancies: Leukaemia, lymphoma, carcinoma
Miscellaneous: Sickle cell disease, healing phase of HUS/TTP

HUS = Haemolytic uraemic syndrome; TTP =Thrombotic thrombocytopaenic purpura.

Clinical Features

The disease affects all age groups but is unusual in children less than 5 years old with a peak incidence in the second and third decades. MPGN type I affects women more than men while the sex ratio is equal in type II MPGN. There is a preceding upper respiratory infection in as many as 50% of patients. Patients may present in one of five ways, viz. (i) asymptomatic proteinuria and haematuria detected on routine urinalysis, (ii) nephrotic syndrome, (iii) ANS, (iv) rapidly progressive renal failure, and (v) proteinuria and haematuria are often found together (nephritic-nephrotic presentation). Hypertension

is present in approximately 80% of patients at onset. A strong association is present between partial lipodystrophy and dense deposit disease. Finding of Drusen on fundus examination in a patient with glomerulonephritis suggests MPGN type II.

Laboratory Features

Nephrotic range proteinuria is seen in 50% of patients. Urine microscopy reveals an active urinary sediment. Hypocomplementemia is a characteristic finding in all types of MPGN. In MPGN type I, C3 levels are low in 70% patients and there is activation of the classic pathway of complement. In MPGN type II, C3 levels are low in 70% to 80% of patients due to activation of the alternate pathway. The pathogenesis of membranoproliferative glomerulonephritis type II is not known. C3 nephritic factor (C3 NeF) is present in more than 70% of patients. C3 NeF is an autoantibody to C3b,Bb. The binding of C3 NeF to C3b, Bb stabilises the complex, preventing degradation by its normal inactivators, resulting in complement activation and chronic consumption of C3. In type III MPGN, C3 levels are decreased in 50% of patients.

Pathology

On light microscopy, glomeruli are enlarged and hypercellular, with an increase in mesangial cellularity and matrix. Mesangial expansion leads to lobular accentuation. The capillary basement membranes are thickened by interposition of mesangial matrix into the capillary wall leading to a tram-track appearance (**Figure 6**). Crescents may be visible in 10% of biopsy specimens. On Immunofluroescence, C3 deposits are seen in a granular pattern in the capillary walls and mesangium along with IgG and IgM deposits. On electron microscopy, electron dense deposits in subendothelial sites are characteristic of this disease. In type II disease on light microscopy, the basement membranes of the glomerulus, Bowman's capsule, tubules, and peritubular capillaries are thickened. The basement membrane appears irregular and ribbon like on special stains. On immunofluroescence, C3 is deposited in an irregular granular pattern in the basement membranes on either side but not within the dense deposits or the mesangium. On electron microscopy, the basement membrane is thickened by discontinuous, amorphous, electron dense deposits in the lamina densa.

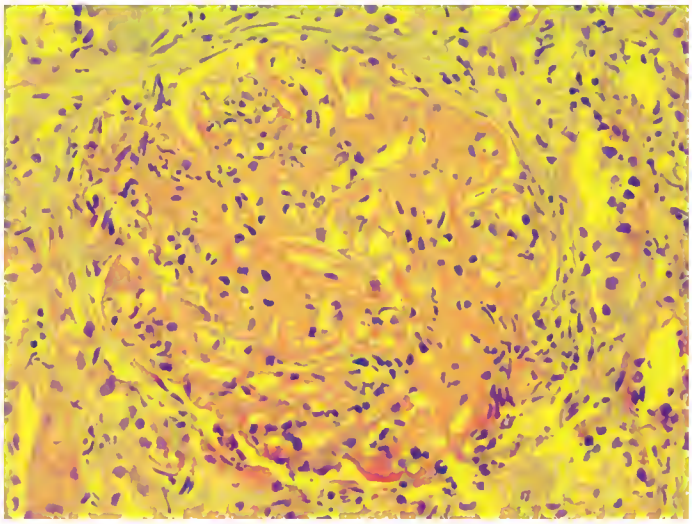

Figure 6: MPGN—Glomerulus showing lobular accentuation with increase in cellularity and mesangial matrix.

Course and Therapy

MPGN type I is a progressive disease, with 15% of non-nephrotics and 60% of nephrotics developing ESRD after 10 years. MPGN type II generally is more aggressive than MPGN type I and has a median renal survival of 5 to 12 years. The main predictors of an adverse outcome are nephrotic syndrome, hypertension and low GFR at presentation, older age, crescent formation, interstitial fibrosis and tubular atrophy. The optimal treatment of idiopathic MPGN is not clearly defined. The underlying cause of secondary forms of MPGN should be treated. Patients with hepatitis B virus–associated often go into spontaneous remission but may benefit from antiviral agents. Patients with HCV related disease and cryoglobulinaemia may benefit from antiviral treatment including interferon and ribavarin. Steroid therapy has proven to be beneficial only in children.

19.6 Secondary Glomerular Diseases

OP Kalra

INTRODUCTION

Glomerular diseases may occur during the course of various systemic disorders such as collagen vascular diseases, neoplastic conditions, infectious diseases, amyloidosis, heredofamilial conditions, etc. In any patient presenting with glomerular disease, the clinician must always look for signs and symptoms of various systemic diseases which may be diagnosed for the first time on doing various biochemical and serological investigations or on renal biopsy, such as systemic lupus erythematosus (SLE), amyloidosis, etc.

SYSTEMIC LUPUS ERYTHEMATOSUS

SLE is characterised by a wide spectrum of involvement of various organ systems coupled with various laboratory abnormalities, such as development of antibodies directed against various nuclear components, typically double stranded deoxyribonucleic acid (DNA). It predominantly affects women during their childbearing years. Female to male ratio is 10:1. Lupus nephritis (LN) is a frequent and potentially serious complication of SLE. Approximately 30% to 70% patients with well documented lupus have evidence of renal involvement. LN usually develops within 2 to 3 years after the diagnosis of SLE. However, renal biopsy studies show some evidence of involvement due to lupus in majority of the cases.

Aetiopathogenesis

LN is characterised by production of wide variety of autoantibodies against various nuclear components. Overactivity of B-cells associated with defects in T-cell auto-regulation play a crucial role. Certain genetic and environmental factors play a significant role in the development of disease. Patients with SLE have been found to inherit certain specific human leucocyte antigen (HLA) haplotypes (e.g., HLA-B8, DR3) with a higher frequency. Besides this, viral or bacterial peptides may precipitate the disease. Patients with clinical renal disease have been found to have high titres of auto antibodies directed against double stranded DNA (anti-dsDNA) antibodies and these bind the complement more avidly.

A few drugs have been implicated in inducing lupus-like disease in persons who are predisposed to the disease. These include procainamide, phenytoin, methyldopa, isoniazid, penicillamine, sulfonamides and few other drugs. Clinical features include mainly musculoskeletal manifestations; however, renal involvement is very uncommon. Majority of the patients have antihistone antibodies. Presence of elevated anti-dsDNA antibodies and low serum complement level is unusual. Most patients achieve remission following cessation of offending drug.

Pathology

A wide spectrum of histopathological changes may be seen which may involve every structure of the kidney. LN is a classical example of immune complex mediated glomerulonephritis. Even in the absence of clinically evident renal disease and normal renal histology on light microscopy, immunofluorescence studies may demonstrate evidence of deposition of immunoglobulins and complements. The location of immune deposits and the host response may result in a wide spectrum of renal lesions which may range from normal looking glomeruli to sclerotic glomeruli. The World Health Organisation (WHO) classification of LN has now been replaced by International Society of Nephrology/Renal Pathology Society (ISN/RPS) classification as shown in **Table 1**.

Table 1: The 2003 ISN/RPS Classification of Lupus Nephritis (LN)

Class I	Minimal mesangial LN → Normal glomeruli but presence of mesangial immune deposits on immunofluorescence
Class II	Mesangial proliferative LN → Mesangial hypercellularity along with mesangial immune deposits
Class III	Focal LN (<50% of glomeruli) → It may be focal, segmental or global endo- or extra-capillary glomerulonephritis III (A) : Active lesions III (A/C) : Active and chronic lesions III (C) : Chronic lesions
Class IV	Diffuse LN (≥50% of glomeruli) (**Figure 1**) Diffuse segmental (IV-S) or global (IV-G) LN IV (A) : Active lesions IV (A/C) : Active and chronic lesions IV (C) : Chronic lesions
Class V	Membranous LN (may occur in combination with Class III or IV LN)
Class VI	Advanced sclerosing LN (≥90% glomeruli globally sclerosed)

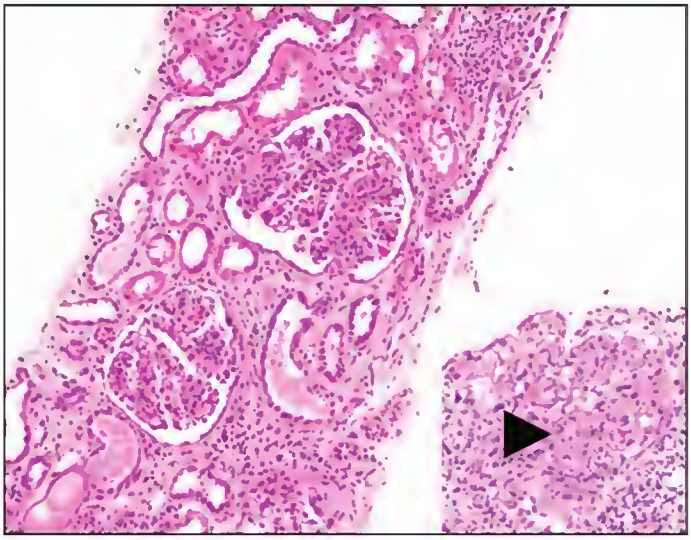

Figure 1: Lupus nephritis Class IV: There is uniformly diffuse and global endocapillary proliferation and neutrophilic infiltration. There is patchy tubulo-interstitial inflammation. (Haematoxylin-Eosin x 100). *Inset:* Higher power view of another glomerulus showing fibrinoid deposits (arrowhead) and tuft necrosis (Haematoxylin-Eosin x 200).

Cellular proliferation, fibrinoid necrosis, polymorphonuclear infiltration, karyorrhexis, haematoxylin bodies, wire loops, hyaline thrombi and cellular crescents indicate active disease; whereas lesions such as glomerular sclerosis, fibrous crescents, interstitial fibrosis and tubular atrophy suggest chronicity. High activity index and especially chronicity index have been associated with a poor prognosis. Immunoglobulin (Ig) deposits are found in all renal compartments. The predominant immunoglobulin (Ig) is IgG. The presence of IgG, IgA and IgM along with C3, and Clq in the biopsy specimens is known as 'full house' pattern and is highly suggestive of LN.

Clinical Features

Renal involvement often develops concurrently or shortly following the onset of SLE and may follow a protracted course with periods of remissions and exacerbations. The main features are proteinuria, with microhaematuria and red cell casts, hypertension and progressive renal dysfunction. Only one-third of the patients who develop LN present with renal disease as the first manifestation, some patients with LN initially show only mild urinary abnormalities such as asymptomatic proteinuria or microhaematuria. Some patients may present with full blown nephrotic syndrome, acute nephritic illness or impairment of renal function. On the other hand, a few cases may present with rapidly progressive renal failure or an established chronic renal failure. Rarely, a syndrome resembling thrombotic thrombocytopaenic purpura may develop in patients with severe disease.

The clinical course of LN is highly variable and is remarkably influenced by severity of the disease and the response to treatment. Patient may develop variable periods of remissions following treatment and later on develop flare up of disease process. When untreated or undertreated, majority of the patients with renal disease progress to develop end-stage renal disease (ESRD).

Diagnosis

The diagnosis of SLE is usually obvious in a young female presenting with multisystem disease, renal involvement and serologic markers of the disease. However, sometimes, renal disease may manifest in the absence of extra-renal manifestations. The diagnosis of SLE is often clinically established by the presence of certain clinical and laboratory features defined by the 1997 modified American Rheumatism Association criteria (**Table 2**). Development of 4 of the 11 criteria either serially or simultaneously gives 75% sensitivity and 95% specificity for the diagnosis of SLE. However, the diagnosis of lupus in an individual patient can be made without regard to the above-mentioned criteria.

Immunologic tests in lupus nephritis

Abnormal autoantibody production is the hallmark of SLE. Antinuclear antibodies are a highly sensitive screen for SLE, being found in more than 95% of untreated patients, but they are not specific for SLE and occur in many other rheumatologic diseases, chronic infections, chronic liver disease, etc. Anti-dsDNA are more specific but less sensitive marker of SLE and are found in almost three-fourths of untreated patients with active SLE. Anti-Sm antibodies although very specific for SLE are found in only about 30% of lupus patients. The presence of various patterns of antinuclear antibody (ANA), e.g. speckled, diffuse, etc. is not helpful in distinguishing SLE from other rheumatologic diseases. Besides this, certain other autoantibodies may be present such as anti-ssDNA, anti-nRNP antibodies and anti-phospholipid antibodies. Hypocomplementaemia is found at presentation in more than three-quarters of untreated patients with lupus, and is more common with evident nephritis. The concentration of C4 and Clq tends to be more depressed than C3, which suggests complement activation via the classical pathway.

Table 2: Revised American Rheumatism Association Criteria for Diagnosis of Systemic Lupus Erythematosus (SLE) (1997)

1. Malar rash: Fixed erythema, flat or raised
2. Discoid rash: Erythematous raised patches with keratotic scaling
3. Photosensitivity: Skin rash due to unusual reaction to sunlight
4. Oral ulcers: Oral or nasopharyngeal ulcers observed by the physician
5. Arthritis: Non-erosive, involving 2 or more peripheral joints
6. Serositis: Pleuritis/pleural effusion, or pericarditis/pericardial effusion
7. Renal disorder: Persistent proteinuria >0.5 g/day or 3+, or cellular casts
8. Neurologic disorder: Seizures or psychosis
9. Haematologic disorder: Haemolytic anaemia or leukopaenia (<4000/μL) on two or more occasions or lymphopaenia (<1500/μL) on two or more occasions or thrombocytopaenia (<100,000/μL) in the absence of offending drugs
10. Positive anti-nuclear antibody (in the absence of drugs known to be associated with 'drug-induced SLE')
11. Anti-ds DNA or anti-Smith antibody and/or positive anti-phospholipid antibody

Note: Diagnosis requires 4 of the 11 criteria, either serially or simultaneously.

Serial estimation of various biochemical and serologic parameters may help in predicting clinical flare of the disease. These include erythrocyte sedimentation rate, C-reactive protein, C3, C4 and anti-dsDNA antibodies level. Typically, increase of proteinuria associated with active urinary sediment, fall of serum complement and rise of anti-dsDNA antibodies indicate reactivation of disease process.

Treatment

The aims of therapy of LN include early control of disease activity, prevention of relapses and retardation of progression of renal disease with minimal adverse effects of treatment. The choice of treatment should be based on clinical presentation, laboratory parameters and renal histopathology.

In general, patients with Class I and Class II LN do not need immunosuppressive therapy directed at the kidney, however, treatment may be required for extra-renal manifestations. Patients with class III LN with only mild or moderate proliferative lesions involving a few glomeruli, with no necrotising features and no crescent formation and normal and stable GFR have a good prognosis. They may be followed closely without the need for immediate institution of immunosuppressive agents or may require a short course of high dose corticosteroid therapy. However, patients with more severe focal proliferative or segmental lesions and with necrotising features and crescent formation usually require more vigorous therapy similar to patients with Class IV lesions to avoid irreversible renal damage and progression to ESRD. In the acute phase, high dose oral or pulse steroids in conjunction with monthly pulse cyclophosphamide are the mainstay of treatment.

Typically, treatment for Class IV or severe Class III LN is initiated with intravenous pulse methyl-prednisolone in doses of 0.5 to 1g per day given for 3 or more consecutive days, followed by oral prednisolone in decreasing doses. Initial dose of prednisolone should be 0.5 to 1 mg/kg per day depending upon the severity of the disease. Cytotoxic agents should be given in conjunction with corticosteroids for induction therapy in patients with Class IV or severe Class III LN. Intravenous cyclophosphamide is given once a month for 3 to 6 consecutive months in a dose of 0.5 to 0.75 g/m^2 body surface area, ensuring that the mid-cycle leucocyte count remains above 3000/mm^3. Because of risk of bladder or gonadal toxicity and neoplasia, cyclophosphamide should not be given beyond 6 months and should be replaced by oral azathioprine 1.5 to 2.0 mg/kg body weight, which is better tolerated in the long term. In patients with impaired renal functions, the dose of cyclophosphamide should be adjusted. During the last decade, mycophenolate mofetil has been found to be a good alternative to cyclophosphamide because of its better safety profile. It can be used both for induction therapy as well as long term maintenance therapy along with low dose corticosteroids. Other treatment options for class IV/severe class III LN include low dose cyclosporine, tacrolimus, rituximab, plasmapheresis, total lymphoid irradiation, thromboxane antagonists, blockers of co-stimulatory molecules and intravenous immunoglobulins.

There is no consensus regarding therapy of membranous LN (ISN/RPS class V). The response to treatment and progression of renal injury depend on the severity of proteinuria and the degree of superimposed proliferative changes. Patients with pure membranous nephropathy with subnephrotic proteinuria show very slow progression of the disease and may do well with short course of cyclosporine with low dose corticosteroids along with inhibitors of renin angiotensin system. On the other hand, patients at high risk of progression of renal disease may benefit from intravenous pulses of cyclophosphamide, mycophenolate mofetil and prednisolone on the same lines as diffuse proliferative glomerulonephritis.

Prognosis

Availability of newer and safer immunosuppressive agents and better interpretation of the renal biopsy have significantly improved patient survival during the last two decades. Patients with ISN/RPS Class I and II LN have excellent prognosis. However, patients with diffuse proliferative and necrotising lesions fare worse than those with mesangial or mild proliferative disease. Among patients with membranous LN, disease progression is rapid among patients having nephrotic range proteinuria and proliferative disease on kidney biopsy. Besides this, higher age, black race, nephrotic range proteinuria and serum creatinine >2.4 mg/dL at presentation are associated with poor prognosis. Patients having higher scores on activity and chronicity indices on kidney biopsy also have worse prognosis.

SMALL VESSEL VASCULITIDES

The kidneys are affected by a large number of systemic vasculitides, especially those that affect small vessels. Small vessel vasculitides including Wegener's granulomatosis, microscopic polyangiitis and Churg-Strauss syndrome affect multiple organ systems including the kidneys. These diseases lead to necrotising polyangiitis and affect vessels which are smaller than arteries, including capillaries, arterioles and venules. The most common targets for these diseases in the kidneys are glomeruli, and therefore, the most common renal manifestations are those of glomerulonephritis. There is often considerable overlap in the clinical, histologic, and laboratory features of these entities; all may be associated with anti-neutrophil cytoplasmic antibodies (ANCA). Immunofluorescence typically reveals no immunoglobulin deposits. These 'pauci-immune' small vessel vasculitides can be differentiated from similar form of immune complex mediated small vessel vasculitides such as Henoch-Schönlein purpura (HSP) and cryoglobulinemic vasculitis by the absence of immune complex deposits in the vessel walls and the treatment for all is often similar involving potent immunosuppressives. Differentiation between various types of small vessel vasculitides is done by the type and the extent of involvement of various organ systems.

Wegener's Granulomatosis

Wegener's granulomatosis has been traditionally defined by the triad of systemic vasculitis associated with necrotising, granulomatous inflammation of the upper and lower respiratory tracts, and glomerulonephritis. The classic histopathologic finding is a focal segmental necrotising and crescentic glomerulonephritis (**Figure 2**). The course of the active glomerulonephritis is typical of rapidly progressive glomerulonephritis with progression to renal failure over days to months. Cyclophosphamide and steroids are the mainstay of therapy.

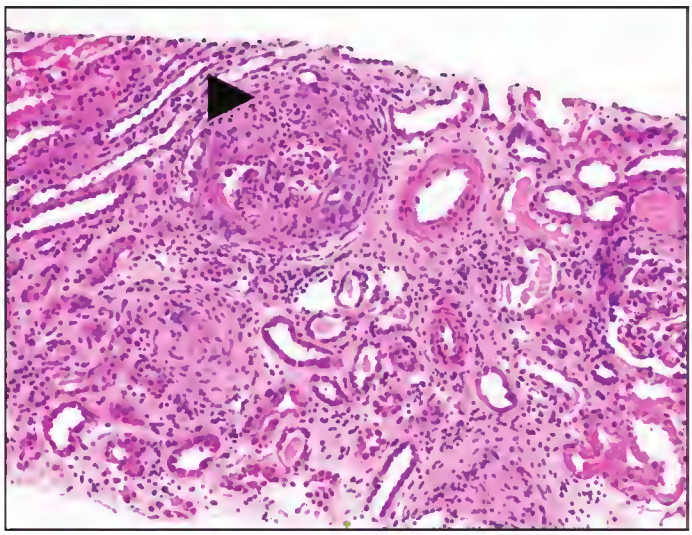

Figure 2: Glomerulus from a patient with Wegener's granulomatosis showing segmental fibrinoid necrosis associated with neutrophilic infiltrate and cellular crescents (arrowhead). Note the periglomerular tubulointerstitial oedema and inflammation (Haematoxylin-Eosin x 100).

Microscopic Polyangiitis

It is characterised by necrotising inflammation of small arteries, veins, and capillaries involving multiple viscera, including lungs and dermis and producing lesions of similar age, usually without aneurysms. Clinical manifestations include rapidly progressive glomerulonephritis, haemoptysis, mononeuritis multiplex, gastrointestinal tract and cutaneous vasculitis. Available data support a therapeutic approach similar to that used in Wegener's granulomatosis.

Churg-Strauss Syndrome

Churg-Strauss syndrome, or allergic granulomatosis and angiitis, is a rare systemic disease characterised by vasculitis, asthma, organ infiltration by eosinophils, and peripheral eosinophilia. Renal biopsies in Churg-Strauss syndrome vary from normal kidney tissue to severe glomerulonephritis, vasculitis, and interstitial inflammation. There may be a focal segmental necrotising glomerulonephritis sometimes with small crescents. Corticosteroid therapy is successful in most patients with Churg-Strauss syndrome.

Pathogenesis

Wegener's granulomatosis, microscopic polyangiitis, Churg-Strauss syndrome and isolated pauci-immune crescentic glomerulonephritis are all associated with the presence in the serum of autoantibodies against certain components of cytoplasm of neutrophils: ANCA. The most common antigen specificities of ANCA in patients with vasculitis and glomerulonephritis are for proteinase 3 (PR3) and myeloperoxidase (MPO). On immunofluorescence, using normal human neutrophils as substrate, two major staining patterns are observed: cytoplasmic (c-ANCA/PR3 ANCA) has specificity for PR3 and peripheral or perinuclear (p-ANCA/MPO-ANCA) which has specificity for MPO.

ANCA testing has good sensitivity for pauci-immune small vessel vasculitis and glomerulonephritis in 80% to 90% cases. The type of ANCA helps in differentiating various types of pauci-immune small vessel vasculitides and crescentic glomerulonephritis. PR-3 ANCA/c-ANCA are most prevalent in Wegener's granulomatosis whereas MPO-ANCA/p-ANCA are most prevalent in renal-limited pauci-immune glomerulonephritis. It has been postulated that ANCA are involved in the pathogenesis of the disease process. Besides this, it has been shown that ANCA titres correlate with the disease activity.

Pathology

In majority of these cases, renal biopsy shows focal, segmental necrotising glomerulonephritis. Early mild lesions have segmental fibrinoid necrosis. In some cases, crescent formation may occur leading to rapidly progressive glomerulonephritis. Wegener's granulomatosis is associated with necrotising granulomatous lesions involving the lungs and kidneys. Besides kidneys, focal necrotizing lesions can affect blood vessels of different organ systems such as skin, upper respiratory tract, lungs, abdominal viscera, etc.

Treatment

Treatment of renal involvement due to small vessel vasculitis involves induction therapy using combined treatment with corticosteroids and cytotoxic agents, such as cyclophosphamide. In severe disease, plasma exchange may be beneficial along with induction therapy. Long-term maintenance therapy using low dose corticosteroids along with cytotoxic therapy is required in majority of the cases to decrease the frequency of relapses during follow-up.

Henoch-Schönlein Purpura

HSP is a systemic vasculitic syndrome with involvement of small vessels (capillaries, arterioles and venules) of the skin, gastrointestinal (GI) tract and joints in association with a characteristic glomerulonephritis having IgA containing immune complexes. Renal involvement in HSP is similar to IgA nephropathy and the diseases can be differentiated only by extra-renal manifestations. It is mainly a childhood disease with a peak during the first decade of life although the disease can occur at any age.

Pathogenesis and pathology

Polymeric IgA1 containing immune complexes get deposited in the skin, kidney, and other organs in association with an inflammatory reaction of the vessels resulting in a leucocytoclastic angiitis in skin, ulcerations in the GI tract and glomerulonephritis in kidney. The typical light microscopic picture is of mesangio-proliferative glomerulonephritis with variable crescent formation. Immunofluorescence typically demonstrates IgA deposits in the mesangium which may extend into the subendothelial area (**Figure 3**).

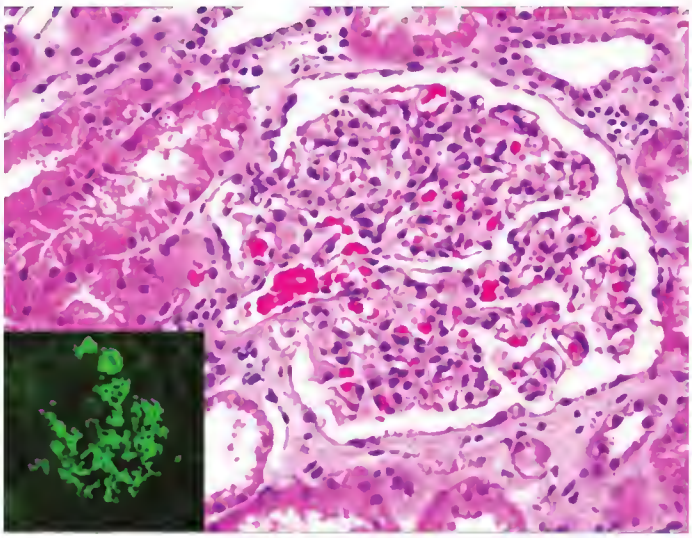

Figure 3: Henoch-Schönlein purpura with diffuse mesangial proliferative glomerulonephritis. There are only mild tubulointerstitial changes (Haematoxylin-Eosin x 100). *Inset:* Immunofluorescence shows global granular to globular staining for IgA limited to the mesangium (FITC anti-human IgA).

Clinical features

It presents with fever, malaise, fatigue and weakness and may be associated with active isolated dermal involvement or full-blown systemic disease. As per the ARA guidelines, the diagnosis of HSP may be considered in the presence of two out of four criteria—age less than 20 years at disease onset, palpable purpura, bowel angina and skin biopsy showing evidence of leucocytoclastic vasculitis. Later on, it was emphasised that presence of IgA vascular deposits is very helpful in establishing the diagnosis. Sometimes, history of infection or exposure to an allergen may precipitate the onset of illness. Skin lesions may include palpable purpura which usually occurs on the extensor surfaces of the legs and buttocks. GI manifestations may be present in the form of colicky pain, nausea and vomiting, bloody diarrhoea, haematochezia, intussusception or perforation. The onset of active renal disease usually follows the onset of the systemic manifestations by days to weeks and is characterised by microscopic haematuria, active urinary sediment, and proteinuria. Approximately 25% patients may develop nephrotic range proteinuria. Sometimes, the disease may present with rapid decline of renal function.

Course and therapy

In most of the patients, HSP has a benign course punctuated with relapses and remissions. In children, the disease is usually self limiting; however, adults have a worse renal prognosis. A poor renal prognosis is predicted by an acute nephritic presentation, older age, and especially nephrotic range proteinuria. There is no proven therapy for HSP. The extra-renal manifestations of the disease are managed by appropriate symptomatic measures. The role of immunosuppressive agents is controversial with no controlled trial showing definite benefit.

AMYLOIDOSIS

Amyloidosis is characterised by extracellular deposition of proteinaceous material having well defined morphologic and ultrastructural features usually involving multiple organ systems. Amyloid represents a family of proteins and several different types of amyloid have been identified. Amyloid fibrils are typically composed of linear, non-branching fibrils. AL amyloidosis is due to deposition of immunoglobulin light chains produced by plasma cells. On the other hand, AA amyloidosis is due to deposition of amyloid A protein in various chronic inflammatory diseases, such as tuberculosis, chronic osteomyelitis, rheumatoid arthritis, etc.

Pathology

Renal involvement occurs in both forms of amyloidosis, though it is more common in AL amyloidosis. Earliest lesions in the kidney are seen as amorphous hyaline material in the mesangial matrix and in the blood vessel walls. It is not associated with any increase in the mesangial cellularity or proliferative changes. The amyloid deposit is eosinophilic and weakly PAS positive. It stains orange on Congo-red staining and gives an apple green birefringence under polarised light (**Figure 4**).

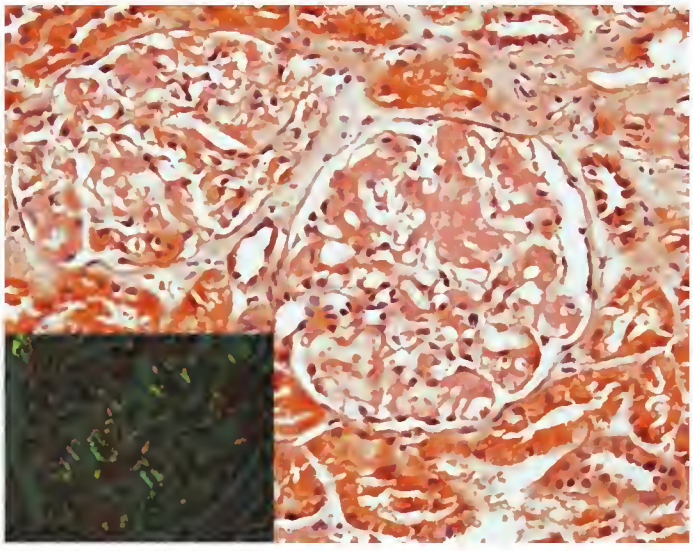

Figure 4: Amyloidosis kidney. Two glomeruli showing salmon pink staining of amorphous acellular deposits by Congo-red. *Inset:* The material was confirmed as amyloid by apple green birefringence elicited on polarisation (Congo-red x 100).

Clinical Features

The patient may present with symptoms due to involvement of kidney, heart, gastrointestinal tract, bones, peripheral nerves, skin, etc. Major renal manifestations include proteinuria and impairment of kidney function usually not associated with haematuria or hypertension. Kidney size is usually enlarged even in the presence of advanced renal failure. In some cases, proteinuria may lead to full-blown nephrotic syndrome; however, serum cholesterol is usually normal. Besides renal biopsy, histologic diagnosis can be made by examination of various tissues, such as gum, rectal mucosa, abdominal fatty tissue, etc.

Treatment and Prognosis

Development of AL amyloidosis during the course of plasma cell dyscrasias indicates severe disease with a median survival of around one year. Presence of cardiac involvement and impaired renal function indicates poor prognosis. Therapy with melphalan and prednisolone or vincristin, adriamycin and dexamethasone (VAD) therapy may result in decrease of proteinuria and retard the rate of progression of renal disease. Besides this, colchicine therapy has also been found to be useful. In a few cases, high dose chemotherapy followed by peripheral blood stem-cell transplantation may lead to significant decrease of proteinuria and improvement of renal function. In patients having AA amyloidosis, management of the underlying disease process such as tuberculosis, rheumatoid arthritis, etc. along with immunosuppressive agents may help in stabilisation of renal function. Besides this, supportive therapy, such as salt restriction, diuretics and blockers of renin angiotensin system have been found to be helpful.

INFECTION-RELATED GLOMERULAR DISEASE

Glomerulonephritis Associated with Infective Endocarditis

Embolic non-suppurative glomerulonephritis as a complication of infective endocarditis was described nearly a century ago. Although multiple renal infarcts and microabscesses have been well described complications of infective endocarditis, the role of immune complex aetiology has been emphasised during the last three decades in the aetiopathogenesis of acute glomerulonephritis. Similar disease is also seen in intravenous drug abusers with right sided endocarditis. Pathogenesis is immune-mediated as evidenced by the presence of circulating immune complexes, glomerular immunoglobulin deposits and hypocomplementaemia. Classical pathway for activation of complement is usually involved. Clinical presentation may vary from mild asymptomatic urinary abnormalities including haematuria, pyuria, and albuminuria to severe glomerulonephritis with renal insufficiency and uraemia. Kidney biopsy may reveal focal proliferative glomerulonephritis, however, few cases may develop diffuse proliferative or membrano-proliferative glomerulonephritis (**Figure 5**). The illness should be differentiated from drug-induced acute interstitial nephritis or renal artery embolism. Glomerulonephritis usually subsides with the control of infection with parenteral antibiotic therapy. In a few cases, corticosteroids and plasmapheresis have been used with variable outcome. Development of glomerulonephritis increases the morbidity and mortality in patients with infective endocarditis.

Shunt Nephritis

Glomerulonephritis has been reported following infection of ventriculo-atrial as well as ventriculo-peritoneal shunts used for the management of hydrocephalus. Common infective organisms include *Staphylococcus epidermidis*, *Staphylococcus aureus* and less frequently diphtheroids, Serratia species, etc. Patients usually present with low grade fever, arthralgias,

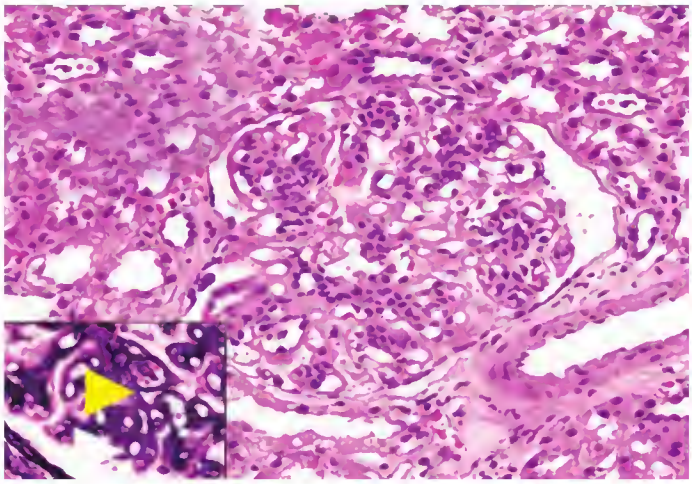

Figure 5: MPGN in a patient having infective endocarditis: Glomerulus from patient with MPGN type I showing enlarged glomerulus with increased glomerular tuft cellularity creating an accentuation of lobular pattern (Haematoxylin-Eosin x 200). *Inset:* Silver methenamine staining showing thickened capillary wall with clear region between (arrowhead) creating a tram-track appearance.

anaemia, weight loss, skin rash and hepatosplenomegaly. Renal manifestations include haematuria (microscopic or gross), proteinuria, azotaemia and hypertension. Antibiotic therapy and prompt removal of the infected catheter usually lead to remission of the renal disease in majority of the patients.

Other Infections

Glomerulonephritis may follow visceral infections involving abdominal organs, lungs or pleura. Overall clinical picture is similar to glomerulonephritis following infective endocarditis. Besides this, various other bacterial, fungal and parasitic infections are known to be complicated by glomerular involvement.

Hepatitis B and C Infection

See chapter 5 of section 14, Hepatology.

GLOMERULONEPHRITIS ASSOCIATED WITH MALIGNANT DISEASE

Besides direct involvement of renal parenchyma, neoplastic lesions involving various organ systems may be complicated by development of glomerular lesions during the course of illness. Glomerular lesions may manifest before the development of neoplastic disease, occur concurrently or after the development of neoplastic disease. Common malignant disorders associated with glomerular disorders include solid tumours involving breast, lung, stomach and colon and Hodgkin's lymphoma. Majority of the patients are above 50 years of age.

A wide spectrum of renal histopathological lesions may be seen in patients with neoplastic disorders. These include membranous nephropathy (**Figure 6**), minimal change disease, focal segmental glomerulosclerosis, IgA nephropathy, membranoproliferative glomerulonephritis, amyloidosis, etc. Sometimes, microangiopathic haemolytic anaemia may complicate the course of neoplastic disorder. Of these, membranous nephropathy has been found to be the most common lesion. The renal lesions may improve following surgical removal of the tumour or successful chemotherapy. Following recurrence of the neoplastic disease, relapse of renal lesions may occur.

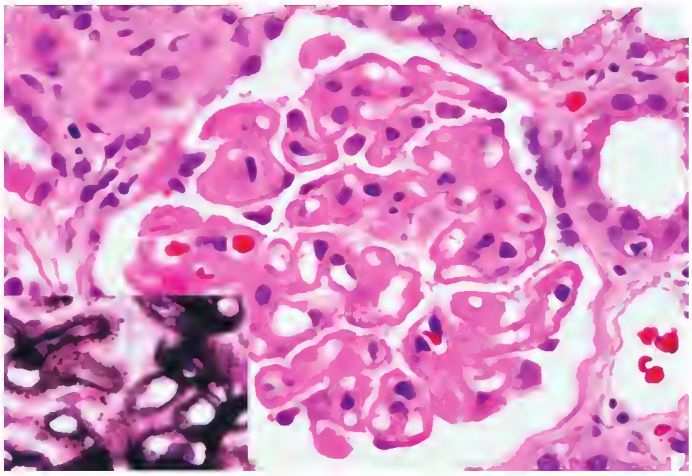

Figure 6: Membranous glomerulonephritis in a patient with placental site trophoblastic tumour: Histopathology of MGN with definite GBM thickening. There is diffuse thickening of glomerular capillary wall without any increase in mesangial cellularity. (Haematoxylin-Eosin x 200). *Inset:* MGN with spikes. Every capillary loop in this glomerulus has diffuse small spikes projecting from the epithelial side of GBM (Silver methenamine (Jones) stain x 400).

19.7 Urinary Tract Infections

R Kasi Visweswaran, Praveen Namboothiri

DEFINITION AND EPIDEMIOLOGY

Urinary tract infection (UTI) is a common, distressing, and occasionally life-threatening condition. UTI may be defined as a condition in which bacteria enter, persist and multiply within the urinary tract. The clinical features, diagnosis, treatment, complications and long-term sequelae depend on the site of the infection and the presence of any structural abnormality. The infection is mostly caused by Gram-negative bacteria such as *Escherichia coli, Klebsiella, Enterobacter, Pseudomonas* and *Proteus*. *Fastidious organisms, anaerobic bacteria* and *fungi* like *Candida* may occasionally be responsible for hospital-acquired UTI. The presence of predisposing factors render the host vulnerable to complicated UTI (**Table 1**). In addition, bacterial virulence factors increase the chances of establishing infection. The incidence of UTI is 0.5 to 0.7 episodes per person per year in females of whom 25% of them have recurrences. It may manifest as acute or recurrent uncomplicated cystitis, acute uncomplicated pyelonephritis, recurrent, relapsing or complicated pyelonephritis or asymptomatic bacteriuria.

Table 1: Host Factors Predisposing to Urinary Tract Infection

Anatomical factors
Posterior urethral value
Vesico-ureteric reflux
Urethral stricture
Benign prostatic hypertrophy
Functional factors
Neurogenic bladder
Other factors
Males and females
Diabetes mellitus
Immunosuppression (post-transplant)
Calculi
Congenital abnormalities
Foreign bodies: catheters, stents
Females
Post-menopausal state (oestrogen deficiency)
Voiding habits
Spermicidal jelly
Vaginal douching
Perineal hygiene

AETIOPATHOGENESIS

The entry of uropathogens into the urinary tract is often from periurethral colonisation in females or from preputial colonisation in uncircumcised males. When host defences are weakened, urethral colonisation and mucosal adhesion of bacteria occurs. Sexual intercourse, catheterisation or instrumentation may also help transfer of bacteria into the bladder. When predisposing factors like vesicoureteric reflux or ureteral dilatation are present, infection ascends via the ureter to reach the renal parenchyma. The invasion of the normal upper tract depends on the virulence of the strain and the expression of bacterial fimbriae. Thus, ascending infections account for the vast majority of urinary infections. However, blood stream infection may sometimes result in haematogenous spread of bacteria to the renal parenchyma.

In a normal individual, a series of non-specific and specific defence mechanisms prevent adhesion and colonisation of bacteria. The non-specific mechanisms are the flushing effect of urine, normal vaginal flora and Tamm-Horsfall glycoprotein which complexes with the bacteria which are then eliminated through the urine. Circulating immunoglobulin (Ig)G and IgM in upper urinary tract are specific immunological barriers. Secretory IgA in the urinary tract, particularly the urethra, provides a barrier to the ascent of infection. In addition to humoral defences, cellular responses also play a role in preventing ascent of infection.

Only some strains of *E. coli* are capable of infecting the intact urinary tract. Bacterial virulence factors increase the chances of establishing infection of a given strain. Strains of *E. coli* causing symptomatic UTI in non-catheterised patients belong to a small number of specific O, K and H sero-groups. Adherence of bacteria to uroepithelial cells is the critical first step in the initiation of infection. For both *E. coli and Proteus*, fimbriae mediate attachment of bacteria to specific receptors on epithelial cells. Haemolysin and aerobactin produced by uropathogenic strains of *E. coli* make them resistant to the bactericidal action of human serum. The presence of O antigens, capsular K antigens, production of siderophores, haemolysins, adhesions and urease enhance the chances of a particular strain to cause infection. The virulence factors favour the release of bacterial toxins, replication and antibiotic resistance. Iron trapping characteristics of bacteria like *E. coli* also contribute to the pathogencity.

Urine flow and the act of micturition are important defence mechanisms which help to eliminate the bacteria. Other factors like low osmolality and low pH hinder bacterial growth. The presence of lactoferrin and anti-microbial peptides in the urine also help to prevent bacterial colonisation.

Infection of the parenchyma occurs when the bacteria enter and multiply in the parenchyma. In the case of vesico-uretric reflux (VUR), intra-renal reflux of urine from the renal pelvis to the collecting duct results in entry of bacteria into the renal parenchyma. This results in inflammation followed by scarring mainly at the poles of the kidney. Blood stream spread results in multiple micro abscesses which may be cortical or cortico-medullary in location.

CLINICAL FEATURES

The clinical features depend on whether the infection involves the upper or lower urinary tract. Irritative voiding symptoms are more common in lower tract infection whereas constitutional symptoms are more common in upper tract infections.

Cystitis and Urethritis

Infection of the bladder is common in women during their reproductive years. Patients with cystitis or urethritis may be

asymptomatic or present with frequency, urgency, dysuria, nocturia, urge incontinence, suprapubic pain or a sensation of incomplete bladder emptying. The urine may have an offensive smell and haematuria occurs in approximately 30% cases. Physical examination usually may reveal mild suprapubic tenderness.

About 30% of women with acute dysuria, frequency and pyuria have negative urine cultures. Sexually transmitted genital infection due to *Chlamydia*, *Neisseria* or herpes simplex virus may account for some of these cases. In addition, organisms like *Ureaplasma urealyticum* and *Myocoplasma hominis* can cause symptomatic cystitis with a sterile urine culture. These patients usually present with persistent frequency and dysuria called the 'urethral syndrome' or 'dysuria-pyuria syndrome'. Interstitial cystitis of the bladder is a condition of unknown aetiology with symptoms resembling bacterial cystitis, but negative urine cultures. The diagnosis can be confirmed by cystoscopy and biopsy.

Prostatitis and Seminal Vesiculitis

The usual symptoms of prostatic infection are frequency, dysuria, perineal or groin pain, difficulty in voiding and painful ejaculation. Per-rectal digital examination may reveal an enlarged, tender prostate or seminal vesicle. Relapsing UTI, associated with the above symptoms in men is suggestive of chronic bacterial prostatitis. A diagnosis of bacterial prostatitis is made on the basis of microscopy and culture of expressed prostatic secretions. In acute bacterial prostatitis, the patient is often acutely ill with sudden onset of fever and chills in addition to other symptoms. Per-rectal digital examination should be avoided in them during the acute stage.

Pyelonephritis

Infection of the renal parenchyma is called pyelonephritis. It may be acute or chronic. Symptoms of acute pyelonephritis include fever with shaking chills, myalgia, nausea, vomiting and loin pain which develop rapidly over a period of hours to days. Physical examination reveals renal angle tenderness. Most patients have significant leukocytosis and bacteria may be detected in the urine deposit by microscopy. Leucocyte casts confirm renal parenchymal involvement. Microscopic or macroscopic haematuria may also be present. Positive blood cultures are seen in 10% to 25% of patients with acute pyelonephritis. Emphy-sematous pyelonephritis is a particularly severe form of upper UTI seen in diabetic patients. It is characterised by accumulation of fermentative gases in the kidney, collecting system and perinephric tissues. It is mostly caused by *E. coli* and may also be associated with urinary tract obstruction.

Chronic pyelonephritis is diagnosed by radiological demonstration of clubbed calyces associated with focal or diffuse renal scarring and it may be unilateral or bilateral. It is known to develop as a result of infection and vesicoureteric reflux in early childhood. Many adults with chronic pyelo-nephritis do not have bacteriuria, remain asymptomatic for long and present later with hyper-tension or renal functional impairment.

Renal Abscess

Renal cortical abscess (renal carbuncle) occurs as a result of haematogenous spread of *Staphylococcus aureus* from a primary focus elsewhere in the body. Patients present with fever and loin pain. Bladder symptoms are absent. Clinical presentation is similar to acute pyelonephritis and imaging studies show hypoechoic or hypodense areas in the renal cortex. The diagnosis of abscess can be confirmed by aspiration and culture from the suspicious areas under ultrasound guidance.

Perinephric abscess is infection and abscess formation within the perirenal space and is often due to extension or rupture of an intra-renal abscess. A perinephric abscess usually presents more insidiously compared to renal abscess and may remain undiagnosed for a long time. Patients may complain of progressive ill health and intermittent fever for many weeks. A flank or abdominal mass may be found on examination. Surgical drainage under appropriate antibiotic cover is indicated.

Xanthogranulomatous Pyelonephritis (XGP)

XGP is a distinct form of chronic kidney infection which predominantly affects elderly women. The condition is commonly associated with renal calculi or obstructive uropathy and is usually unilateral. Infections are caused by *Proteus mirabilis*, *E. coli* or *Klebsiella* group of organisms. The renal parenchyma is replaced by foam cells which infiltrate the perinephric tissue and retroperitoneum. The kidney is enlarged, and non-functioning and may even mimic a renal tumour. Once established, treatment for XGP is partial or total nephrectomy.

MODALITIES OF DIAGNOSIS

Microscopic examination of urine is the crucial first step in confirming UTI. A properly collected early morning sample of urine is ideal. Random samples may also be used for regular testing. Pyuria is defined as presence of more than 5 WBCs/high power field (hpf) in a centrifuged urine sample. In women of child bearing age group, more than 10 WBCs/hpf is considered significant. Pyuria in the absence of bacteriuria is called 'sterile pyuria'. It indicates either infection with unusual bacterial agents like *Chlamydia*, *Ureaplasma*, tuberculosis or fungal infections or urological conditions like calculi, nephrocalcinosis, vesico-ureteric reflux, interstitial nephritis, polycystic kidney disease, tumours or renal transplant rejection.

The gold standard for diagnosis of UTI is urine culture. For bacteriological testing, a clean catch mid-stream urine sample is collected and transported to the laboratory without delay. In case of delay, the sample is refrigerated. Growth of 10^5 colony forming units (CFU) of a single bacterial strain signifies a positive culture. In the case of suprapubic aspirate, growth of even one CFU is significant. In a catheterised sample, more than 10^3 CFU is taken as significant. The growth of multiple organisms is usually due to contamination. The sensitivity pattern helps to choose the appropriate antibiotic. Rapid methods of detection of bacteriuria have been developed as alternatives to standard urine cultures. These methods detect bacterial growth by photometry or bioluminescence and provide results in 1 to 2 hours. Compared to urine cultures, these methods exhibit a sensitivity of 95% to 98%. If the bioluminescence test is negative, UTI can be ruled out with 99% accuracy.

Localisation of the infection to the bladder or the upper tract is important to decide the treatment methods. It is possible to differentiate lower and upper tract involvement by history and symptoms. A number of direct and indirect tests can also be employed to differentiate between the two. The direct approach
